CONTENTS

PAPERS

No. Page

2128 **EXPERIENCES IN OPERATING A CHEMICAL-MECHANICAL SEWAGE TREATMENT PLANT.**

By **George J. Schroepfer** 1

Discussion:

By F. C. Roberts, Jr. 33
Rolf Eliassen 36
Frederic Bass 37
Darwin W. Townsend 40
Lloyd H. Flickinger 42
Isador W. Mendelsohn 44
Ralph E. Fuhrman 47
R. W. Rowen 49
George J. Schroepfer 50

2129 **EXPANSION OF CONCRETE THROUGH REACTION BETWEEN CEMENT AND AGGREGATE.**

By **Thomas E. Stanton** 54

Discussion:

By R. W. Carlson 85
Bailey Tremper 85
Hubert Woods 88
N. T. Stadtfeld 88
W. C. Hanna 93
J. C. Witt 97
R. F. Blanks 98
J. MacNeil Turnbull 105
Robert A. Kinzie, Jr. 107
Thomas E. Stanton 109

2130 **AN INVESTIGATION OF STEEL RIGID FRAMES.**

By **Inge Lyse and W. E. Black** 127

Discussion:

By C. J. Posey 158
W. J. Eney 159
LaMotte Grover 167
William R. Osgood 171
M. Hirschthal 173
Jaroslav J. Polivka 176
A. C. Barrow 181
W. E. Black 183

2131 **LABORATORY INVESTIGATIONS OF SOILS AT FLUSHING MEADOW PARK.**

By **Donald M. Burmister** 187

Discussion:

By Gordon E. Thomas and M. N. Sinacori 205
E. J. Kilcawley 207
Dimitri P. Krynine 209
B. K. Hough, Jr. 211
T. B. Rights 212
Donald M. Burmister 214

No. Page

2132 **HYDRAULICS OF SPRINKLING SYSTEMS FOR IRRIGATION.**

By **J. E. Christiansen** 221

Discussion:

By Arthur F. Pillsbury 240
Tom A. Bither 243
Ralph W. Powell 245
Harry F. Blaney 247
J. E. Christiansen 248

2133 **PLASTIC THEORY OF REINFORCED CONCRETE DESIGN.**

By **Charles S. Whitney** 251

Discussion:

By L. E. Grinter 283
Basil Sourochnikoff 285
R. W. Stewart 287
George C. Ernst 289
Homer M. Hadley 292
Robert W. Abbett 295
Paul Andersen 296
R. A. Caughey 298
Roberto Contini 299
A. A. Eremin 305
Jaroslav J. Polivka 307
Paul W. Abeles 311
O. G. Julian 316
Charles S. Whitney 321

2134 **DYNAMIC STRESS ANALYSIS OF RAILWAY BRIDGES.**

By **R. K. Bernhard** 327

Discussion:

By R. S. Chew 341
R. K. Bernhard 344

2135 **CONCRETE IN SEA WATER: A REVISED VIEWPOINT NEEDED.**

By **Homer M. Hadley** 345

Discussion:

By Thomas E. Stanton 359
W. F. Way 359
Glenn S. Paxson 362
Lester C. Hammond 362
Ladis H. Csanyi 363
G. M. Williams 366
Harry E. Squire 366
J. W. B. Blackman 371
E. C. Jack 373
Alfred M. Freudenthal 375
T. B. Rights 377
Homer M. Hadley 378

2136 **ANALYSIS OF STATICALLY INDETERMINATE TRUSSED STRUCTURES BY SUCCESSIVE APPROXIMATIONS.**

By **O. T. Voodhigula** 395

Discussion:

By Francis L. Castleman, Jr. 407
Charles A. Ellis 409
David J. Peery 411
L. E. Grinter 417
O. T. Voodhigula 420

No. PAGE

2137 **CAVITATION IN OUTLET CONDUITS OF HIGH DAMS.**

By **Harold A. Thomas and Emil P. Schuleen** 421

Discussion:

By Jerome Fee 457
V. E. Leman 461
P. S. O'Shaughnessy and E. S. Randolph 465
Carroll F. Merriam 467
Hunter Rouse 470
G. H. Hickox 472
J. M. Mousson 477
J. H. Douma 479
Harold A. Thomas and Emil P. Schuleen 482

2138 **DESIGN OF ACCELERATION AND DECELERATION LANES.**

By **Adolphus Mitchell** 494

Discussion:

By H. F. Holley 506
D. W. Loutzenheiser 508
Hawley S. Simpson 510
Milton Harris 511
T. F. Hickerson 512
W. L. Waters 513
R. A. Moyer and Donald T. Davidson 513
Stephen E. Butterfield 519
Adolphus Mitchell 521

2139 **CRACK PREVENTION PROGRAM, HIWASSEE DAM.**

By **O. Laurgaard** 525

Discussion:

By Douglas McHenry 548
Reginald H. Thomson 549
W. R. Waugh 552
O. Laurgaard 554

2140 **FORMULAS FOR THE TRANSPORTATION OF BED LOAD.**

By **H. A. Einstein** 561

Discussion:

By Joe W. Johnson 578
A. A. Kalinske 580
O. G. Haywood, Jr. 583
Samuel Shulits 590
John S. McNown 591
H. A. Einstein 594

2141 **VALUE OF PUBLIC WORKS.**

By **J. P. Hallihan** 598

Discussion:

By Clarence W. Post 606
Uel Stephens 606
William J. Wilgus 608
Bernard L. Weiner 610
Albert Ed. Scheible 612
H. B. Cooley 614
Philip W. Henry 618
Baxter L. Brown 620
Evan S. Martin 620
Isador W. Mendelsohn 621
W. W. Crosby 627
J. P. Hallihan 628

No. Page

2142 **RELIABILITY OF STATION-YEAR RAINFALL-FREQUENCY DETERMINATIONS.**

By **Katharine Clarke-Hafstad** 633

Discussion:

- By Paul V. Hodges 653
  - C. S. Jarvis 656
  - Howard W. Brod 657
  - Merrill Bernard 660
  - Charles F. Ruff 666
  - Eugene L. Grant 667
  - Waldo E. Smith 668
  - Robert L. Lowry, Jr. 670
  - Herbert C. S. Thom 672
  - Katharine Clarke-Hafstad 677

2143 **TUNNEL CONSTRUCTION, SIXTH AVENUE SUBWAY, NEW YORK, N. Y.**

By **Jacob Feld** 684

Discussion:

- By John H. Myers 720
  - Jacob Feld 721

2144 **FORT PECK SLIDE.**

By **T. A. Middlebrooks** 723

Discussion:

- By Jacob Feld 743
  - Joel D. Justin 744
  - William Gerig 748
  - Alfred J. Ryan 749
  - Glennon Gilboy 752
  - Frank E. Fahlquist 755
  - Irving B. Crosby 758
  - T. A. Middlebrooks 759

2145 **ON THE METHOD OF COMPLEMENTARY ENERGY.**

By **H. M. Westergaard** 765

Discussion:

- By I. K. Silverman 794
  - George R. Rich 799
  - R. V. Southwell 801
  - H. M. Westergaard 802

2146 **SOME ECONOMICS OF AIRPORTS.**

By **W. Watters Pagon** 804

Discussion:

- By William E. Rudolph 819
  - Donald M. Baker 820
  - W. Watters Pagon 823

2147 **METHOD OF PREDICTING THE RUNOFF FROM RAINFALL.**

By **Ray K. Linsley, Jr., and William C. Ackermann** 825

Discussion:

- By Bertram S. Barnes 836
  - Richard van Vliet 841
  - LeRoy K. Sherman 842
  - Franklin F. Snyder 843
  - Ray K. Linsley, Jr., and William C. Ackermann 844

No. PAGE

2148 **THE SUSPENSION BRIDGE TOWER CANTILEVER PROBLEM.**
By **Blair Birdsall** 847

Discussion:
By FRANCIS P. WITMER 863
JOHN I. COPP 863
BLAIR BIRDSALL 869

2149 **EVALUATION OF FLOOD LOSSES AND BENEFITS.**
By **Edgar E. Foster** 871

Discussion:
By E. L. CHANDLER 895
E. F. CHANDLER 897
CHARLES B. BURDICK 898
H. K. BARROWS 900
ROGER E. AMIDON 901
HYMAN J. FINE 903
OTTO F. BUZHARDT 906
MALCOLM ELLIOTT 911
JOHN B. MCALEER AND JOHN B. DRISKO 912
EDGAR E. FOSTER 919

2150 **WIND STRESS ANALYSIS BY THE *K*-PERCENTAGE METHOD.**
By **F. P. Witmer** 925

Discussion:
By C. M. GOODRICH 939
FRANCIS L. CASTLEMAN, JR. 940
CLYDE T. MORRIS 943
OTTO GOTTSCHALK 944
F. P. WITMER 950

2151 **SIMPLIFIED THEORY OF THE SELF-ANCHORED SUSPENSION BRIDGE.**
By **C. H. Gronquist** 955

Discussion:
By A. J. MEEHAN 976
C. B. MCCULLOUGH 979
JAROSLAV J. POLIVKA 983
WILLIAM BERTWELL 984
A. A. EREMIN 986
C. H. GRONQUIST 988

2152 **ANALYSIS OF BUILDING FRAMES WITH SEMI-RIGID CONNECTIONS.**
By **Bruce Johnston and Edward H. Mount** 993

Discussion:
By MAURICE P. VAN BUREN 1020
WAYNE W. SMITH, LEONARD P. ZICK, JR., AND CONRAD C. WAN 1020
S. D. LASH 1022
DEAN F. PETERSON, JR. 1025
R. W. STEWART 1026
JAROSLAV J. POLIVKA 1030
BRUCE JOHNSTON AND EDWARD H. MOUNT 1033

2153 **SURFACE RUNOFF DETERMINATION FROM RAINFALL WITHOUT USING COEFFICIENTS.**
By **W. W. Horner and S. W. Jens** 1039

Discussion:
By L. L. HARROLD 1076
C. E. RAMSER 1077
LEROY K. SHERMAN 1078

No. Page

A. J. Schafmayer 1080
C. S. Jarvis 1082
G. W. Musgrave 1091
F. L. Flynt 1095
W. I. Hicks 1097
Albert S. Fry 1102
W. W. Horner and S. W. Jens 1106

2154 **MOMENTS IN CONTINUOUS RECTANGULAR SLABS ON RIGID SUPPORTS.**

By **L. C. Maugh and C. W. Pan** 1118

Discussion:
By Maurice P. van Buren 1132
Ralph E. Byrne, Jr. 1134
Pierce P. Furber 1138
L. C. Maugh 1139

2155 **TRAFFIC ENGINEERING AS APPLIED TO RURAL HIGHWAYS.**

By **Milton Harris** 1143

Discussion:
By Charles E. Conover 1167
Stephen E. Butterfield 1168
Nathan Cherniack 1169
Park H. Martin 1170
Charles M. Noble 1175

2156 **MISSOURI RIVER SLOPE AND SEDIMENT.**

By **William Whipple, Jr.** 1178

Discussion:
By Samuel Shulits 1201
Leo M. Odom 1203
E. W. Lane 1205
Elliott J. Dent 1211
William Whipple, Jr. 1211

2157 **RIGID FRAMES WITHOUT DIAGONALS (THE VIERENDEEL TRUSS).**

By **Louis Baes** 1215

Discussion:
By Jaroslav J. Polivka 1229
W. A. Miller 1236
A. A. Eremin 1237
Yves Nubar 1237
Léon G. Rucquoi 1241

2158 **CONSUMPTIVE USE OF WATER FOR AGRICULTURE.**

By **Robert L. Lowry, Jr., and Arthur F. Johnson** 1243

Discussion:
By E. B. Debler 1267
Rhodes E. Rule 1268
Edgar E. Foster 1275
Charles H. Lee 1277
Harry F. Blaney 1282
J. L. Burkholder 1287
S. T. Harding 1290
C. S. Jarvis 1292
R. W. Davenport and Gordon R. Williams 1295
Robert L. Lowry, Jr., and Arthur F. Johnson 1297

No. Page

2159 **AN INVESTIGATION OF PLATE GIRDER WEB SPLICES.**

By **J. M. Garrelts and I. E. Madsen** 1303

Discussion:

By C. H. GRONQUIST 1321
CHARLES STRATTON DAVIS 1321
BRUCE JOHNSTON 1322
FRANCIS L. CASTLEMAN, JR. 1324
J. M. GARRELTS AND I. E. MADSEN 1326

2160 **COMPACTION OF COHESIONLESS FOUNDATION SOILS BY EXPLOSIVES.**

By **A. K. B. Lyman** 1330

Discussion:

By REUBEN M. HAINES 1342
R. G. HENNES 1343
JOHN D. WATSON 1344
PAUL BAUMANN 1345
A. K. B. LYMAN 1347

2161 **OPERATION EXPERIENCES, TYGART RESERVOIR.**

By **Robert M. Morris and Thomas L. Reilly** 1349

Discussion:

By NICHOLLS W. BOWDEN 1374
EDGAR E. FOSTER 1376

2162 **THE SURVEYOR AND THE LAW.**

By **A. H. Holt** 1379

Discussion:

By E. F. CHANDLER 1394
HARRY RUBEY 1395
WILLIAM H. RICHARDS, JR. 1396
C. B. HUMPHREY 1397
D. D. HAINES 1399

2163 **COST OF PUBLIC SERVICES IN RESIDENTIAL AREAS.**

By **F. Dodd McHugh** 1401

Discussion:

By DONALD M. BAKER 1433
HOWARD WHIPPLE GREEN 1435
T. T. MCCROSKY 1436
F. DODD MCHUGH 1438

2164 **EXTENSOMETER STRESS MEASUREMENTS, NORTH AVENUE BRIDGE, CHICAGO, ILL.**

By **Lawrence T. Smith and Paul Lillard** 1447

Discussion:

By ARTHUR R. LORD 1470
J. CHARLES RATHBUN 1471
THEODORE BELZNER 1476

2165 **SALTS IN IRRIGATION WATER.**

By **Raymond A. Hill** 1478

Discussion:

By C. S. SCOFIELD 1494
HERMAN STABLER 1496
M. R. LEWIS 1501
LOUIS J. ALEXANDER 1502
W. D. COLLINS 1503
JOHN H. BLISS 1510
RAYMOND A. HILL 1512

No. PAGE
2166 **A DIRECT METHOD OF FLOOD ROUTING.**
By **C. O. Wisler and E. F. Brater** 1519

Discussion:
By Ray K. Linsley, Jr. 1530
Harold C. Hickman 1532
Robert B. Horonjeff and Herbert G. Crowle 1539
L. K. Sherman 1541
Alfred L. Brosio 1543
W. B. Langbein 1548
Fred E. Tatum 1550
H. C. Woster 1551
C. O. Wisler and E. F. Brater 1552

2167 **PIPE-LINE FLOW OF SOLIDS IN SUSPENSION: A SYMPOSIUM.**
EFFECT ON THE CHARACTERISTICS OF CENTRIFUGAL PUMPS.
By **Leigh C. Fairbank, Jr.** 1564
MECHANICS OF FLOW, WITH NONCOLLOIDAL, INERT SOLIDS.
By **Warren E. Wilson** 1576

Discussion:
By Arthur L. Collins 1587
H. A. Einstein 1589
H. E. Babbitt and D. H. Caldwell 1590
Warren E. Wilson 1592

2168 **DESIGN AND CONSTRUCTION OF SAN GABRIEL DAM NO. 1.**
By **Paul Baumann** 1595

Discussion:
By E. Soucek 1635
William P. Creager 1635
Joseph Jacobs 1636
Jacob Feld 1640
Walter L. Huber 1642
Federico Barona 1642
G. H. Hickox 1643
Paul Baumann 1644

2169 **FINAL REPORT OF THE JOINT COMMITTEE OF THE SANITARY ENGINEERING DIVISION AND THE IRRIGATION DIVISION ON THE SALVAGE OF SEWAGE** 1652

2170 **THE AMERICAN SOCIETY OF CIVIL ENGINEERS TODAY: ADDRESS AT THE ANNUAL CONVENTION, MINNEAPOLIS, MINNESOTA, JULY 22, 1942** 1688

XI

MEMOIRS OF DECEASED MEMBERS

ERRATA

Transactions, Vol. 105 (1940)

Page 1404, Table 11, Column R, line 3(*b*), insert "+ 0.510"; and change "*CN* (in 0.1 ft)" to "*CN* (in 0.01 ft)."

Transactions, Vol. 107 (1942)

Page 990, change Eq. 50*a* to read:

$$\Delta L = \frac{8}{3 \sec^2 \alpha} \left[\frac{f^2}{L} - \frac{(f + \Delta f)^2}{(L + \Delta L)} \right] + \Delta L_d \sec \alpha \text{ (very nearly)} \ldots (50a)$$

Page 991, lines 12 to 15, delete the last sentence of this paragraph.

PAPERS AND REPORTS OF COMMITTEES PUBLISHED IN PROCEEDINGS, AM. SOC. C. E., NOVEMBER, 1941, TO SEPTEMBER, 1942, INCLUSIVE, NOT PUBLISHED IN TRANSACTIONS, VOL. 107

	Number of *Proceedings*.
FUNDAMENTAL ASPECTS OF THE DEPRECIATION PROBLEM: A SYMPOSIUM	November, 1941
STABILITY OF GRANULAR MATERIALS. By **R. E. Glover and F. E. Cornwell**	November, 1941
TIMBER FRICTION PILE FOUNDATIONS. By **Frank M. Masters**	November, 1941
BENDING MOMENTS IN THE WALLS OF RECTANGULAR TANKS. By **Dana Young**	November, 1941
ENERGY LOSS AT THE BASE OF A FREE OVERFALL. By **Walter L. Moore**	November, 1941
DESIGN OF ST. GEORGES TIED ARCH SPAN. By **J. M. Garrelts**	December, 1941
ALLOCATION OF THE TENNESSEE VALLEY AUTHORITY PROJECTS. By **Theodore B. Parker**	December, 1941
DEVELOPMENT OF TRANSPORTATION IN THE UNITED STATES. By **J. E. Teal**	December, 1941
LATERAL STABILITY OF UNSYMMETRICAL I-BEAMS AND TRUSSES IN BENDING. By **George Winter**	December, 1941
DRAINAGE OF LEVEED AREAS IN MOUNTAINOUS VALLEYS. By **Gordon R. Williams**	January, 1942
HYDRAULIC DESIGN OF DROP STRUCTURES FOR GULLY CONTROL. By **B. T. Morris and D. C. Johnson**	January, 1942

EXPERIENCES IN OPERATING A CHEMICAL-MECHANICAL SEWAGE TREATMENT PLANT

BY GEORGE J. SCHROEPFER,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. F. C. ROBERTS, JR., ROLF ELIASSEN, FREDERIC BASS, DARWIN W. TOWNSEND, LLOYD H. FLICKINGER, ISADOR W. MENDELSOHN, RALPH E. FUHRMAN, R. W. ROWEN, AND GEORGE J. SCHROEPFER.

SYNOPSIS

The Minneapolis-St. Paul (Minn.) sewage treatment plant began operating on June 1, 1938. In reporting the experiences of the first two years of operation, data are included on the performance of the plant and the cost of operation and maintenance, as well as on the improvement of the Mississippi River which has resulted from its operation. Some of the problems that arose in early operation, and the methods used to overcome them, are discussed, as well as other improvement changes which have been incorporated to simplify operation or effect economies. It is hoped that such statements will encourage the presentation of data on similar experiences at other plants, as well as make available for the benefit of others the experiences at this plant.

DEGREE OF TREATMENT

Because of its importance to a proper consideration of the results of operation and the statements concerning experiences made herein, as well as because it is the most important factor in the consideration of any pollution abatement project, some space is devoted to the degree of treatment provided in this project.

The Mississippi River at St. Paul fluctuates widely, both as to discharge (which varies from a minimum of 864 cu ft per sec to a maximum estimated flow of 107,000 cu ft per sec with an average annual flow of 8,800 cu ft per sec) and in the physical, chemical, and biological factors that affect its capacity to receive and assimilate pollution. This condition, and the fact that the Twin City sewage formerly discharged, and now the effluent of the treatment plant discharges, into pools created by the canalization project, affects to a greater

---

NOTE.—Published in January, 1941, *Proceedings*.

[1] Chf. Engr. and Supt., Minneapolis-St. Paul San. Dist., St. Paul, Minn.

or lesser extent the type of treatment selected, the degree, and the duration for which various degrees of treatment must be maintained. In the studies of treatment necessary, the information collected on river conditions by various authorities over the relatively long period of practically continuous record from June, 1926, to October, 1934, when the decision on type of treatment was made, was of prime importance in adjusting proposed sewage treatment to river requirements. This record of analytical data has been continued, so that at the present time (1941) it covers a period of fifteen consecutive years.

The pollution load on the river is predicted to reach a 1,300,000 population-equivalent for the Twin City metropolitan area by 1945, exclusive of South St. Paul and Newport, Minn., from a tributary population of 910,000. Computations using the 42-yr period of river record, from 1892 to 1933, inclusive, indicated, for the foregoing pollution load, (1) that sedimentation alone (36% B.O.D. reduction—that is, 5-day biochemical oxygen demand) would suffice to meet river standards as interpreted herein, except for 12.5% of the time; (2) that sedimentation plus effluent filtration (45% B.O.D. reduction) would be sufficient except for about 8% of the time; and (3) that sedimentation and effluent filtration, plus chemical treatment (to 70% B.O.D. removal), would maintain standards except for 1.5% of the time.

A 5-day B.O.D. removal of 70% was adopted as the degree of treatment necessary to meet all reasonable river requirements satisfactorily. A variety of treatment processes were investigated progressively in the period from 1927 to 1934 to provide this removal. As a result, sedimentation plus effluent filtration, augmented at times of critical river flow by chemical treatment, was adopted as the process which would meet the river requirements most satisfactorily and economically.

A clearer conception of the variation in treatment requirements can be had from the following: Considering river flows in the period from 1892 to 1933, and the expected 1945 pollution load, chemical treatment would be required during only 40 months of the total of 504 months, and the average B.O.D. removal required during the 40 months that chemical treatment was necessary was approximately 58%. Expressed in another way, sedimentation plus effluent filtration would be sufficient treatment based on past river flows for a continuous period of fourteen years; and then, after a 2-yr period when chemical treatment would be required, preliminary treatment again would be sufficient for another 12-yr period. Sedimentation plus effluent filtration would be sufficient, and no chemical treatment would be required for thirty years out of the 42-yr period of record.

General Plant Description

The treatment plant[2] was designed for an average daily flow of 134 mgd expected from a tributary population of 910,000 in 1945. The intercepting sewer leading to the plant has a capacity of 610 mgd, which flow will be reached on infrequent occasions during storms.

Described briefly, the sewage treatment plant consists of screen and grit chambers, flocculating and settling tanks, and effluent filters, with provision

---

[2] For a more detailed description of the treatment process see "Layout and Plan of Operation of the Minneapolis-St. Paul Sewage Treatment Plant," by George J. Schroepfer, *Sewage Works Journal*, Vol. 9, 1937, p. 913.

for chlorination and chemical treatment (see Fig. 1). The sludge disposal process consists of concentration tanks, vacuum filters, and incinerators. A distinct effort was made in the design of the plant to provide a maximum of flexibility and dependability. From this standpoint, and also to secure information on the relative economy and effectiveness of various processes and chemicals, the entire plant, from the point of entrance of raw sewage to the discharge of treated effluent into the river, is divided into two distinct and separately operated divisions. Similar flexibility is obtainable in the sludge disposal processes. Features are incorporated in the design for treatment by a variety of processes.

Screen and Grit Chambers.—The intercepting sewer conducting the sewage to the screen and grit chambers is a double-barrel section, each of which is 9.5 ft wide and 10 ft deep, with a total design capacity of 610 mgd. From each intercepting sewer barrel the sewage passes through the two separate batteries of the screen and grit chambers, the individual units of which are described briefly, as follows:

Coarse Bar Racks.—Two hand-raked racks in channels 10 ft wide with a maximum flow depth of 10 ft and with clear openings of 6 in.

Bar Screens.—Four mechanically and automatically cleaned bar screens with one-inch clear openings, each 10 ft wide, with a maximum sewage depth of 8.7 ft.

Grit Chambers.—Eight grit chambers, 62.75 ft long, from the inlet gate to the outlet gate. The width of the chambers is 12 ft and the depth of flow varies from 4.5 ft to 9.0 ft. The velocity of flow varies from 0.45 to 1.18 ft per sec.

Auxiliary Units.—Provision was made for two screenings shredders, each with a capacity of 3,500 lb per hr; a grit elevator and hopper for discharge of grit into trucks or freight cars; bins for emergency grit and screenings storage; and a 5-ton crane equipped with a ¾-yd bucket to be used for handling grit and screenings from these bins, as well as for several other purposes.

Chemical Control Building.—The chemical control building is a part of the superstructure over the screen and grit chamber. It houses the dry chemical feeders, chlorinators, pneumatic conveying equipment, and storage bins, described in more detail as follows:

Chemical Feeders.—Three dry chemical feeders of the gravimetric type, each having a feeding rate infinitely variable between 400 and 2,500 lb per hr.

Lime Feeders.—Two lime feeders, each of which has a capacity range from 400 to 2,500 lb per hr, equipped with lime slakers.

Chlorinators.—Five solution feed chlorinators, each with a capacity range from 850 to 6,000 lb of chlorine per twenty-four hours.

Pneumatic Conveying Equipment.—Pneumatic conveying equipment with a capacity of 10 tons per hr for unloading and elevating dry chemicals.

Chemical Storage Bins.—A total of ten concrete storage bins, each having a capacity of approximately 2,550 cu ft.

Flocculating and Settling Tanks.—Included under this heading are the venturi meters, combination flocculation and settling tanks, and the settling tanks.

Venturi Meters.—Each of the two venturi meters has an inlet diameter of 9 ft and a throat diameter of 5 ft, and is designed for a minimum flow of 43 mgd and a maximum flow of 350 mgd.

Combination Flocculating and Settling Tanks.—Although they are designated as flocculating tanks, these units have been arranged for multiple functioning, including their use as a by-pass channel, settling tanks, post-chlorination contact tanks, and grease separation tanks, in addition to flocculation with and without chemicals. The tanks proper consist of two units, one adjacent to each battery of settling tanks, each unit consisting of two passes which are each 17.75 ft wide and 290 ft long with an average water depth of 15.5 ft. The tanks provide a detention period of 24.5 min at the average flow of 134 mgd. When used as settling tanks, they therefore add 24.0 min to the sedimentation period.

Settling Tanks.—The two batteries of settling tanks consist of three units, each 56 ft wide, 290 ft long, and with an average water depth of 15.5 ft. Each tank has three passes with a width of 18.0 ft. The detention period in the settling tanks at the average flow of 134 mgd is two hours. The tanks are provided with sludge removal and skimming mechanisms. A rather comprehensive system of effluent weirs has been provided, having a total length of 480 ft for each tank and providing 0.047 million gal per ft of weir length at average flow.

Pump and Blower Building.—In this building are located various services used in connection with flocculation and sedimentation, including two 300-gal-per-min sump-drainage and under-drainage pumps; two 200-gal-per-min scum pumps; eight 210-gal-per-min triplex displacement sludge pumps; two 500-gal-per-min centrifugal sludge pumps for peak and emergency purposes; one 2,500-gal-per-min tank dewatering pump; and three blowers, one 1,200 cu ft per min, one 1,800 cu ft per min, and one 2,400 cu ft per min, along with the switchboard for control of the various equipment, a small office, and various minor miscellaneous services.

Effluent Filters.—The effluent filters are of the downward-flow magnetite sand type, are eight in number, and are divided into two batteries. The total filter area is 31,200 sq ft, which provides a filter rate of 3 gal per sq ft per min at average flow of 134 mgd. Each filter bed is 16 ft wide and 244 ft long.

Filter Service Building.—In this building are located three 1,500-gal-per-min wash-water pumps, two 300-gal-per-min sump pumps, one pump of 300-gal-per-min capacity, and two pumps of 450-gal-per-min capacity each to pump plant effluent for use in sluicing ash or dissolving and transporting chemicals; and three motor generator sets of 50-hp capacity each.

SLUDGE DISPOSAL

General.—The sludge removed from the settling tanks is pumped to the sludge concentration tanks. After concentration the sludge is conducted to the conditioning tanks, thence to vacuum filters, and finally to the incinerators.

Concentration Tanks.—Two such tanks, each 95 ft long, 18 ft wide, and with a total water depth of 24 ft (effective capacity of 41,000 cu ft each), are provided, with sludge collector mechanisms and means for removing scum.

The number of tanks in use, the depth of sludge, and therefore the period of storage are varied with the sludge load.

Filtration and Incineration Building.—In this building, in addition to the vacuum filters, incinerators and their appurtenances, the machine shop, boiler room, and electrical control equipment are located.

Vacuum Filters.—The sludge from the concentration tanks is fed to either of two bucket elevators which discharge into three air-agitated conditioning tanks. From these tanks the sludge discharges by gravity into six vacuum filters arranged in two batteries. Each filter is 11.5 ft in diameter and 14.0 ft long, and has an effective filter area of 500 sq ft. Among the main appurtenances of the vacuum filters may be mentioned three vacuum pumps, each with a capacity of 1,850 cu ft per min; three blowers, each with a capacity of 800 cu ft per min; three filtrate pumps, each with a capacity of 250 gal per min; and two belt conveyers with weighing scales, each having a capacity of from 2 to 30 tons per hr.

Incinerators.—Three incinerators of the multiple-hearth type have an outside diameter of 22.25 ft, with eight hearths, each incinerator having a nominal capacity of 60 tons of dry solids. The incinerator ash is discharged into hoppers, from which it is sluiced to ash pumps, and thence is discharged to the dump. The main appurtenances of the incinerators are three plate-type preheaters, three hot-air fans each with a capacity of about 11,000 cu ft per min, and three hot-gas fans each with a capacity of about 36,000 cu ft per min.

Chemical Handling and Feeding.—A pneumatic conveying system with a capacity of 6 tons per hr has been provided for unloading dry chemicals and discharging them into storage bins.

Chemical feed equipment was installed for feeding lime with either chlorinated copperas, ferric sulfate, or ferric chloride, the use of which will depend on the efficiency and market prices of the various chemicals from time to time. Two gravimetric lime feeders and slakers with a capacity range from 200 to 1,200 lb per hr each, as well as two copperas or ferric sulfate feeders with a capacity range from 100 to 600 lb per hr each, have been installed. In addition to the aforementioned feeders, two solution feeders for ferric chloride have been provided, each with a capacity range from 12 to 120 gal per hr.

PLANT OPERATION

Operation of Plant Started.—Shortly after the dedication of the treatment plant on May 16, 1938, preliminary operation and testing of the equipment were begun. On June 1 the first sewage was turned into the intercepting sewers and into the plant, and by July 15, 1938, practically all of the sewage of the Twin Cities was conducted to the plant.

The plant was placed in operation under a planned and definite schedule which called for a gradual starting of the various units. As already stated, the plant is divided into two separately operated halves or batteries that can be operated independently of each other. Advantage was taken of this fact in starting the plant. The various plant units were placed in operation one battery at a time. The schedule of placing the plant in operation (which was carefully adhered to) was as follows:

June 1—One battery of screen and grit chambers placed in operation.
June 7—Operation of second battery begun.
June 9—One battery of settling tanks started.
July 2—Vacuum filtration of sludge started and filter cake hauled to dump.
July 6—Settled effluent turned into magnetite filters.
July 7—Second battery of settling tanks placed in service.
July 21—Incineration of sludge begun.

Operation of the various units was begun without unusual difficulty except as might be expected with mechanical equipment of the type required in a large plant of this type. The manufacturers of the magnetite effluent filters and the incinerators experienced the greatest difficulties in placing their equipment in satisfactory operation. Some of these difficulties are discussed in more detail subsequently.

Continuous 24-hr operation of the plant was begun on July 20. From then on all the equipment that had been accepted by the Minneapolis-St. Paul Sanitary District performed in an acceptable manner. However, because of the manufacturer's difficulties with the incinerators, it was necessary to by-pass varying quantities of sewage from time to time, depending on the quantity of sludge that could be incinerated. After October 3 no sewage was by-passed at the plant with the exception of excess storm flows, the excess sludge that could not be handled by the incinerators being pumped directly to the river. It was not until the latter part of November, 1938, that the incinerators were capable of incinerating all the sludge produced at the plant.

With the large volume of equipment in a modern sewage treatment plant, some of which has been used in this field only a few years, the process of placing a large plant in operation is rather involved, especially from a mechanical standpoint. The writer wishes to record with satisfaction the fine cooperation accorded by manufacturers of various equipment. It is gratifying to note that, although extensive guarantee and maintenance bonds of various types were provided for in the mechanical contracts, it has not been necessary to invoke any of their compliance provisions.

General.—The sewage flow arriving at the plant was less than the estimated flow of 120 mgd for the year 1938, averaging 98.8 mgd for the period from July 1, 1938, to May 31, 1940, inclusive. The strength of the incoming sewage, however, was somewhat greater than was anticipated, averaging 275 ppm on a suspended-solids basis, and 210 ppm on a 5-day B.O.D. basis. This compares with expected strengths of 185 ppm and 200 ppm, respectively. The increased strength on a suspended-solids basis places a greater load on the treatment plant, especially on the sludge disposal processes, than was anticipated.

Up to May 31, 1940, a total of 66,864.1 million gal of sewage was treated by the plant, from which a total of 79,944 cu ft of screenings and 501,278 cu ft of grit was removed. In addition, solids equivalent to a total of 183,497.6 tons of filter cake were removed and incinerated. More detailed operating data are given in Table 1.

As already stated, the plant was designed so that treatment by a variety of processes can be provided to meet varying river requirements. Operation

Screen and Grit Removal.—Sewage was first taken through the screen and grit chambers on June 1, 1938. From that time this unit of the plant functioned in a satisfactory manner. Until May 31, 1940, a total of 79,944 cu ft of screenings and 501,278 cu ft of grit was removed. Related to the 66,864.1 million gal of sewage treated, this amounts to an average of 1.2 cu ft per million gal of screenings and 7.5 cu ft per million gal of grit. Based on a study of 117 screen installations throughout the United States, the average quantity of screenings removed by screens with one-inch openings was 3.1 cu ft per million gal. The quantity of screenings produced by the Twin City plant fortunately was only about one third of the quantity that might have been expected. The quantity of grit removed compares with an average in a number of plants in the United States of 4.1 cu ft per million gal. A relatively clean grit containing an average of 11.7% of volatile solids was produced.

Velocities in the grit chambers were originally maintained at 0.75 ft per sec. In 1940 velocities during dry weather flows were gradually increased to 1.20 ft per sec for the definite purpose of securing a greater percentage of inert material in the sludge, thereby increasing the solids content of the sludge and reducing the quantity of conditioning chemicals required.

Because of the small quantity of screenings in proportion to grit, it was possible to bury the screenings with an appropriate depth of the relatively clean grit. Shredders were used only to test out the equipment and periodically to keep the equipment in satisfactory operating condition. A variety of material was removed on the hand-raked coarse bar racks (6-in. openings) at the entrance to the plant. Material removed at this point has included both vegetable and animal matter and has ranged from logs and timbers, a section of boiler plate 8 ft by 4 ft, and whole trees to dead dogs and quantities of cattle paunches.

A number of improvement changes were made in this part of the plant which resulted in better and more simplified operation. Some difficulty with wear because of sand entering the lower and intermediate bearings on the screw conveyer grit washers was experienced; but this was partly corrected during 1939 by the manufacturers at no expense to the Sanitary District. However, more positive methods of reducing wear still further have been installed by the Sanitary District, consisting essentially of sealed water-washed and lubricated bearings. After almost one year of operation several bearings of this type installed for observation showed little, if any, wear, and as a result of this experience all bearings have been modified to the new type. From a very troublesome installation requiring replacement of the former type bearings after only one month of operation, this equipment has been converted into a very smooth and satisfactory operating installation. Another item of equipment with which considerable difficulty was experienced in the early part of 1939 was the grit bucket elevator. With grit of certain characteristics, principally that containing high moisture content and a large percentage of "fines," the elevator would not unload satisfactorily, and material would enter the bearings and accumulate on the pulleys and otherwise cause difficulty. By the installation of an air jet to sweep the material out of the buckets, and by installing sealed bearings of a special type, the difficulties with this equipment have been largely overcome.

Sedimentation.—From the time the settling tanks were placed in operation on June 9, 1938, they have operated continuously and satisfactorily. The removals accomplished by the settling tanks were unusually high, from the standpoint of the removals expected, and compared with the removals by most of the other primary settling tanks throughout the United States. The fact that the tanks operated satisfactorily, both from the viewpoint of reliability of equipment and efficiency of removals, is gratifying, considering the fact that the long tanks represent, to some degree, departure from precedent, both for the purpose of effecting construction economies and of accomplishing the higher removals expected from a consideration of a number of theoretical factors.

An effort was made to curtail the removals by the settling tanks, until the South St. Paul and Newport plants were in operation, to an average of approximately 60% removal of suspended solids, by reducing the detention period. With an average detention period for the two years of only 1.5 hr, as compared with a possible detention period of somewhat more than three hours at present flows, the average removal of suspended solids was 69% and of 5-day B.O.D. 38%. Considering the four months of 1939 and 1940, when detention periods of more than 2 hr were maintained (averaging 2.4 hr), the removal of suspended solids averaged 74.4% and of B.O.D. 42.9%. By using all of the settling tanks, a detention period of 3.2 hr can be obtained at present flows, which should result in still higher removals.

Because of the long tanks, the settling tank equipment is operated continuously. Sludge is pumped once each shift, and a determined effort is made to secure as concentrated a sludge as possible. That such efforts were successful is shown by the fact that for the 2-yr period the solids concentration in the raw sludge pumped from the settling tanks averaged 7.7% (92.3% moisture). The skimmings removed from the settling tanks are ejected to an area south of the plant where they are covered with incinerator ash without nuisance, by the simple device of discharging the two materials at the same point.

The aforementioned removals may be compared with expected removals (for a detention period of approximately 2.5 hr) of 56% on a suspended-solids basis and 36% on a 5-day B.O.D. basis. These removals were based on a study of thirty sedimentation plants throughout the United States, reported[3] in 1933. It has been suggested that the relatively high removals were due to a relatively low percentage of volatile matter in the raw sewage, but this opinion was determined to be without foundation. As an indication of the fact that the volatiles in the raw sewage are in line with what is experienced elsewhere, the average for the year 1939 was 71.1%.

A number of improvements were made in the appurtenances to the settling tanks to increase dependability, to reduce costs, and to simplify operation. Perhaps the most important is the method of handling scum after its removal from the settling tanks. Automatic skimming mechanisms remove the material from the settling tanks and deposit it in scum troughs from which, with some flushing, it is transported to scum manholes. In the original installation, scum was discharged from this manhole to a sump from which the suction of the scum pumps was drawn. Difficulties were encountered early because of segregation of materials in this sump, and in an effort to remedy this condition the suction was corrected directly to the pumps and various methods of agitation were installed. However, suction and discharge lines, as well as the pumps themselves, frequently became plugged, and in addition to using large quantities of transporting water it was necessary to screen out all material retained on ¾-in. racks. Nevertheless, after four months of operation, the cross-sectional area of the scum discharge line had been reduced to one tenth of its original area by grease incrustations. A number of different methods of handling were considered, from which an ejection method was selected, chiefly because of its possibilities of handling relatively dry scum, which is an important consideration in connection with final disposal. This system was installed with the result that dry material could be handled without the necessity of previously removing large pieces of material, and without attendant stoppage, all of which greatly simplified disposal problems. Although this problem may appear unimportant from the standpoint of general plant performance, it has greatly reduced the labor required in this part of the treatment process.

---

[3] "Factors Affecting the Efficiency of Sewage Sedimentation," by George J. Schroepfer, *Sewage Works Journal*, Vol. 5, 1933, No. 2, pp. 209–232.

No difficulties were experienced with freezing of sewage in the settling tanks of effluent filters during the winter months. Even with temperatures as low as 25° F below zero, sewage temperatures dropped only about 4° F through the plant. Some difficulty was experienced, however, with the automatic skimming mechanisms during cold weather. Heavy frost gathered on moving parts of the equipment during the period that the mechanism was stationary, with the result that some attachment links were broken. It was found much more economical under these conditions to skim the material into the scum troughs by hand than to attempt to keep the equipment operating.

It was expected at the time of design that sludge as removed from the settling tanks usually would contain from 3% to 6% solids. By careful control of sludge pumping, it has been possible to remove sludge from the tanks averaging between 7% and 8%. In order to handle heavy sludge, containing at times as high as 20% solids, without frequent stoppages, it was found necessary to make provisions for blowing back suction lines with plant effluent or compressed air, on a routine schedule. In this manner, difficulties with sludge suction lines as long as 300 ft were eliminated. Careful control of pumping is required to secure a concentrated sludge. The tendency generally is to pump for too long a period. Except under conditions of storm flow, the usual practice is to operate the sludge pumps three times daily, continuing pumping as long as the sludge remains heavy. As a means of maintaining as concentrated a sludge as possible, specific gravities are determined by weighing calibrated containers of sludge periodically during the pumping period.

One of the problems in the early operation of the plant was the difficulty created by mud and silt that were carried into settling tanks during thaws and storms. This material, which was too fine to be removed by the grit chambers, collected in large quantities in the settling tanks and on several occasions stalled the collector mechanisms, with the result that the tanks had to be pumped down and flushed out with a hose. The difficulties resulted partly from the inability to move the mud and silt through the sludge suction pipes, due to stoppage in the lines, which, even after they were cleaned with compressed air, removed only water. Climatic conditions require the use of large quantities of sand and cinders on the streets during the winter months, amounting to a total of approximately 20,000 cu yd during the winter of 1938–1939. Thaws and early rains carry in a fair percentage of this material. Samples taken at half-hour intervals before, during, and after rains in the early summer indicated suspended-solids strength up to 6,000 ppm, compared with averages of approximately 275 ppm. The percentage of volatile material drops very low during these times. Depending on the intensity and interval between rains, present indications are that flows of more than 250% of the average usually result in settling tank and sludge pumping difficulties. It was found that, when a heavy blanket of normal sewage sludge is carried in the tanks previous to storm flows, more inert material can be removed effectively from the tanks because of the evident loosening of the mud and silt which ordinarily packs and results in difficult removal problems. As an indication of practice and experience elsewhere, a study of twenty five of the larger plants in the United States showed that the average of the peak flows treated for these plants was 180% of the average flow treated.

It was found desirable to replace the pistons and the collars on the sludge pumps with heavier parts made in the shop of the Sanitary District at a fraction of the cost of such parts from the manufacturers. Although no unusual difficulty was experienced with the lighter pistons, it was felt that it would be economical to install heavier pistons that would permit resurfacing from time to time, thereby prolonging the life. The only difficulty of any type with the sludge collection equipment in the settling tanks, and that of a minor nature, was the breakage of some of the links of the drive chains, especially during the winter months. A completely satisfactory explanation of the cause of this difficulty has not been found as yet, but after experimenting with different materials and types of chains the conclusion has been reached that the installation of chain tighteners will largely eliminate the previous difficulties. Data on removals by sedimentation for the various periods are presented in Table 2.

TABLE 2.—DATA ON REMOVALS BY SEDIMENTATION

Period of observation	Detention period, in hours	RAW SEWAGE STRENGTH (PPM)		PERCENTAGE REMOVAL			Percentage of total solids in raw sludge
		5-Day B.O.D.	Suspended solids	5-Day B.O.D.	Suspended solids	Settleable solids	
July, 1938, to December, 1938, inclusive	2.15	200	240	36.0	68.8	90.0	7.15
1939	1.3	205	285	38.9	68.9	84.9	7.79
January, 1940, to May, 1940, inclusive	1.5	225	300	38.0	70.1	90.8	8.09

Because of early difficulties in placing the plant in operation, the period from July to December, 1938, is not truly representative of normal operation. Considering the latter two periods, the removals of suspended solids averaged 69.5% and of B.O.D. 38.4%, with a detention period of 1.4 hr (less than one half of the possible period with all tanks in service). The increase in the solids content of the raw sludge with experience is shown in Table 2.

Effluent Filters.—The downward-flow magnetite filters were first placed in operation on July 6, 1938. This equipment was purchased under guarantees providing for removals of suspended solids, as follows:

Influent strength (ppm)	Reduction through filters (ppm)
30	2
50	9
70	18
90	29
110	40
130	50

The filters were designed for an average rate of 3 gal per sq ft per min and a short-time maximum rate of 6 gal. This compares with average rates at other plants generally between 2 and 2.5 gal per sq ft per min.

Early operation indicated that the filters would meet the guaranteed removals, but difficulties with sand erosion and displacement occurred at flows greater than the average. The earlier difficulties were felt to be associated with the hydraulics of the structure, considerable erosion near the inlet ports of the beds being experienced. As a means of overcoming this difficulty, the contractor enlarged the influent ports, which apparently solved the erosion problem. However, with this solved, another problem appeared: The sand was displaced, laterally and longitudinally, by the action of the cleaner carriages in passing over the beds. It is a pleasure to report that, as a result of continued efforts over a long period of time, the manufacturer has apparently corrected these difficulties.

The removals of suspended solids by the effluent filters during thirty-four days of intermittent operation, between May 1 and December 28, 1939, have been as follows:

Suspended Solids (ppm):	
Raw sewage	280
Filter influent	78
Filter effluent	56
Percentage of Removal by:	
Settling tanks	71.1
Effluent filters	8.2
Total	79.3
Detention period in settling tanks, in hr	1.6
Filter rate, in gal per sq ft per min	2.5

During the foregoing period, settling only was used prior to filtration (that is, there was no flocculation or chemical treatment). The sedimentation period prior to filtration was only about one half of the normal detention period in the tanks. Somewhat higher removals prior to filtration can be effected, especially if flocculation (without chemicals) is practiced prior to sedimentation. Partly because of these difficulties, as well as the fact that there operation was not required in any event, the filters were operated only a relatively few days during the 2-yr period covered by this paper.

SHORT-TIME TESTS OF VARIOUS OPERATIONS

Flocculation Without Chemicals.—During the first two years of operation, treatment consisted essentially of plain sedimentation, but flocculation without chemicals, effluent filtration, chemical treatment, and chlorination were practiced for varying periods of time for test purposes. During June, 1939, flocculation without chemicals was practiced in one battery, and plain sedimentation was continued in the other battery for comparison. An average of approximately 0.035 cu ft of air per gallon was used for flocculation. The average removals in suspended solids and 5-day B.O.D. were as follows:

Description	Flocculated and settled	Settled only
Suspended solids	80.1	75.5
5-day B.O.D.	49.8	44.2
Period of flocculation, in min	32.0	...
Period of sedimentation, in hr	1.70	1.64

Chemical Treatment Trials.—During 1939, chemical treatment was not practiced; nor was it considered necessary except to test the various equipment for four days. During this short test period it was impossible to adjust flocculating conditions to secure optimum removals. Ferric sulfate was used as a coagulant and no attempt at *pH*-control was tried. For this test, again, the plant was divided into two halves, in one of which sedimentation alone was practiced; in the other, chemical treatment was used. The results of this short test are as follows:

Description	Plain sedimentation	Chemical treatment
Detention Period:		
Flocculation tanks, in min	...	34.3
Sedimentation tanks, in hr	1.4	1.85
Air, in cu ft per gal	...	0.025
pH-value, raw sewage	7.4	7.4
Chemicals added (in ppm of iron)	...	12
Percentage of Removal:		
Suspended solids	73.0	83.4
5-day B.O.D.	35.3	55.4

Neither of the foregoing tests include effluent filtration, the inclusion of which would increase the removals accomplished.

Disinfection Trials.—Sewage was disinfected with chlorine in half the plant for eleven days in June and July for the purpose of running operating tests on the equipment and obtaining some information on effective dosages. One 16-ton tank car of chlorine was used, and chlorine dosages of 4, 6, and 8 ppm were tried. Pre-chlorination post-chlorination, and split chlorination were used—that is, trials were made applying the chlorine (*a*) to the raw sewage only (pre-chlorination), (*b*) to the settled effluent only (post-chlorination), and (*c*) dividing the dosage between the raw sewage and the effluent (split chlorination). The flocculating tanks were used to provide approximately 30 min contact time for the chlorine added to the settling tank effluent. To avoid

TABLE 3.—DISINFECTION OF SEWAGE (AVERAGE VALUES)

Chlorine dosage (ppm)	BACTERIAL COUNT IN RAW SEWAGE (COLONIES PER ML, 48 HR; AGAR, 37° C)		COLIFORM ORGANISMS IN RAW SEWAGE (*Coli-Aerogenes* PER ML; MOST PROBABLE NUMBER)	
	Total	Percentage reduction	Total	Percentage reduction
4	9,200,000	67.1	170,000	56.1
6	7,600,000	97.9	230,000	97.4
8	6,200,000	99.64	200,000	99.95

any possible changes in bacterial counts in stored samples, only grab samples collected during the morning and afternoon were used to measure the bacterial kill or disinfection. A summary of the results obtained is given in Table 3.

The results of pre-chlorination, post-chlorination, and split chlorination are not shown separately in Table 3. Although they were quite uniform, the tests covered too short a time to justify any definite conclusion regarding the relative effectiveness of the various points of chlorine application. The results indicate that a satisfactory kill of bacteria can be obtained with a comparatively small chlorine dosage of 6 to 8 ppm.

Recirculation of a Percentage of Incinerator Ash.—During the latter part of September, 1940, the return of a percentage of incinerator ash to the raw sewage ahead of the screen and grit chambers was begun. This experiment was conducted as a result of laboratory experiments made approximately two years previously in an effort to improve vacuum filtration and reduce the quantity of conditioning chemicals required. Because this test was begun only recently, it is too early to present conclusive data, but present indications are that very satisfactory reductions in chemicals required for sludge conditioning have been effected, in addition to which appreciable increase in the efficiency of sedimentation resulted. It is the expectation that flocculation will further increase the removals accomplished.

SLUDGE DISPOSAL

Sludge Dewatering; Character of Sludge.—The raw sludge delivered to the concentration tanks varies over quite a wide range in quantity and in the characteristics that affect filtration and incineration. Referring to Table 4, the raw sludge as removed from the settling tanks in the period from September 1, 1938, to May 31, 1940, averaged as follows: *pH*, 6.0; moisture content, 92.26%; and volatile solids, 64.8%. After concentration for a period which generally varies from one to two days, the *pH*-value of the sludge had changed to 5.9, the moisture content to 90.88%, and the volatile solids to 63.6%.

Sludge Conditioning.—The chemicals used for conditioning, except for short periods when ferric chloride alone was used as an experiment, have been lime and ferric chloride. During the period covered by this paper, the quantity of ferric chloride has averaged 2.18% of the weight of dry sewage solids, and the lime 4.87%. However, during the last six months of this period, the quantity of chemicals averaged somewhat less, or 1.89% ferric chloride and 4.37% lime, as compared with the requirements of 2.68% and 9.74%, respectively, during the first six months of operation. Control of the quantity of chemicals used for sludge conditioning has been by a physical examination of the cake and the sludge by the operators, checked by relatively frequent laboratory tests. Early in 1940 continuous control of filtration by the filter operators was begun by means of Bueckner funnel tests. It is of interest to mention that the period of sludge conditioning has been gradually shortened so that in 1940 it averages about 6 min.

Proper mixing and agitation of conditioned sludge prior to filtration is of utmost importance, especially with heavy sludge. The use of large quantities of low-pressure air administered at a number of points resulted in improvement in filtration and a consequent reduction in chemicals required. As originally installed, high-pressure air was supplied through porous tubes. Upon failure of this arrangement to perform in a completely satisfactory manner, various methods were tried, culminating in one in which a total of eighteen small pipes was added to each tank and excess low-pressure air from the blowers, provided for removing cake from the filters, was utilized for agitation. Means for distributing the chemicals more uniformly through the tank were provided, and experiments were made to determine the proper sequence of chemical additions. Studies are under way to effect additional improvements in sludge conditioning.

TABLE 4.—SUMMARY OF DATA ON SLUDGE CHARACTERISTICS AND VACUUM FILTRATION

(September, 1938, to May, 1940, Inclusive)

Month	*pH*-Value		Total Solids (%)			Volatile Solids (%)			Average Tons of Material Daily			Conditioning Chemicals, % of Sewage Solids		Average rate, in lb per sq ft per hr

It has been found that the quantity of chemicals required for sludge is less with heavy sludge, which condition is usually associated with rains carrying inert material into the sewage. With the particular design of sludge piping installed in this plant, sludge containing more than 10% to 12% solids usually requires thinning with plant effluent to permit its movement through the piping system.

Vacuum Filtration.—Dewatering of sludge was begun on July 2, 1938. The sludge cake produced averaged 34.9% solids (65.1% moisture) in the 2-yr period. As a monthly average, during March, 1939, the moisture content was as low as 60.9%. Daily averages have been lower than 50%, these low moisture contents being associated with rains and periods when the volatile solids were exceptionally low. The volatile solids in the filter cake vary widely. During the period from September, 1939, to May, 1940, the volatile solids in the filter cake averaged 58.5% with a range in monthly averages from 51.4% to 68.6%. Daily variations are still greater. In the period since operation started to May 31, 1940, 183,497.6 tons of filter cake were produced by the plant. For the period from September 1, 1938, to May 31, 1940, the quantity of dry sewage solids has averaged 98.5 tons daily, equivalent to 289.0 tons of filter cake daily.

As in sludge conditioning, a number of improvement changes were made in this part of the plant which have resulted in simplified operation and marked reductions in operating cost. As an example of the effect of these changes, including those in sludge conditioning, during early operation approximately 3% ferric chloride and 10% lime were required, which has been reduced by various means to somewhat less than 2% and 5%, respectively. On the basis of 100 tons of dry sewage solids daily, and chemical prices current at this time, this amounted to a saving of $100 per day in chemical costs.

The reduction in the use of lime resulted in other operating advantages. In early operation, difficulty was experienced with lime-blinding of the cloths, and after a period of several months' operation the openings on the screen supporting the cloth had been reduced to less than one quarter of their original area by calcium carbonate deposits. A number of methods of removing this material were tried. At one time it appeared desirable to purchase new screens at a cost of $193 per filter. Finally the screens were removed and sandblasted at a cost of only $15 per filter, with entirely satisfactory results. With the reduction in the quantity of lime, the necessity of cleaning screens has been practically eliminated.

To remove calcium carbonate from the screens, conditioning with ferric chloride alone was tried. It was determined, after a short time of operation on two of the filters, that this method, although effective, was not economical. However, the experiment permitted a determination of the effectiveness of this chemical alone for conditioning. The rate of filtration as compared with lime and ferric chloride was reduced, ranging from 3 to 4 lb per sq ft per hr for dosages of 3% to 4% of ferric chloride.

For the entire period the average filter rate was 4.87 lb per sq ft per hr. During the early period when higher chemical dosages were used, the rates were considerably higher, averaging as much as 10 lb for various periods of time. In addition to the higher operating costs to secure greater rates, the production of a thick cake presented certain undesirable operating problems in the conveying of the cake. In view of the fact that the increased power cost by using more filters was insignificant, and that the extra cost of cloths was small in comparison with the savings in chemicals which could be effected, the desirability of operating with lower filter yields was apparent. In emergencies, or under extreme peak conditions, it is necessary to use higher chemical dosages to increase the filter rate.

The problem of increasing filter cloth life has been given due consideration, brushing and washing with steam and air being tried progressively. In the early period of operation, cloths generally had to be removed after about 150 hours of use. The need for removal was dictated by the fact that lime-blinding necessitated higher chemical dosages and more frequent washing, and ripping or rotting at seams required the use of a large number of tin patches (as many as 30 to 40 on a filter) even with this short life. With reduced lime dosage the economical cloth life has been increased to somewhat more than 300 hours (periods of usage of 500 to 600 hours were common for several months). Beyond this time increased chemical feed is required, incommensurate with the cost of cloth replacement, especially in view of the reduction in cost of cloth which has been effected. The ability to purchase identical cloths locally at a fraction of their original cost has made it possible to change filter cloths more frequently than was formerly the case. In addition, the new cloths are sewed with a different type of thread and with a lock stitch so that difficulties at the seams, requiring patching, have been eliminated.

Changes have been made in the location and angle of incidence of water sprays used in washing filters as compared with the type ordinarily manufactured. Various types of sprays arranged at different angles relative to the drum surface were tried. The original sprays were reversed, and located so that water would impinge almost at right angles to the cloth on the drum. The new arrangement permitted better washing in one third of the time previously required. Less water is used, and the necessity of brushing the cloth has been eliminated, thus insuring a longer cloth life.

The problem of conveying filter cake, containing varying quantities of water, on belts presents many difficulties that are sometimes not recognized. Stoppages are quite frequent with relatively minor restrictions in openings around and over belts and at transfer points. These problems are aggravated with thick cake (heavier than ⅜ in.). It was found early that large blocks of cake, as long as 8 ft and as wide as the filter drum, were broken off as the drum revolved. Various methods of breaking up this cake were considered, resulting in the selection of the simple and effective expedient of installing sloping ¼-in. rods on 12-in. centers in the filter take-off plates. This device cuts the cake into ribbons one foot wide, which break off irregularly and eliminate difficulties from this cause.

Incinerators.—Incineration of sludge was begun on July 21, 1938, and 24-hr operation on July 29. On August 4, 1938, the first incinerator placed in operation became heated to the point at which the manufacturers' representatives considered that it was necessary to shut down in order to insulate the rabble arms on certain of the hearths. Incinerator temperatures up to 2,200° F were recorded as compared with expected maximum temperatures of 1,600° F. The high temperatures required the replacement of several of the rabble arms and a section of the central shaft on this incinerator.

The explanation for this condition is simple. Instead of requiring approximately $2,500 worth of fuel oil a month, as estimated, it was found early that under practically all conditions of operation an excess of heat existed, and no fuel was required for actual incineration. It was the manufacturers' expectation that the location of burning, and the temperatures of combustion, would be controlled by the use of varying quantities of oil introduced at different points. Instead, it was necessary to dissipate heat to the extent of more than 6,000,000 Btu per hr per incinerator. In the beginning the manufacturers attempted to accomplish this by introducing water into the furnace through sprays. Although this was effective, it was considered unsatisfactory by the Sanitary District to use the large quantity of water required. After experimenting with different methods for solving their difficulties, the manufacturers installed a by-pass to conduct preheated air direct to the stack. In this way air at room temperature could be used for combustion, and the water would be reduced to reasonable quantities and its addition required on less frequent occasions.

Continuous operation of all the incinerators was possible beginning November 17, 1938, and in accordance with the specifications the acceptance tests were begun thirty days later, on December 17, 1938, and completed satisfactorily on March 17, 1939.

The method of correcting some of the early difficulties with overheating, etc., was a matter of thorough investigation over a period of five months, and presented some rather interesting problems. Progressively, a number of solutions were considered, and the methods finally adopted were those selected after careful consideration of all factors by the Sanitary District and the contractor. Some of the difficulties appeared insuperable at times, but it is a pleasure to report that they were successfully overcome by the contractor, at no expense to the Sanitary District.

From July 21, 1938, to May 31, 1940, 182,097.6 tons of filter cake were incinerated. The average Btu per pound of combustible solids in the sludge during this period was 10,800, and the average volatile solids in the sludge cake during the period covered herein amounted to 58.5%. The sludge cake was reduced by incineration to an ash containing less than 2% volatile matter (actual average 1.6% during guarantee period). As shown in Table 4, the moisture content in the sludge cake as produced by the filters has averaged 65.1% during the period from December, 1938, to May, 1940, inclusive.

The comparison between the quantity of material incinerated and the guaranteed capacity of the incinerators is interesting. Over a 24-hr period, a maximum of 523.8 tons of filter cake or a total of approximately 225 tons of dry solids have been incinerated. The capacity of each of the three incinerators is 60 tons of dry solids per twenty-four hours. As much as 78.5 tons of dry solids have been incinerated in one incinerator in a 24-hr period. Hourly rates considerably in excess of the foregoing have been handled successfully. For the period from December 1, 1938, to May 31, 1940, the number of tons of dry solids incinerated per day in each incinerator has averaged 55.1 tons as compared with the maximum guaranteed capacity of 60 tons daily.

During the period from December, 1938, to May, 1940, inclusive (see Table 5), 123,911 gal of fuel oil were required by the incinerators. Practically all of this was required in bringing furnaces up to temperatures from a cold condition or in cooling them down, and in holding temperatures in furnaces out of service. The aforementioned quantity of oil amounts to an average of 2.3 gal per ton of dry solids incinerated. Power required for incineration amounted to an average of 17.3 kw per hr per ton of dry solids.

Miscellaneous Sludge Disposal.—Investigations are in progress in connection with the utilization of sludge and ash for various purposes. A research fellowship has been established with the Agricultural College of the University of Minnesota, at Minneapolis, to explore the fertilizing or soil conditioning possibilities of sludge cake as produced by the filters and its use after storing for periods of time. Experiments have been made on the production of partly dried material by removal of a portion of the sludge from the top hearths of the incinerater, using the heat of the remainder of the sludge incinerated for drying purposes. An unusual degree of interest has been shown in the use of the material by farmers, nurseries, golf courses, parks, etc., but to 1940 no material was distributed except to those working in cooperation with the Agricultural College. This has been done with the express purpose of determining the advantages and disadvantages of the material, as well as the proper conditions of use, before general distribution and sale. From the interest and requests to date, it appears likely that a relatively large proportion of the material may be disposed of in this manner during a part of the year.

TABLE 5.—DATA ON SLUDGE INCINERATION, DECEMBER, 1938, TO MAY, 1940

Average	9,147.0	3,211.0	55.1	7,384	55,443

The use of ash has been investigated. Some possible uses that have been suggested are: A binder or filler for various products, a soil conditioner, an ingredient for certain kinds of cement, etc. About 400 tons of the material have been disposed of as filler, in lieu of pulverized limestone, for a commercial fertilizer. A typical analysis of the ash from this plant is as follows:

Silica as $Si\ O_2$	43.6%
Calcium as $Ca\ O$	26.3%
Aluminum as Al_2O_3	9.9%
Iron as Fe_2O_3	6.9%
Potassium as K_2O	2.1%
Phosphorus as P_2O_5	0.7%
Miscellaneous	10.5%

Another interesting possibility relates to the utilization of the heat resulting from incineration. Various possibilities have been developed which may result in the generation of sufficient steam for all heating purposes and electric power requirements.

Everything considered, the methods of sludge disposal used at this plant have proved quite satisfactory, and a number of possibilities for still further improvement are under consideration. The successful and economical operation has been very gratifying, and at times such operation was an absolute necessity, especially when it is considered that the quantities of material to be handled were considerably greater than originally expected (monthly averages as high as 131.8 tons daily, as compared with expected average quantities of 76.5 tons daily).

Cost Features

Construction Cost.—The total construction cost of the plant was approximately $3,750,000 or $28,000 per million gal of capacity. The distribution of this cost was about as follows: Screen and grit chambers with chemical tower, $540,000; settling tanks, effluent filters, and appurtenances, $1,630,000; filtration and incineration building, $1,240,000; laboratory and administration building, $175,000; and miscellaneous, $165,000. Equipment represents about $1,500,000 of the total cost of $3,750,000.

Operation and Maintenance Costs.—The total operation and maintenance costs for the period from June 1, 1938, when preliminary treatment was first begun, to May 31, 1940, was $587,136.03 (see Table 6(*a*)). During this period 66,864.1 million gal of sewage was treated, bringing the average cost per million gallons to $8.80. The entire flow was not received until about July 15, 1938, and furthermore operation during the early months was curtailed because of the manufacturer's difficulties with incinerator operation. For these and other reasons the costs during the early period of operation in 1938 are not typical. During 1938, for example, the average cost per million gallons was $10.65, which compares with $8.20 for 1939, and $8.35 for the first five months of 1940. Of the total cost during the first two years of operation, maintenance costs totaled $45,884.23, or 7.8% of the total.

Table 6(*b*) shows the distribution of operation and maintenance costs by departments for the three periods. In order of descending cost importance the following are the most important items: Vacuum filtration, incineration, supervision and engineering, administrative expense, laboratory expense, sedimentation, etc. This order will be varied, of course, whenever chemical treatment and chlorination are practiced.

Although what follows concerning the comparison between actual expenditures and funds available (see budget provisions, Table 6(*b*)) may not be of general interest, it is nevertheless a matter of local gratification that it has been possible to hold expenditures within budgeted funds. During the first two years of operation, expenditures totaled $587,136.03 as compared with budget provisions of $917,164.81. It is a fact that, although the deliberate reduction in treatment provided (until communities and industries immediately downstream provided comparable treatment) resulted in certain savings, a large part of the reduction in cost was possible by the operation economies effected.

It is interesting to note the large proportion of the total cost directly chargeable to sludge disposal. During 1939, for example, $136,815.43 was expended for vacuum filtration and incineration, which represents $3.70 per million gal, or approximately 45% of the entire cost of operation and maintenance. In 1938 the total cost of sludge disposal was $69,840.65, during which period a total of 10,248 tons of dry sewage solids were processed. The cost of dry sewage solids was approximately $6.80 per ton. For the more representative period of 1939, during which time reductions in sludge conditioning chemicals were effected, the total cost per ton was $3.63, which was further

reduced in the first five months of 1940 to $3.15 per dry ton. Monthly data on the cost of sludge disposal is shown in Table 7.

Of the total cost of disposal for the period from January, 1939, to May, 1940, inclusive ($191,311.19), filtration cost was $137,310.48, or 72%, and incineration $54,000.71, or 28%, of the total cost. As further shown in Tables 8 and 9, the principal item of cost in connection with sludge dewatering is material and supplies, whereas salaries and wages constitute the principal cost factor in sludge incineration. Maintenance (including wages) amounts to

TABLE 8.—DISTRIBUTION OF OPERATION AND MAINTENANCE COSTS FOR THE PERIOD JANUARY 1, 1939, TO MAY 31, 1940

Description	FILTRATION		INCINERATION		TOTAL	
	Cost	%	Cost	%	Cost	%
Operation:						
Salaries and wages	33,198.51	24.2	27,217.36	50.4+	60,415.87	31.5
Material and supplies	75,603.40	55.0	5,606.26	10.4	81,209.66	42.5
Power and light	12,652.80	9.2	13,248.20	24.5	25,901.00	13.6
Miscellaneous	4,651.42	3.4	389.08	0.7	5,040.50	2.6
Maintenance	11,204.35	8.2	7,539.81	14.0+	18,744.16	9.8
Total	137,310.48	100.0	54,000.71	100.0	191,311.19	100.00

about 10% of the entire cost of disposal. Although it is true that maintenance costs in the first two years of operation of a plant are expectedly lower than they will be after, say, ten years (and that therefore it might be held to follow that costs will increase after a period of years), operation of this plant to 1940 indicates that such apparent increase will be offset by economies effected in other cost items of greater magnitude.

TABLE 9.—SUMMARY OF UNIT COSTS

Treatment	DRY SEWAGE SOLIDS		FILTER CAKE		Average cost (cost per month)
	Tons	Cost per ton	Tons	Cost per ton	
Filtration	....	$2.56	....	$0.89	$8,080
Incineration	....	1.01	....	0.35	3,180
Total	53,520	$3.57	154,820.6	$1.24	$11,260

The total operating and maintenence personnel, including administration, supervision, laboratory, etc., numbers 74 employees, involving a monthly payroll of approximately $13,500. Operation and maintenance costs are financed in the two cities by sewer rental charges which in one city are based on the volume of water consumed, and in the other on the basis of the size of water meter installed on the premises.

MISSISSIPPI RIVER CONDITIONS

General Data.—A very marked improvement in the physical, biochemical, and bacteriological condition of the Mississippi River became apparent shortly after the Twin Cities' sewage treatment plant was placed in operation. With the passage of time and the gradual elimination of "loose ends" of pollution, the river condition through Minneapolis and St. Paul has gradually approached that entering Minneapolis at Camden, Minn. (see Fig. 2).

Through the Twin Cities the floating scum, sleek and large masses of sludge which in former summers covered as much as 50% of the water surface in some areas, has practically disappeared. The foul odors of past years are no longer in evidence. Game fish are returning to this section of the river which previously did not provide satisfactory environment for even the rougher forms of fish life. Boating is being enjoyed by an increasing number of people.

Occasionally some debris is seen floating on certain sections of the river following heavy storms. The Twin Cities' sewer systems are combined and therefore both storm water and sewage must overflow to the river during heavy storms. The sewer departments of both cities strive to hold such overflow to a minimum by the use of automatic regulators and by inspecting the sewer outlets following storms. The Sanitary District also makes a monthly inspection of all former sewer outlets and reports its findings to the sewer departments of both cities.

The river below the Twin Cities has shown an improvement although it is still seriously affected by the untreated sewage and packing plant wastes from South St. Paul and Newport. Some idea of the relative effect of the sewage and

wastes from South St. Paul and Newport can be had from the fact that the population equivalent of the untreated sewage and wastes from these communities varies from 200,000 to 400,000, depending upon the animal kill, as compared with a total population equivalent of untreated sewage from the Twin Cities of from 1,000,000 to 1,200,000. It is unfortunate that at this writing (1940) all sewages and wastes from the metropolitan area are not receiving treatment so as to permit a more definite comparison of river conditions farther downstream "before and after."

Each winter commercial fishermen seine rough fish from the river at Grey Cloud Island, 14 miles below St. Paul. They report the presence of crappies and sunfish for the first time during the winter of 1939, indicating that some of the better forms of fish life are returning even to this section of the river. At other points on the river, both upstream and downstream from the treatment plant, catches of game fish are reported by fishermen, where formerly only the more hardy varieties of "rough fish" were able to survive.

Analytical Data.—The general evidence of improved river conditions discussed herein is substantiated by the analytical data on the river water samples collected regularly for analysis. The continuous record of analytical data on the Mississippi River and its tributaries in the period from 1926 to 1940 is valuable in a comparison of river conditions.

Data contained in Table 10 show the improved condition of the water at the Twin City Lock and Dam during the summers of 1938 and 1939 compared with previous summers before the discharge of sewage into the pool had been stopped. The years 1929, 1930, 1935, and 1937 were selected for comparison because the river flows for those summers most nearly correspond with the flows for the summers of 1938 and 1939. As indicated in Table 10, the dissolved oxygen in the river passing the Twin City Lock and Dam has materially increased, whereas the biochemical oxygen demand and bacterial counts have greatly decreased since the Twin Cities' sewage disposal system was placed in operation in the summer of 1938. This improvement is shown further in Fig. 3, containing a plot of the river data at this station since 1926.

That the river condition through the Twin Cities is gradually approaching that entering Minneapolis is shown by the data contained in Table 11 (see also Table 10). Some added pollution is indicated, however, probably made up from the Minnesota River pollution, from storm water overflow through the

A more complete picture of the effect of the operation of the Twin Cities' plant on river conditions is shown in Table 12, which contains data on dissolved oxygen concentration at various sampling stations in a 100-mile stretch of the Mississippi River. The location of the sampling stations in relation to the Twin Cities and the treatment plant is shown in Fig. 2. Referring to Table 12, it will be seen that oxygen concentrations through the Twin Cities (stations

[a] Indicates mileage from the head of navigation at the lower Northern Pacific Railway bridge in Minneapolis—see Fig. 2. [b] Twin Cities' sewage treatment plant was placed in operation during the summer of 1938. [c] River flow at St. Paul. [d] Estimated from flow at Lock and Dam No. 1.

M 0–4.8 to M 16.6) are, as would be expected, appreciably higher than before the sewage was intercepted and treated. Immediately below the plant the dissolved oxygen dropped to 5.05 ppm, and at a point 10 to 14 miles below the Minneapolis-St. Paul plant (9 miles below South St. Paul and Newport) dropped to its low average value of 2.60 ppm in 1938 and 1.25 ppm in 1939. The standard tentatively fixed for this section of the river (pool of the Hastings Dam) is 2 ppm of dissolved oxygen during the summer months. Below this point the river quickly recovered, so that at Hastings, approximately 22 miles below the Twin Cities' treatment plant, the water contained more than 6 ppm of oxygen.

In the winter periods, critical conditions formerly prevailed during January, February, and March. This was from the standpoint of fish life below the confluence with the St. Croix River, for which a tentative standard of 4 ppm of dissolved oxygen has been set. Table 13 contains comparative data for February, 1935, and February, 1939 and 1940. February, 1935, was selected because during that month the river flow of 1,613 cu ft per sec at St. Paul was extremely critical. Instead of 4 ppm below the St. Croix River, as tentatively set, individual samples collected in Lake Pepin have been practically devoid of oxygen at various times. In February, 1940, with flows of 1,400 cu ft per sec, the lowest individual sample of dissolved oxygen below the St. Croix River was 4.5 ppm, and the average minimum for the month was 5.9 ppm. During this period the Minnesota River entered the Mississippi River with an average of only 1.5 ppm (lowest 0.6 ppm) of oxygen, and the packing plants at South St. Paul and Newport were enjoying an unusually heavy volume of business with a consequent heavy pollution load. The river flow at St. Paul in February, 1940, was the lowest winter flow, with the exception of one month, than at any time in the 53-yr period of record.

River Bottom Conditions.—In October, 1939, a study was made of the river bottom conditions in that part of the Hastings pool below the Twin Cities' sewage treatment plant, a distance of 21 miles. Cross-section soundings were made at 22 stations and composite bottom samples collected at 14 stations. It was found that this stretch of river divided itself into three sections, on which some of the pertinent data are summarized in Table 14.

TABLE 14.—River Bottom Study (Treatment Plant to Hastings Dam)

Section	Cross-Sectional Water Area, in Sq Ft		Relative River Velocity		5-Day B.O.D. of Bottom Material, in PPM		Physical character of bottom material
	Average	Maximum	Average	Minimum	Average	Maximum	
(*A*) M 16.6–18.5	5,800	7,900(M 16.8)	1.0	1.0	630	690(M 16.8+380 ft)	Dirty sand and gravel
(*B*) M 18.5–26.5	9,600	15,100(M 20.5)	0.6	0.5	1,050	1,650(M 19.5)	Considerable sludge and silt
(*C*) M 26.5–37.5	15,000	28,000(M 35.5)	0.4	0.3	820	895(M 28.5)	Some sludge and silt deposits

Section (*A*) is a 2-mile stretch of river extending from a point immediately upstream from the Twin Cities' sewage plant to a point just upstream from the South St. Paul packing plants. The data showed that the river bottom through this section was of uniform character, being mostly sand and gravel with just enough organic matter to give the comparatively low average B.O.D. of 630 ppm. The bottom was quite clean, with practically no sludge deposits. Such material as existed may originate from storm runoff and overflow from sewers during storms, by-passing of excess storm flows at the sewage treatment plant, general river silt (of which the Minnesota River contributes a large proportion), and any suspended solids remaining in the treatment plant effluent.

Section (*B*) is an 8-mile stretch of river extending from a point just upstream from the South St. Paul packing plants to a point 4 miles downstream from the Invergrove Bridge. This is the section most affected by the packing plant wastes in respect to bottom deposits. There are considerable deposits in this section which exert a large oxygen demand on the overlying water. The oxygen demand of the bottom samples from this section was about twice as great as in section (*A*) and does not appear to have decreased much, if any, in comparison with recent years. The untreated sewage and packing wastes of South St. Paul and Newport discharging into the upper part of this section no doubt have contributed heavily to these deposits. In general, the river bottom in section (*B*) may be described as sand and gravel covered to a considerable extent with deposits of sludge, silt, and straw.

Section (*C*) is an 11-mile stretch of river extending from a point 4 miles downstream from the Invergrove Bridge to the Hastings Dam. This section contains many large but shallow backwater areas more or less cut off from the main river and not believed to affect the channel velocity appreciably. In general, the river bottom in this section may be described as mostly sand, gravel, and rock, covered to some extent with deposits of sludge and silt, which exert a somewhat smaller oxygen demand on the overlying waters than in section (*B*) but greater than in section (*A*). The oxygen demand of the bottom material in this section appears to be about the same as in 1937, the last previous year of complete cross-sectional sampling in this area. The oxygen demand exerted by the sludge deposits in sections (*B*) and (*C*) tends to reduce the dissolved oxygen in the overlying waters very appreciably and correspondingly affects the maintenance of the desired minimum dissolved oxygen in this part of the river.

General.—It is unfortunate that it is impossible to make a complete evaluation of the recovery of the Mississippi River through, and downstream from, the Twin Cities from its former heavy pollution load because of the fact that comparable treatment is not being provided by downstream communities. The writer has looked forward anxiously to the time when the original river calculations, on which the degree of treatment decided upon was based, could be checked by actual observations and a determination made of several factors affecting deoxygenation and re-aeration after the system was in operation. Such preliminary calculations as have been made, substantiated by analytical data and observation, indicate that the original assumptions, if anything, were conservative, and that the type of treatment selected will meet maximum requirements and at the same time will permit variations of treatment provided with river dilution conditions and requirements.

ACKNOWLEDGMENT

The Minneapolis-St. Paul Sanitary District is under the direction of a Board of Trustees of seven members. In charge of plant operation are Clifford R. Raiter, John C. Sager, Warren H. Sleeger, Assoc. M. Am. Soc. C. E., and Benjamin M. Storey, plant operators. Kerwin L. Mick is chief chemist in charge of the laboratory, and Stanley J. Larsen is mechanical engineer in charge of maintenance. The writer wishes to acknowledge the fine cooperation of all the members of his staff, as well as of superintendents of other plants and of other engineers engaged in this field, the effect of whose assistance and free interchange of information and experience has been a constant source of encouragement in the operation of this plant as it has in many others.

CONCLUSION

The foregoing review of experiences in the first two years of operation of the Twin Cities' plant should be considered as in the nature of a progress report. So many interesting possibilities of producing economies and effecting simpler and even better operation have presented themselves that operations here cannot be considered to be on a standardized basis. As a matter of fact, it is the writer's hope and expectation that operation will not be considered to have reached that point for some time, but rather that the possibilities of new developments will be continually explored. As many plant operators will agree, it is these possibilities that make operation of a sewage treatment plant, over a period of years, a succession of interesting problems, rather than a repetition of routine and standardized tasks.

DISCUSSION

F. C. Roberts, Jr.,[4] Assoc. M. Am. Soc. C. E. (by letter).—In this very complete paper, Mr. Schroepfer has outlined the various steps involved in the new plant for the Minneapolis-St. Paul Sanitary District. When all units of this plant are in service, the sewage passes through the following steps: A coarse bar screen with 6-in. openings and a bar screen with 1½-in. openings; then from these screens the sewage flows to the grit chambers; and thence to the flocculating tanks, the settling tanks, and finally the magnetite filter units. Before flocculation, the sewage entering these basins may be dosed with chemicals to aid in sedimentation and clarification.

One of the features of this plant is the vacuum filtration and incineration of solids removed from the sewage. It is to be noted from the information presented by Mr. Schroepfer that the cost of this disposal represents approximately one half of the plant operation cost. A question arises as to the relative cost of this process over the digestion tank processes, or its necessity, in so far as construction and operation costs are concerned.

Throughout this paper it is apparent that the objective was the improvement of the pollution of the Mississippi River. The paper is presented in terms of the tonnage load of pollution delivered to the river. In most public health work engineers are not concerned with the percentage of removal of solids by a particular unit of a disposal plant. They are not interested in the percentage efficiency of the settling basin, or the secondary or tertiary processes; but they are interested in the final effluent that reaches the river. If the plant effluent is consistently of the same degree of purity, so that the river is neither a nuisance nor a public health menace, then they are satisfied. With the most complicated disposal process, the final results may not be satisfactory to the river, and a river pollution condition results. It is of no little interest to note that this paper refers to the end product that must be met, and the plant is built back from this criterion.

This plant was not designed unit by unit for maximum flow or average flow conditions, but rather to meet the variable flow conditions that might be expected at the plant. As Mr. Schroepfer states, the period of time that chemical treatment will be needed will be about 29 days in one year. One may imagine the necessity for chemical treatment during this relatively short period. The availability of chemical treatment will furnish the operator with a tool with which to meet adequately a condition that will arise at intervals, and a uniform result may be expected at the point of plant outfall. Flexibility appears to be the cardinal virtue of this plant.

The writer has had no experience with that part of the country around Minneapolis and St. Paul. In discussing chemical treatment, it is necessary that his remarks be confined to the six or seven chemical treatment plants in Arizona in order to furnish some basis of comparison with the plant presented in the most thorough and excellent paper by Mr. Schroepfer. It was thought that it might be of value to discuss the Scott-Darcy process as it has been developed in Arizona. The development of this process has been the one major contribution that Arizona has made to the field of chemical treatment to date.

---

[4] Tucson, Ariz.

The needs within Arizona are different from those encountered elsewhere in the United States. Because of its freight rates, high temperatures, and wide variations in sewage flow due to a high rate of water usage, it was necessary to use some chemical treatment process that was flexible, and that would be available when needed and stable until needed. A chemical that might be delivered to any point with a minimum of cost and inconvenience was also a requisite.

There are four general types of chemical treatment: First, chemical treatment is used to aid in coagulation and flocculation, as provided in the Minneapolis-St. Paul plant; second, sewage is treated with certain chemicals to remove objectionable characteristics, such as the sulfur compounds that cause the most objectionable odors and the deterioration of concrete sewers; third, chemicals are used to maintain the sewage in a fresh condition until it reaches the plant; and fourth, sewage is sterilized to remove the bacteria.

The first classification of this purely arbitrary grouping is accomplished with any of the metal precipitants, such as ferric iron, alum, etc. The second process is the application of ferrous iron or iron in such form that it combines readily with sulfur. The third and fourth types are differentiated only in the degree of treatment that is used. These types of treatment make use of chlorine and its compounds of hypochlorite. The latter type satisfies the entire demand of the sewage and then leaves a "residual," or excess, for the complete sterilization of the flow.

In Arizona the problems have involved all of these types. The Scott-Darcy process has been used for the manufacture of iron in such form that it may be used for the first and second uses outlined previously. By modifying the equipment, the plant may be used for the other two purposes, although this has not been the general practice to the present time (1941). Many installations in Arizona have been made on collection and outfall sewer systems for the purpose of removing the sulfides from the field of action, to reduce odors, and to retard the corrosive action of the sulfides on concrete sewers.

It will be recalled that chlorine and some of its compounds have been used for a number of years for the aforementioned purpose. As long as the sewage is sterilized in its initial or very fresh stage, the use of chlorine has been effective. After decomposition has proceeded to a certain point, the use of chlorine is expensive and does little to remove sulfides already formed.

In line with the pioneer work of the Scott-Darcy process as established in Oklahoma, the City of Tucson, Ariz., installed the first Scott-Darcy plant in Arizona. This was for the purpose of removing sulfides already formed in the sewage, and for the addition of sufficient iron to the sewage to react with the sulfide delivered to the outfall from the many interceptors that discharge into it below the point of application. Also, a major purpose of this installation was to control odors at the disposal plant. An installation similar to the original Scott-Darcy was installed. This installation allows superchlorinated water to enter one end of a contact or reaction tank that is filled with scrap iron. After a period of contact therein, the iron and chlorine solution flows out of the far end of the tank and enters the sewage.

This installation has resulted in a lower "free sulfide content" of the sewage to a point 2 miles below the point of iron-chloride application, where the sulfides again begin to increase until the plant is reached. It is apparent that either a larger dosage of iron-chloride at the present plant or another plant is necessary at the point where the sulfides again begin to increase.

This same type of installation was made at Chandler, Glendale, Phoenix, and Wickenburg, Ariz. In each instance the control of odors was of extreme importance, and the plants have achieved this purpose. It has been expensive to operate them, yet in each instance any chemical or other treatment would have been expensive. The installation of these plants has forestalled some expensive litigation, which in at least two instances had been instituted against the cities or towns.

Phoenix has stopped the deterioration of concrete sewers with the process by the installation of some four plants throughout the system. This fact has been determined by visual inspection only. Prior to the installations, the wall thickness of some concrete sections had deteriorated 50% in four years. It is hoped that this process will extend the life of these sewers to last out the length of the bond issue, or until 1962. Chandler has stopped the odors from a septic tank. Lawsuits were pending against the city. By the addition of Scott-Darcy, these lawsuits have been dropped at least temporarily. Glendale has corrected an odor condition at this plant, and is using the iron as a precipitant after the addition of lime to form the iron hydrate. This installation has worked satisfactorily for the manufacture of deodorant and precipitant. Wickenburg has installed such a plant, but it needs further investigation to determine how effectual it will be.

During this period of development, the more modern Scott-Darcy process was developed at the Tovrea Packing Plant. It was the purpose of this installation to provide odor control and a precipitant, to have free chlorine available for the coagulation of blood in the slaughterhouse waste, and to have available a sterilizing solution if it was found to be of use. The use of the Scott-Darcy plant for the latter two purposes has not been found to be necessary to the present time (1941). The raw waste entering the plant ranges in strength from 1,000 to 5,000 ppm of suspended solids. After flocculation and sedimentation with the use of iron chloride from the Scott-Darcy unit, the final effluent has a suspended solid range from 65 to 442 ppm. The effluent has been reduced in B.O.D. strength, with a range of from 750 to 2,200 ppm down to 113 to 300 ppm.

The difference between this Scott-Darcy plant and the other plants is that the iron-chlorine solution is recirculated through special pumps so that the iron solution may be chlorinated to that particular point desired by the operator, and the required type of iron chloride produced. The flexibility of the plant to meet changing hourly demands has proved an excellent tool in the solution of this problem. The packing plant officials, health agencies, and the neighbors are all satisfied with this plant.

The conditioning of this sewage has made available an irrigation water supply that is used on 160 acres of land for the production of forage crops to be fed to the beef cattle held at the plant. Prior to the installation of this plant, packing house waste was discharged into the Salt River to the embarrassment of the various health departments and to the despair of those living in that vicinity.

From the detail of information offered in Mr. Schroepfer's analysis of the Minneapolis-St. Paul plant, and from these casual observations, it might be concluded that chemical treatment is vitally necessary when needed. It furnishes a flexibility of operation that is difficult to attain otherwise. It may be for only a short period of time during the day, week, or month that chemical treatment might be needed. When available, it levels off a peak effectively, and improves operation.

In conclusion, the writer desires to express appreciation to J. A. Carollo and Dario Travaini, Associate Members, Am. Soc. C. E., Phil J. Martin, Jr., of Tucson, and W. J. O'Connell of San Francisco, Calif., for the generous assistance that they have provided in the preparation of this discussion.

Rolf Eliassen,[5] Assoc. M. Am. Soc. C. E. (by letter).—Complete operation and cost data on the vacuum filtration and incineration of the raw sludge at the Minneapolis-St. Paul Sewage Treatment Plant are presented in this paper. Data of this nature are essential in order to obtain a better economic evaluation of the various methods of sludge treatment and disposal.

Most of the larger cities in the United States have complex problems of sludge disposal. The sludge is usually digested, followed by drying on sand beds or vacuum filters and ultimate disposal on land as fertilizer or fill. Some cities prefer to subject raw or digested sludge to vacuum filter and either dry it mechanically or incinerate it before ultimate disposal. As the author has stated, in the Minneapolis-St. Paul plant the raw sludge is conditioned with chemicals, partly dewatered on vacuum filters, then dried and incinerated in multiple-hearth furnaces.

The City of New York, N. Y., is more fortunate in that it is located on the Atlantic Ocean and can utilize that body of water for disposal of its sludge. In 1940, Wellington Donaldson,[6] M. Am. Soc. C. E., described New York's method of sludge disposal. The sludge from three treatment plants is transported in sludge vessels designed for that purpose. They are three sea-going vessels of the latest design and have sludge storage capacities of 55,000 cu ft each. The sludge dumping grounds are 34 miles out to sea from the Ward's Island Sewage Treatment Plant. These grounds are far enough removed from the shore to preclude any danger of harbor or coastal pollution.

Utilizing data presented by the author and Mr. Donaldson,[6] an interesting comparison may be made between these two distinctly different methods of sludge disposal.

---

[5] Assoc. Prof., San Eng., Coll. of Eng., New York Univ., New York, N. Y.

[6] *Waterworks & Sewerage*, December, 1940, p. 583.

These comparative data for the year 1939 are as follows:

	Minneapolis-St. Paul	New York City
Initial cost, in dollars	1,240,000	1,500,000
Total sewage flow treated, in million gal	36,705.3	62,696.1
Total sludge, dry tons	37,703	54,088
Operating and Maintenance Costs (in Dollars):		
Total	136,815.43	137,931.50
Per million gal of sewage treated	3.74	2.20
Per ton of dry sludge	3.63	2.55

In the case of Minneapolis-St. Paul, the initial cost includes the cost of constructing the filtration and incineration building and appurtenances. For New York, the cost is that of constructing the three sludge vessels. As far as one may ascertain from an analysis of the supporting data and discussions, these cost analyses are on a comparable basis.

Further economies are possible in both cases. This is evidenced by the fact that data for the first five months of 1940 at Minneapolis-St. Paul show costs of sludge disposal at $3.15 per ton of dry solids, a reduction of 13.2%. This has resulted from more efficient use of chemicals, filters, and incinerators. Even greater economies are possible in New York as means are devised for the thickening of the sludge before loading on the vessels. The 55,000 cu ft of storage capacity should be filled with the heaviest possible sludge in order that the tonnage of dry solids may be at a maximum for each trip to the dumping grounds.

FREDERIC BASS,[7] M. AM. SOC. C. E. (by letter).—The Minneapolis-St. Paul sewage disposal plant was located and designed after a preliminary study extending over a period of seven years, from 1927 to 1934. During this period the science and art of sewage disposal was rapidly advancing, and the design ultimately adopted embodied a number of features not previously available. Perhaps the most notable characteristic of the design is its flexibility, which enables it to function with economy under the varying conditions of flow in the Mississippi River. Among other features which, at the time of design, were considered by some engineers as innovations, but which were included after careful observation and study, were the unusual length of the sedimentation tanks, the elimination of sludge digestion, and the incineration of filtered sludge. The performances and costs of operation, presented in the paper, appear to justify the many studies made by the author.

Although conclusions from the limited period of operation covered by the author must be regarded as tentative, they unmistakably hold special interest for all sanitary engineers. For the purposes of this discussion the author has made available to the writer certain operating data obtained later than April 30, 1939. The records previous to January 1, 1939, because of the usual process of adjustment in a new plant, probably do not represent normal averages of performance and cost as closely as do the subsequent records. Table 15 contains statistics of operation for the year 1940.

---

[7] Cons. Engr.; Head, Dept. of Civ. Eng., Univ. of Minnesota, Minneapolis, Minn.

The quantity of sewage was somewhat less than expected, the strength expressed in B.O.D. was approximately equal to that expected, but the suspended solids (perhaps because of changing industrial conditions and effect of surface runoff) were more than 50% greater than the expected amounts. This heavy load fortunately was offset by the unusually high removal of suspended solids in the sedimentation tanks. In these tanks (290 ft long with unusually long overflow weirs) the average removal of 71.1% (detention period 1.5 hr) of suspended solids, which itself is greater than the performance of most plants, has been raised under average conditions over a period of several weeks to approximately 80% by the use of air flocculation at the trifling cost of 6 cents per million gal treated. The expected 56% removal of 185 ppm would have left 81 ppm in the effluent, whereas the actual performance of 80% removal of 300 ppm has left only 60 ppm in the effluent.

TABLE 15.—OPERATING DATA FROM JANUARY 1, 1940, TO DECEMBER 31, 1940

Item	Description	Monthly			Expected at time of design
		Maximum	Minimum	Average	
1	Flow (mgd)	113.87	90.16	104.17	122
	Sewage Strength (ppm):				
2	Suspended solids	345	245	300	185
3	B.O.D.	240	160	210	200
4	Screenings (cu ft per million gal)	1.96	0.78	1.06	3.1
5	Grit (cu ft per million gal)	9.3	3.1	6.2	4.1
	Total Removal in Plant (%):				
6	Suspended solids	83.5	64.0	77.2	56
7	Settleable solids	96.5	84.1	91.5	....
8	B.O.D.	53.0	35.4	43.2	36
9	Filter cake produced (tons), average daily	340.2	264.7	308.3	235
10	Cake moisture (%)	68.1	61.1	64.8	68
11	Cake volatiles (%)	68.6	51.4	59.8	55
12	Ash from sludge (tons)	1,760	820	1,275	....
	Sludge Conditioning Chemicals (%):				
13	Ferric chloride	2.32	1.59	1.83	3.0
14	Lime	6.53	3.53	4.51	10.0

The B.O.D. removal was boosted by flocculation as well as by removal of suspended solids, the author's figures showing 49.8% with flocculation as against 44.2% without flocculation. The total capacity for removals of suspended solids and B.O.D. with the use of chemical precipitation will be awaited with much interest. From the performance of the plant already given, the maximum removals as expected by the author, in the tabulation preceding the heading "Plant Operation: Screen and Grit Removal," appear to be readily obtainable. The bacteriological results from the use of chlorine, although of short duration, are interesting.

The conclusions from this phase of the operation seem to extend the usefulness of this type of flexible plant design to many situations where a variable river flow exists. For such conditions, a careful study of quantity and quality of both river and sewage may result in economy of both first cost and operation.

The sludge disposal department of the plant appears to have been as successful as the sewage treatment department. Drawing sludge frequently from the sedimentation tanks to the concentration tanks and stopping withdrawal with thinning sludge have resulted in a heavier sludge. A quantity of sludge 35% higher than expected, offset by higher heat value, less moisture, higher volatiles, and unusually close control of sludge conditioning and filter operation, has led to a lower over-all cost of sludge disposal than was estimated. It is remarkable that practically no oil fuel is necessary. The costs given by the author compel attention.

The improvement of the river above the plant is very satisfactory in appearance, as the analytical results indicate. Improvement of conditions in the river below the plant can be appraised only after the installations of treatment plants for the large packing plants located there.

Supplementary data on cost supplied by the author permit the summary in Table 16 for the 12-month period ending December 31, 1940:

TABLE 16.—COST OF OPERATION AND MAINTENANCE, JANUARY 1, 1940, TO DECEMBER 31, 1940

Item	Description	Operation	Maintenance	Total	Percentage of total
1	Administration, engineering laboratory....	$74,637.24	$1,326.01	$75,963.25	25.6
2	Sewage treatment........................	43,843.65	8,917.08	52,760.73	17.8
3	Sludge disposal..........................	112,580.62	18,218.60	130,799.22	44.1
4	Miscellaneous............................	33,508.90	3,376.68	36,885.58	12.5
	Total..................................	$264,570.41	$31,838.37	$296,408.78	100.0

In this period a total of 38,038 million gal of sewage was treated at a cost of $7.80 per million gal for all operating and maintenance items. During this period the magnetite filters have not been in full operation and chemical precipitation has not been used. Consequently, over a sequence of years, which includes a considerable proportion of drought when all facilities of treatment are used, the costs may be somewhat higher. It might be concluded that the cost of administration, engineering, and laboratory, at about 25% of the total cost of operation and maintenance, is unduly high, but it is probable that every dollar thus spent is reflected in much greater savings in the other items.

It has been a pleasure to examine the detailed records of performance and accompanying cost data available in the office of the author. It will be a great public benefit when all sewage works are as carefully and economically managed as the one in Minneapolis and St. Paul; plant operators will be stimulated to greater interest when comparative figures are made available. These cities are indeed fortunate in having conceived and built a plant so well fitted to the existing conditions and so effectively and economically operated.

The emphasis in this paper upon performance, and particularly upon costs, deserves more than passing notice at this time. A sewage treatment plant is but one of the agencies of the promotion of health and cleanliness of a community; there are others of perhaps even greater importance, which need consideration and call for the expenditure of public funds. Since public financial resources are limited, the analysis of costs and relative value of various public works is an important duty resting upon engineers who are becoming increasingly responsible for the conservation of national resources.

Darwin W. Townsend,[8] M. Am. Soc. C. E. (by letter).—The practice of pollution control by cities on the upper Mississippi River has been marked during the past decade (1930–1940). Modern sewage treatment works are now (1941) in operation in the cities of Minneapolis-St. Paul, and South St. Paul; Rock Island, Ill.; and Davenport, Iowa, as well as in other populated centers of lesser magnitude. The Minneapolis-St. Paul plant, which Mr. Schroepfer's excellent paper treats, and the South St. Paul plant, designed by the writer's firm, are the two most northerly plants of magnitude on the Mississippi River in the foregoing group. Upon the completion of the Newport, Minn., treatment works, the pollution control in the populous and highly industrial Minneapolis-St. Paul metropolitan area will have been effectively accomplished. Of unusual note, perhaps, is the fact that three separate treatment plants will serve this area, these plants being within sight of each other.

It may be of interest, by way of contrast, to comment briefly upon sewage B.O.D. concentrations obtaining in each of the aforementioned instances. Sewage delivered into the Minneapolis-St. Paul treatment plant has a 5-day B.O.D. concentration—approximating 200 ppm, as stated by Mr. Schroepfer. At this concentration, a sewage of average domestic character is indicated, in which case little, if any, difference might be anticipated between human and equivalent populations.

Available dilutions and dissolved oxygen (D.O.) supply afforded by the waters of the Mississippi River for the assimilation of organic pollution indicated that B.O.D. removals from Minneapolis-St. Paul sewage, approximating 70% for ten months and 33% for two months, would prove adequate to maintain in the receiving waters a 2.0 ppm D.O. residual at all except infrequent times of unusually low river stage. It is evident from the data presented by Mr. Schroepfer that, when contrasted with the volume of river flows shown, plant removals thus far obtained have been quite adequate to accommodate the D.O. standard established.

The requirements as to degree of treatment for the South St. Paul-Newport area differ vastly from those of the Minneapolis-St. Paul area and call for a much higher degree of treatment. In South St. Paul, as well as in Newport, the meat-packing industry predominates, and as a result the sewage treatment problem is essentially that of treating packing-house and stockyard wastes containing an average B.O.D. concentration approximating 1,000 ppm, the peak concentrations reaching as high as 3,000 ppm. The human population of South St. Paul approximates 15,000, whereas, at times, the equivalent population may exceed 300,000.

To comply with the requirement of the Minnesota Board of Health (namely, that the effluent from the South St. Paul treatment plant contain a B.O.D. concentration that would not be greater per unit of volume than the Minneapolis-St. Paul effluent), it was necessary to design treatment works of biologic character to obtain 90% to 95% B.O.D. removal, these works to include three stages of sedimentation, flocculation, grease removal, and trickling filters. Effluent chlorination is to be practiced during the summer months.

---

[8] Cons. Engr. (Consoer, Townsend & Quinlan), Milwaukee, Wis.

The lead taken by the Minneapolis-St. Paul Sanitary District in pollution control of Mississippi River waters provided the necessary stimulus to downstream cities for subsequent participation in work of similar character, some of which have been referred to herein.

Although Mr. Schroepfer has performed a yeoman's task in preparing and presenting a well-conceived and well-written paper, supplemented with interesting data, the writer takes the liberty of suggesting that, in the closing discussion of his paper, something additional be written regarding the extensive river-water studies made by himself and the late J. A. Childs, M. Am. Soc. C. E., former sanitary engineer for the District. The writer had occasion to study this work while serving the District as consultant, and it is most certain that the results of these water reoxygenation studies would appeal to many sanitary engineers.

Of particular interest to the writer is the subject of sludge disposal as practiced at the Minneapolis-St. Paul plant. This installation is believed to be the most extensive of its particular kind in existence, and may be considered unusual, perhaps, in that raw, rather than digested or otherwise treated, sewage solids are filtered and incinerated.

The partial dehydration of sewage solids by means of vacuum filters has become standard practice during comparatively recent years, the first sizable installation having been placed in operation at Milwaukee, Wis., about 1925. This installation dehydrates activated sludge, which subsequently is heat-dried for use as a fertilizer. The solids filtered at this plant may be classified as raw activated sewage solids, as differentiated from digested solids, and raw untreated solids. They possess radically different filtering characteristics from those of the two last-named materials. Sludge filtering at Milwaukee, therefore, is not comparable with generally similar work done at the Minneapolis-St. Paul plant.

Many treatment plants throughout the United States now use vacuum filters and appropriately designed incinerators as a means of sludge disposal, and this method appears to be becoming increasingly popular. However, general practice recognizes certain economies indicated and attainable through the use of an intermediate step in sludge-disposal procedure—namely, that of reducing sludge volume through the process of digestion.

Instances may be cited wherein the available power contained in the gas resulting from controlled sludge digestion equals or exceeds the entire power and heat requirements of a treatment plant. Since power is a substantial item of expense in any sewage treatment plant (more so in some than in others, depending upon plant type and prevailing rates), savings that may accrue to a city through the use of gas-engine equipment, motivated by gas produced from the sewage within the plant, have in recent years met with almost universal favor.

Perhaps the author may make some reference in his closing discussion to vacuum filtration of raw solids, and incineration versus digestion and gas utilization as studied in connection with the Minneapolis-St. Paul project. Such references would be most interesting.

LLOYD H. FLICKINGER,[9] ASSOC. M. AM. SOC. C. E. (by letter).—The subject of sewage treatment has received a valuable contribution by Mr. Schroepfer. Designers and operators of many treatment plants, whether of the chemical-mechanical type or other types, can learn valuable lessons from this paper. When this plant was designed, it was more than twenty times as large as any other one of its type then in operation. Many new ideas were incorporated in the plant and it is gratifying to find that the results have been very satisfactory, with a few minor exceptions.

The writer was employed on the Minneapolis-St. Paul project throughout the design and construction period of the treatment plant, and for a short time after the plant was placed in operation. The purpose of this discussion is to call attention to certain features of the design and operation that merit close attention by future designers of similar plants.

The kind of treatment selected for this project was of a type having great flexibility to provide a degree of treatment in direct proportion to the demands of the Mississippi River. This procedure is not subscribed to by many state boards of health. Too often they require "complete treatment" with little regard for the ability of the stream to absorb a pollution load. It is economically unsound to provide a continued high-grade treatment where a large part of the pollution load can be absorbed by the stream without nuisance or danger to the community. This procedure would be comparable to operating a furnace in a home at full capacity regardless of the temperature outdoors, merely because of the available capacity of the heating plant.

The type of plant selected for this project is economically sound and provides a very high degree of treatment only when it is required. This is sound economics and should be observed.

The plant was designed on a basis of 185 ppm suspended solids in the raw sewage. The actual amount found by operation was about 275 ppm. Contrasted to this the estimated B.O.D. was 200 ppm and the actual was 210 ppm. The unusual amount of suspended solids has never been explained fully. The quantity of sewage in gallons was about 20% less than estimated for the years 1938–1940. This accounts only partially for the high suspended solids content.

In 1933 principal sewers were weired and samples collected for about two weeks. The principal outlets were attended by a sample collector 24 hr per day throughout the test period, and the quality of the analytical work has never been questioned. The only deduction is that something caused a great change in the sewage in the 5-yr interval from 1933 to 1938. However, no substantial industrial change took place except in the brewing and malting plants.

The extra-long settling tanks, almost 300 ft, were selected because they fit the site very well and were lower in first cost than the shorter ones. The estimated removal of suspended solids was 56% and the actual was about 70%. Designers should note that these tanks have a very high weir ratio. The amount of weir length per million gallons of sewage was about halfway between that used for circular tanks and that usually used for rectangular tanks. These tanks are 56 ft by 290 ft and have 480 lin ft of weir per tank. The unusual results from the extra long tanks with high weir ratios should be carefully noted by all designers of settling tanks.

---

[9] Capt., Corps of Engrs., Quartermaster Corps, U. S. Army, Operations Officer, Kansas Ordnance Plant, Parsons, Kans.

The scum handling methods originally installed proved unsatisfactory in operation. Pneumatic ejectors definitely proved their worth. Line stoppages can be eliminated with this method, if the scum influent lines to the ejector are short and have an appreciable slope.

The plant is arranged so that several kinds of chemical can be used. Engineers have long suspected that the price of many chemicals does not depend on the cost of production or the supply. It is suspected that the price is controlled, perhaps on the basis of all the traffic will bear. Engineers can meet this practice by designing for several chemicals. All the added cost can be saved easily in purchases of the most economical chemical. In other words, while the chemical producers are using chemical prices as so many poker chips in an industrial game of chance, the sanitary engineer can buy the chemical that is in the "bear" market.

The sludge in the concentration tanks actually became too concentrated to be handled at times. The need for concentration can be questioned, but the storage facilities providing a reservoir on the line proved the worth of the tanks. Future concentration tanks can properly include facilities for diluting the sludge when necessary.

Sludge containing 10% to 12% solids needs thinning for proper handling through a piping system of any length. Thick sludge frequently disobeys some of the fundamental laws of hydraulics. Sludge pipe design demands that a little "salt" be taken with theoretical results assumed using hydraulic computations for water.

It is gratifying to note the low chemical dosage required to condition the sludge. The writer recommends no change from the original dosage of 3% ferric chloride and 10% lime, as a basis of design. The chemical demand for the conditioning of sludge usually cannot be determined before the plant is put n operation, with the exception of additions to existing plants and plants other than the first in a city.

The favorable results of vacuum filtration of raw sewage solids at this plant definitely put an end to the argument that digestion is necessary to satisfactory and economical vacuum filtration. Mr. Schroepfer's experiments with different kinds of filter cloth are very enlightening, and similar tests should be made at other plants to confirm the results.

Incineration of sewage solids was in its infancy when the Minneapolis-St. Paul plant designers decided to use this method of sludge disposal in 1936. The use of extensive and delicate heat-recovery units does not appear economically sound in the light of present knowledge. They are very costly and expert operation is necessary to prevent serious damage to the units. The problem at the Minneaplis-St. Paul plant seemed to be one of disposing of excess heat instead of recovering it.

The writer recommends that screenings and grit be disposed of by incineration, omitting the extensive grit washing operation and screening grinders.

This waste can be carried direct to the incinerators by one belt conveyer. The belt can be operated manually as required, dumping the unwashed grit and unground screenings on a horizontal belt conveying the sludge cake to the incinerators. Close control of the grit chamber velocities becomes unnecessary because high putrescible contents of grit to be incinerated are not objectionable. Due to existing arrangements at the Minneapolis-St. Paul plant, it is probably not practical to do this, but designers of new plants can well consider this possibility.

The profession is indebted to Mr. Schroepfer and the operating staff of the Minneapolis-St. Paul Sanitary District for the extensive and valuable data obtained from the first two years of operation. The plant is so designed that one half can be used as a control and the other half for experimental work. At the present rate more valuable contributions to the science of sewage treatment can be expected from this plant.

The writer is very pleased to learn of the vast improvement in the condition of the Mississippi River and is particularly pleased to have been a part of the design staff that made this improvement possible.

Isador W. Mendelsohn,[10] M. Am. Soc. C. E. (by letter).—As expected, Mr. Schroepfer has presented a fitting complement to his notable contribution on "Economics of Sewage Treatment" published in 1938.[11] This paper is more than a repository of interesting experiences for the first two years of operation of the sewage treatment plant serving the Minneapolis-St. Paul Sanitary District. It should prove a source of unending stimulation to operators and designers of sewage treatment plants, large and small, for it is replete with ever-promising, economy-producing experiments and studies in mechanical equipment and plant operation. Throughout all of these studies, the engineers never lost sight of the purpose of producing as economically as possible an effluent that would merge with the varying receiving body of water in a manner not prejudicial to public health and comfort.

The lengthy and remarkable list of tests on plant equipment and operation performed by Mr. Schroepfer and his organization in this period includes:

For screen and grit removal—

(1) Increasing the velocities of flow from 0.75 to 1.20 ft per sec to secure a greater percentage of inert material in the sludge, thereby increasing the solids content of the sludge and reducing the quantity of conditioning chemicals required;

(2) Burial of the proportionately small quantity of screenings with an appropriate depth of relatively clean grit;

(3) Reducing sand wear on the lower and intermediate bearings on the screw conveyer grit washers by installing sealed water-washed and lubricated bearings;

(4) Overcoming difficulty with the grit bucket elevator by installing an air jet to sweep high moisture content, large "fines" percentage grit out of the buckets, and installing sealed bearings of a special type.

---

[10] Capt., Corps of Engrs., U. S. Army, Utilities Officer, Fort Worth, Tex.

[11] *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 1210.

For sedimentation—

(5) Careful pumping control of raw sludge from the settling tanks once during each of the three shifts so as to average 7.7% solids (92.3% moisture);

(6) Providing an ejection method of handling scum after its removal from the settling tanks, thereby reducing labor required;

(7) Providing for blowing back sludge suction lines as long as 300 ft with plant effluent or compressed air to handle heavy sludge containing as much as 20% solids;

(8) Carrying a heavy blanket of normal sewage sludge in the tanks previous to storm flows to remove the inert material more effectively because of evident loosening of the mud and silt which ordinarily packs and produces difficult removal problems;

(9) Replacing pistons and collars on sludge pumps with heavier parts made in the Sanitary District shop at a fraction of the cost of such parts from manufacturers to permit resurfacing from time to time, thereby prolonging their life;

(10) Installing chain tighteners on the sludge collection equipment to reduce breakage of links of drive chains.

For magnetite effluent filters—

(11) Overcoming sand erosion and displacement difficulties at greater than average flows by enlarging influent ports and other improvements.

For sludge conditioning—

(12) Shortening the period of sludge conditioning to an average of 6 min with continuous control of filtration by means of funnel tests;

(13) Improving sludge for filtration and at the same time reducing the quantity of chemicals used by agitation with excess low-pressure air from the blowers, provided for removing cake from the filters;

(14) Providing means for distributing the chemicals more uniformly through the conditioning tanks;

(15) Determining the proper sequence of chemical (lime and ferric chloride) additions.

For vacuum filtration—

(16) Recirculation of a percentage of incinerator ash to the raw sewage ahead of the screen and grit chambers to improve vacuum filtration, reduce the quantity of conditioning chemicals, and increase sedimentation efficiency;

(17) Reducing the quantities of chemicals (3% ferric chloride and 10% lime) to less than 2% and 5%, respectively, amounting to a saving of approximately $100 a day in chemical costs alone;

(18) Increasing filter cloth life from about 150 hr of use to more than 300 hr;

(19) Purchasing identical filter cloths locally at a fraction of their original cost;

(20) Sewing filter cloths with a different type of thread and with a lock stitch to eliminate seam difficulties;

(21) Improving the washing of filters by impinging the water at right angles to the cloth on the drum, thereby reducing the washing time to one third, using less water, and eliminating brushing of the cloth;

(22) Installing sloping ¼-in. rods on 12-in. centers in the filter take-off plates to break up the cake and prevent stoppages.

For incinerators—

(23) By by-passing preheated air direct to the stack to save rabble arms and other incinerator parts.

For sludge disposal—

(24) Exploring the fertilizer or soil conditioning possibilities of sludge cake as produced by the filters and its use after storing for periods of time;

(25) Experimenting with the production of partly dried material by removing portions of the incinerator top-hearth sludge, using heat from the remainder of the sludge incinerated for drying purposes;

(26) Investigating the use of ash for binder or filler for various products, such as a soil conditioner or an ingredient for certain cements;

(27) Testing the utilization of heat from incineration in the generation of steam for all heating purposes and electric-power requirements.

For flocculation without chemicals—

(28) Testing for a brief period to determine the degree of improvement that may be obtained in sedimentation.

For chemical treatment—

(29) Testing for four days to determine possible sedimentation-removal improvements.

For chlorination—

(30) Experimenting on bacterial removal with chlorine dosages of 6 to 8 ppm with favorable results. A large part of the great reduction (approximately $330,000) in operation costs of the first 2 yr is attributed to the operation economies effected by the tests mentioned.

The paper is notable also for the detailed operation and maintenance cost data presented. For comparative purposes with other sewage treatment plants, it would be desirable, when more complete operation data are available, to show for each plant unit the construction cost, the operation and maintenance costs, the specific parts-per-million removals in suspended solids and B.O.D., and all three costs per 1% reduction in suspended solids and B.O.D.

The fact that vacuum filtration and incineration of sludge cost $3.70 per million gal, or approximately 45% of the entire plant operation and maintenance costs, is noteworthy. The relative cost seems high for sludge disposal alone. It presents a great opportunity for improvement. Whether the cost of sludge disposal would have been lower with some other process or combination of processes cannot be determined from the data presented. As bearing on this question, it would be of interest to note what studies were made regarding sludge disposal in the design of the plant, what construction, operation, and maintenance costs were estimated for each method considered, and why vacuum filtration and incineration were adopted.

As between vacuum filtration and sludge incineration operation and maintenance costs, it would be desirable, for comparison with similar data in other plants, to learn the basis of allocating labor and supervision expenditures to each.

With reference to the incinerator, it is surprising to learn that "It was the manufacturers' expectation that the location of burning, and the temperatures of combustion, would be controlled by the use of varying quantities of oil introduced at different points" (see heading, "Sludge Disposal: Incinerators"). Acceptance tests on multiple-hearth sludge incinerators at Auburn and Elmira, N.Y., sewage treatment plants in May, 1937, disclosed excess heat, requiring by-passing of preheated air direct to the stack to prevent damage to incinerator parts, and use of oil only for warming up and maintenance of temperature in off-burning periods.

Mr. Schroepfer refers to extensive guarantee and maintenance bonds of various types included in mechanical equipment contracts for the plant. In view of his experience with such provisions, it would be of value to learn his views as to what kind of guarantees and maintenance bonds should be included in specifications and for what kind of mechanical equipment, what tests should be made to determine whether or not the guarantees are complied with, how the tests should be conducted, and for what time periods.

Before concluding these remarks, it is most important to note that the worthy results obtained in the operation of this sewage treatment plant are the outgrowth of a capable and energetic operator with an experienced organization, adequate laboratory and plant recording equipment, and above all a body of intelligent, sewage-minded Sanitary District officials, representing a community that desires, and is willing to back, disposal of its sanitary sewage in a manner which will not prove harmful. Similar fully trained, equipped, and cooperating groups are a vital necessity in all communities, however large or small, for sanitary disposal of their sewage.

RALPH E. FUHRMAN,[12] Assoc. M. AM. SOC. C. E. (by letter).—In a comprehensive manner, Mr. Schroepfer has described the development of the sewage treatment scheme for the Twin Cities. From the inception of the project, the primary purpose of the plant (that of eliminating pollution from the Mississippi River) has received first consideration.

The design of the plant has, as its fundamental basis, the varying requirements of the receiving stream. This rational basis has provided, through the author's analysis, the degree, and probable duration and frequency of varying degrees of treatment imposed by river conditions. The result, a chemical-mechanical sewage treatment plant, provides the range of treatment and flexibility to relieve the river of pollutants economically.

The District of Columbia sewage treatment plant and receiving stream present some interesting parallels with the Twin City plant and its receiving stream, namely:

---

[12] Asst. Supt., Sewage Treatment Plant, District of Columbia, Washington, D. C.

Description	Twin City	District of Columbia
Design flow (mgd)	134	130
Full-time operation begun	July 20, 1938	August 1, 1938
Original construction cost	$3,750,000	$3,400,000
Construction cost per design (mgd)	$28,000	$26,100
Minimum flow of receiving stream (cu ft per sec)	864	700
Maximum estimated flow (cu ft per sec)	107,000	480,000
Annual average flow (cu ft per sec)	8,800	9,480

Similarity ends, however, when the plant processes themselves are considered. At the Twin City plant, sewage is screened, grit is removed, coagulating chemicals may be added prior to metering, flocculation, and sedimentation. When desired, more solids may be removed by use of the effluent filters. At the District of Columbia plant, sewage is pumped, grit is removed, the sewage is metered and aerated for grease separation before sedimentation, the last step in the sewage treatment process. At the Minneapolis-St. Paul plant, raw solids are dewatered on vacuum filters and incinerated. At Washington, D. C., raw solids are digested, digested solids are elutriated and dewatered by vacuum filters. Most of the sludge cake is shipped to the District of Columbia penal institutions for agricultural uses. Between the two plants, practically all current sewage and sludge treatment methods except activated sludge are used.

Since the dates of design and initial operation of the two plants are very close, some operating experiences have been common to both plants. For instance, the failure of the underwater and grit thrust bearings of the grit conveyers described by Mr. Schroepfer was also experienced at Washington, D. C. At the District of Columbia plant this failure occurred at an early date and the difficulty was corrected by installing standard ball thrust bearings at the shaft coupling above the sewage level. Completely satisfactory operation of the conveyers has been gained by this alteration.

Although the sedimentation tanks of the District of Columbia plant are circular, experiences in tank skimming have been similar to those at the Minneapolis-St. Paul plant, except for difficulties caused by climatic conditions. At the Washington, D. C., plant, completely automatic skimming was not provided originally. Collection of the scum from the surface of the sedimentation tank was mechanical and continuous, but removal of the scum was manual and intermittent. New skimmers have been installed which give continuous skimming and removal of scum. Minor stoppages have occurred in the lines conveying scum to the hoppers from which the sludge pumps take suction to pump the scum to the sludge digestion tanks; but as these lines are short, clogging is easily relieved mechanically.

Because of the completely different nature of sludge treatment by the two plants, an operating cost comparison of sludge treatment is interesting. From Mr. Schroepfer's paper, Twin City costs for the 1939 calendar year for vacuum filtration and incineration were $136,815.43, giving unit costs of $3.70 per million gallons or $3.63 per ton of dry solids treated. At Washington, D. C., for the 1939 fiscal year (July 1, 1938, to June 30, 1939), the operating costs for sludge digestion, sludge elutriation, sludge dewatering (vacuum filtration) and sludge cake disposal were $54,486, giving unit costs of $1.59 per million gallons or $4.41 per ton of dry solids removed. These data should not be taken in direct comparison, as they are based on early operating periods of both plants. They do indicate, however, that ultimate operating costs of both methods will be reasonable and of a comparable nature. The final cost analysis must include fixed charges, and energy recoveries by both methods. In the Minneapolis-St. Paul layout this will mean heat from the incinerators and ash value, whereas at Washington, D. C., it will mean sludge gas, both as heat and power and the fertilizer value of the sludge produced.

R. W. ROWEN,[13] ESQ. (by letter).—This was the first large plant to adopt filtration and incineration of undigested sludge. After a careful investigation of the various types of sludge incinerators, it was decided to install three multiple-hearth, mechanically rabbled incinerator units. When they were placed in operation it was found that the filter cake contained less moisture and a higher percentage of combustible matter than anticipated. As a result, no auxiliary fuel was required and, in fact, there was an excess of heat that had to be dissipated. Therefore, hot air from the air preheater units was by-passed directly to the stack, and air at ordinary temperature was used for combustion. The center shaft and rabble arms on the hottest hearths were insulated, and this has effectively overcome the danger of overheating.

Grit and screenings are not incinerated at the Minneapolis-St. Paul plant, although they are now being incinerated at Detroit, Mich., and at several other smaller plants using multiple-hearth incinerators.

The volume of waste, deodorized gases leaving the incinerators at about 1,000° F would produce enough steam for plant heating and all electric power requirements of the plant and still have an excess of steam with only one incinerator unit in operation. The raw sludge filter cake, containing an average of about 65% moisture, 20% combustible material, and 15% ash on the wet basis, has sufficient heat content not only to be self-combustible, but also to furnish all heat and energy required for the entire plant. The economics of heat and power generation are being investigated, and it may prove advantageous to install waste heat boilers and turbo generators.

Another means of utilizing this waste heat is being studied at the Minneapolis-St. Paul plant, which consists of feeding a part of the thickened sludge, containing about 90% water, directly to the incinerator without mechanically dewatering. As the author has pointed out, filtration cost is 72% and incineration is only 28% of the total cost of sludge disposal. By feeding a part of the liquid sludge directly to the incinerator and utilizing the excess heat from the part that is filtered, a further substantial saving in operation costs may be obtained through the elimination of filtration costs on part of the sludge. This is along the line of developments made during 1940 at the Piqua, Ohio, and Ashland, Ohio, sewage treatment plants where all of the undigested, unfiltered sludge is incinerated directly as a liquid in multiple-hearth incinerators, eliminating entirely the cost, mechanical difficulties, and skill formerly required for filtration at these two plants.

---

[13] Vice-Pres., Nichols Eng. & Research Corp., New York, N. Y.

The type of sewage treatment and means for sludge disposal at the Minneapolis-St. Paul plant were decided only after long and intensive study of the requirements. A program of investigation, studies, and tests during operation has resulted in economies well beyond those anticipated when the plant was constructed. Frequent meetings of the operating staff for discussion of minor mechanical matters, as well as major developments or theorizing on some idea, have borne fruit.

George J. Schroepfer,[14] Assoc. M. Am. Soc. C. E. (by letter).—The writer has enjoyed reading the discussions of his paper and appreciates the time spent by the various writers in the preparation of their comments. The discussions developed no controversial issues, but rather were replete with suggestions that will serve as a source of encouragement in improvement of the operation of the Minneapolis-St. Paul sewage treatment plant.

Professor Eliassen makes an interesting comparison between the costs of sludge disposal by dumping at sea, as practised in New York City, and by filtration and incineration, as used at Minneapolis and St. Paul. It is evident that even the seemingly simple expedient of hauling to sea is a comparatively expensive process, involving costs approximating two thirds to three fourths of those at Minneapolis and St. Paul. As Professor Eliassen has stated, the initial cost of $1,500,000 includes only that of the three sludge vessels. To be comparable it would be desirable to include also the costs of the rather extensive sludge storage building and storage tanks, as well as of dockage facilities and other appurtenances required at the Ward's Island plant in connection with sludge barging.

The performance of the unusually long sedimentation tanks, as discussed by Professor Bass, has been a constant source of gratification to the writer. It appears likely that even greater removals can be effected with graded adjustment of the long effluent weirs—which are now set at a uniform elevation—in relation to the varying detention periods provided at points along the length of the tanks.

Mr. Townsend suggests the desirability of further statements by the writer concerning the question of digestion versus no digestion, prior to vacuum filtration. Throughout the paper the writer attempted to confine himself to factual information concerning the Minneapolis-St. Paul project. Realizing that every sludge disposal problem is (or at least should be) a special subject of investigation for the peculiar conditions of a particular situation, and remembering the sagacious proverb to the effect that "the most consistent thing about sewage is its inconsistency," the writer would prefer not to generalize concerning the merits or demerits of various combinations of processes of sludge disposal. Referring only to the Minneapolis-St. Paul conditions, however, the writer can state that the decision concerning the filtration and incineration of raw sewage sludge was well justified, as is indicated by the relatively low total costs of sludge disposal at this plant.

---

[14] Chf. Engr. and Supt., Minneapolis-St. Paul San. Dist., St. Paul, Minn.

Mr. Mendelsohn has requested the writer's views concerning guarantees and maintenance bonds that should be included in specifications. This is an important point. The only equipment on which guarantees and appropriate bonds insuring compliance with these guarantees were required, in connection with Sanitary District contracts, related to the screenings centrifuge, magnetite filters, and incinerators. At the time this equipment was designed in 1935 and 1936, these items of equipment were relatively new, at least in their applications in this particular plant, and in some cases competition was precluded by reason of their special and patentable nature. Operating experience over a period of time has now furnished the designing engineer with what information he requires concerning the performance of such equipment before he makes a selection. Venturing an opinion in a field in which views are certain to differ, the writer would state that qualified engineers, having prepared satisfactory specifications, need not require guarantee bonds on performance of proved equipment in the sanitary engineering field, since the direct and hidden costs resulting therefrom might exceed by several times the risks involved.

Maintenance bonds in the amount of 50% of the contract price for a period of one or two years were required on all equipment. Such bonds were written in connection with the general performance bond without increase in premium. They act as a protection to the qualified manufacturer and contractor, and the city alike, since they serve notice in a forceful way that what is required is well-designed and well-constructed equipment, which will perform successfully and satisfactorily without unusual maintenance costs for a specified period of time.

Mr. Fuhrman presents rather interesting comparative values on the Washington, D. C., and the Minneapolis-St. Paul, plants. As stated, these plants are of comparable size and were constructed and placed in operation about the same time. Enlarging somewhat on the information presented in Mr. Fuhrman's comparison, an interesting point concerning comparisons between various plants can be made:

Description	Minneapolis-St. Paul	Washington, D. C.
Total annual cost of sludge disposal	$136,815.43	$54,486
Million gallons treated	36,705.3	34,200
Tons of dry solids removed	37,703.0	12,350
Cost per million gallons treated	$3.70	$1.59
Cost per dry tons of solids removed	$3.63	$4.41

It will be observed that the quantity of sewage treated is approximately the same in the two plants. The quantity of dry solids removed from the sewage in the two plants differs markedly, however, being only about one third in the case of the Washington, D. C., plant. The difference is probably due to difference in strength of the raw sewage and in removals accomplished. It is for these reasons that the commonly used comparison on a million-gallon basis is inapplicable in many cases, even for plants using similar processes. Strength of raw sewage may easily vary from 150 to 300 ppm of suspended solids in two different plants, and removals by sedimentation may differ in the range of 40% to 75%. Using these illustrative examples, it is manifestly improper to compare on a million-gallon basis the costs at a plant having a dilute sewage, on which a low removal is effected, with another plant treating a strong sewage containing quantities of industrial wastes and which removes high percentages of material. For the illustrative range chosen, which is by no means uncommon in practise, one plant might remove and have to dispose of four times the quantity of material that another plant at the other extreme of the range would. It is this fact that in general makes comparisons on a million-gallon basis unsatisfactory and indicates the greater propriety of a comparison on a tonnage basis. Especially is this true of comparisons of sludge disposal costs in which many of the major cost elements vary in direct proportion to the quantity of material handled. The foregoing statements are of a general nature, and are not presented solely because of the specific comparison Mr. Fuhrman has made. It is simply an expression of an opinion that the writer has had for some time.

Returning to Mr. Fuhrman's discussion, it should be stated that in the case of the Minneapolis-St. Paul plant it is possible that at certain times incineration (which is not employed in the Washington, D. C., plant) may be eliminated, at a saving of approximately $1 per ton. This could be accomplished by farmer hauling of sludge cake for fertilizer purposes, at no expense to the District. Rather, it appears quite likely from present indications that a certain income may be realized.

Mr. Rowen points out possible additional savings in connection with incinerator operations that are under consideration. One such possibility that was thoroughly investigated in the period since the paper was presented (January, 1941) and has since become a reality, is the following:

> As a result of the elimination of the preheater on one furnace, marked savings in power have been effected. As mentioned under the heading "Sludge Disposal: Incinerators" in the paper, the average power consumption in the two years of operation reported on therein has been 17.3 kw per hr per dry ton. The average power consumption for two months in the furnace from which the preheater has been removed has been approximately 5.5 kw per hr per dry ton. Similar changes will be made in the other two units at an estimated total annual saving in power, replacement, and maintenance costs of $12,000 annually.

Several discussions made mention of flexibility of the plant in regard to the degree of treatment capable of being provided to meet varying river dilution conditions. Although such possibilities might not be desirable in the very small plants, the writer agrees that flexibility in the degree of treatment is extremely advantageous, especially for a large project in which continuous examination of the requirements of the receiving body is made. After all, the aim is to meet required standards determined upon in relation to stream use, and therefore a certain end product is required, varying with the capability of the stream to assimilate pollution, and with the use to be made of the water.

The writer would like to have answered each point of information raised, but inasmuch as several of them involved matters of a specific rather than a general nature, and since many such questions have already been discussed in other publications, they are not specifically replied to herein.

At the time the paper was presented, the guarantee tests had not as yet been completed on the magnetite effluent filters, because of certain difficulties, principally those occasioned by displacement of sand in the beds. It is a pleasure to be able to report that as a result of the efforts of the manufacturer the filters have been placed in satisfactory operation and the performance tests relating to removals have been acceptably accomplished. The average removals in the four guarantee tests covering different seasons of the year were as follows:

Suspended solids	ppm
Filter influent	78
Filter effluent	52
Removal by filters	26

The writer wishes to emphasize a matter relative to type of personnel, which is sometimes not sufficiently well recognized, especially on the part of elective public officials. This relates to the desirability of having a sufficient number of qualified professional engineers and chemists on the staff of a sewage treatment plant of any magnitude. Especially is this important when a plant is looked upon as a necessary and considerable investment to be improved and perfected with the rapidly changing status of the art. What might appear on the surface to be a disproportionate expense in "overhead" pays ample dividends in present and future savings in operation and maintenance costs. The Minneapolis-St. Paul Sanitary District is fortunate in having on its staff thirteen engineers and chemists, in addition to a number of others with subprofessional experience, out of a total staff of seventy-nine employees. Lest an impression be created that all such men need be supervisors and "straw bosses," the fact is that many are far from such in the case of the Minneapolis-St. Paul plant, but rather carry their proportionate share of actual work.

The writer appreciates the complimentary remarks concerning the operation of this plant by several of the discussers, and passes on to those who have earned and deserve it whatever credit is due. It is generally realized that to effect important improvement changes, and to increase efficiency and economy, a conscientious, cooperative, and loyal staff is essential.

Paper No. 2129

EXPANSION OF CONCRETE THROUGH REACTION BETWEEN CEMENT AND AGGREGATE

BY THOMAS E. STANTON,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. R. W. CARLSON, BAILEY TREMPER, HUBERT WOODS, N. T. STADTFELD, W. C. HANNA, J. C. WITT, R. F. BLANKS, J. MACNEIL TURNBULL, ROBERT A. KINZIE, JR., AND THOMAS E. STANTON.

SYNOPSIS

Tests have demonstrated that excessive expansion of concrete may occur through chemical reactions between cements of relatively high alkali content and certain mineral constituents in some aggregates, such as certain types of shales, cherts, and impure limestones found along the coast of California between Monterey Bay on the north and Los Angeles County on the south. A new test procedure is described in this paper through which it is possible, in a comparatively short time, to develop the deleterious characteristics of cement-aggregate combinations similar to those reported in the California study. The procedure consists of curing the specimens in sealed containers at normal temperatures.

INTRODUCTION

Numerous tests conducted during recent years have established the value of low-heat cements in minimizing the shrinkage of concrete, and the value of the sulfate-resistant standard and puzzolanic-type cements in resisting attack by the sodium and magnesium sulfates and other deleterious constituents in alkali soils and sea water. Designers must now consider a third important factor in cement composition which may so affect the characteristics of a portland cement concrete as to produce excessive expansion and possible ultimate failure of a structure even if it is subjected to only normal curing and weathering conditions.

Given a properly designed cement-aggregate combination, such a condition can occur even when the cement is perfectly sound (in the generally accepted interpretation of the word) and of such a chemical composition as to be highly

---

NOTE.—Published in December, 1940, *Proceedings*.

[1] Materials and Research Engr., State Div. of Highways, Sacramento, Calif.

resistant to exterior attack by deleterious agents. This is fully and conclusively demonstrated through the tests described in this paper. A new test procedure is also described without which it would probably have been impossible to make the laboratory tests.

Continual wetting or alternate wetting and drying of test specimens failed to develop (in any reasonable period of time, at least) any of the abnormal expansion characteristics experienced on many projects in certain districts of the state. It is now known that at least some of the field conditions of expansion can be duplicated in the laboratory when the specimens are cured in sealed containers, thereby retaining the original mixing water with few, if any, additions or subtractions through immersion or drying. It was not until this fact was discovered that invariable measurable expansion was obtained with certain cement-aggregate combinations, and that negligible, if any, expansion occurred with other combinations.

The complete documentary evidence sustaining the conclusions of the tests are presented for the first time in this paper, although a very brief preliminary report has been presented elsewhere.[2]

Salinas Valley Pavement Failure

Early in 1938, a section of concrete pavement north of the town of Bradley in the Salinas Valley, Monterey County, Calif., failed because of excessive expansion. An intensive field and laboratory investigation followed to determine the causes of the failure and to develop safeguards to prevent a recurrence of the condition in future work. The failed pavement was built in the fall, winter, and spring of 1936–1937. Most of it had passed through two winters when portions began to show distress in the spring of 1938. The distress became manifest in the form of excessive expansion which caused buckling at the expansion joints and a severe cracking throughout the length of certain slabs (Fig. 1(*a*)).

A coarse aggregate from a local commercial plant, located on a tributary to the Salinas River, was used throughout. The fine aggregate came from two sources, one the local deposit (herein referred to as Oro Fino), from which all of the coarse aggregate was secured, and the other (Coyote) imported from a commercially operated deposit near San Jose, Calif., in the San Francisco Bay area. The sands from these two deposits were used during alternate periods so that it was easy to identify the source of the fine aggregate in each section or day's run. A close inspection of all sections readily disclosed that excessive expansion had occurred only in those sections in which the local (Oro Fino) fine aggregate had been used, and it was obvious, therefore, that aggregates from this area contained at least one of the sources of trouble.

Earlier Failures

The Bradley pavement failure culminated a series of concrete failures along the coast area from Monterey County in the north to the northern part of Los Angeles County in the south, throughout which aggregates of the same typical characteristics are encountered.

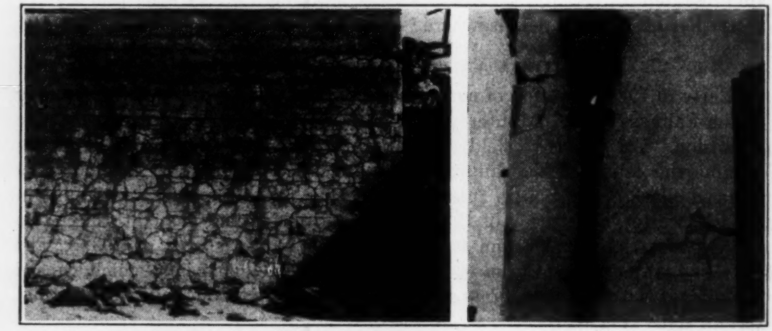
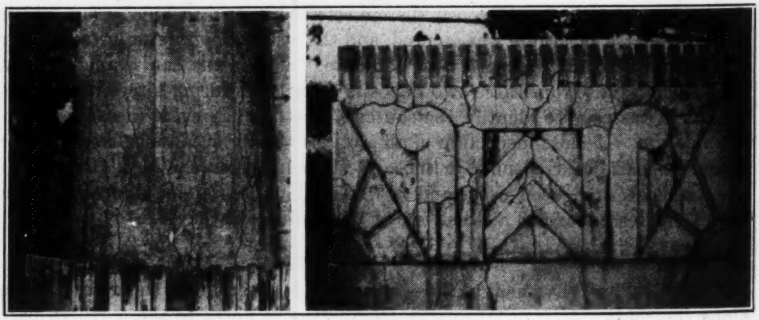
(*a*) Pavement (*b*) Bridge Girder



(*c*) Sea Wall (*d*) School Building



(*e*) Bridge Pier (*f*) Bridge Pylon

FIG. 1.—TYPICAL CONCRETE FAILURES RESULTING FROM COMBINATIONS OF CERTAIN AGGREGATES AND HIGH-ALKALI CEMENTS

The first structure in which distress developed to such an extent as to attract attention was the King City Bridge (Fig. 1(*e*)) built in 1919–1920 across the Salinas River at King City, Monterey County. This bridge consists of an all-concrete trestle approach to a series of concrete piers and steel trusses over the main channel of the river. The channel structure consists of steel trusses resting on concrete piers of two circular sections with battered sides connected by a 12-in. diaphragm wall.

The coarse aggregate was imported from an unquestioned source, but the fine aggregate was taken from the bed of the Salinas River, or a small tributary (Pine Creek) emptying into the river a short distance upstream from the bridge.

Within three years after construction, well-defined cracks were in evidence in the caps of the piers. Later, these cracks extended into the columns of the piers. By July, 1924, all of the pier caps were more or less affected.

The concrete in the pile and trestle construction has shown little, if any, distress, the severe distress being confined to the piers. Although it is possible that the cement was not of a uniform quality, so far as is known the two concretes differed only in the sands used. Pine Creek sand was used at first; then sand from pits in the stream bed of the Salinas River and later surface sand from the bed of the same river, deposited during the winter rains, was used.

The condition of the King City Bridge has been investigated by a number of agencies, including representatives of the Bureau of Public Roads, the Bureau of Standards, the Portland Cement Association, and the cement companies, as well as engineers and chemists of the California Division of Highways. In general, the number of opinions expressed equaled the number of reports made. The causes of failure advanced by the different investigators were the sand; unsound cement; excess water; extreme variations in temperature; faulty curing; faulty concrete design; variable coefficient of expansion between different parts (including reinforcing steel); electrolysis; overstressing or under design; and rusting of anchor bolts, reinforcing steel, iron pipes, washers, etc. All of the assumed causes, however, were purely speculative without any substantiating foundation and (in 1940) have remained in the category of interesting theories.

The King City Bridge has been enphasized because it was the first partial failure of a major structure to attract attention and because the definite cause of the difficulty has been an unsolved mystery. Subsequent to the King City Bridge trouble, several concrete trestles, built afterward in Monterey County, in which fine aggregate from the Salinas River or its tributaries had been used, developed serious distress (Fig. 1(*b*)).

Similar trouble had been noted in Ventura County where the concrete piers of the Southern Pacific Main Line Bridge over the Santa Clara River near Montalvo, built in 1914–1915, had developed map cracking similar to the Salinas Valley structures. On June 5, 1933, George W. Rear, M. Am. Soc. C. E., bridge engineer for the Southern Pacific Railroad Company, wrote that the piers showing distress had been built in 1914, using local sand from the bed of the stream, whereas imported sand had been used the following year in constructing the piers which were still in good condition after eighteen years.

Other pavement and structure failures were noted in Los Angeles, Ventura, Santa Barbara, San Luis Obispo, and Monterey counties, where the aggregate was all of the same general type, containing from 4% to 15% total of shale, cherty shale, and chert. A number of the more important failures were some sections of pavement and sea walls in Ventura and Santa Barbara counties (Fig. 1(*c*)).

Although the sulfates in sea water undoubtedly contributed to the serious deterioration of the sea walls, it was obvious that this deterioration was accelerated by the infiltration of sea water through cracks resulting from excessive expansion occasioned by other causes. The concrete walls of a school building in Santa Barbara, built in 1931, had cracked to such an extent by 1934 as to require at least partial reconstruction (Fig. 1(*d*)). All of the failures noted followed the same general pattern and were apparently due to the same underlying cause.

The solution of the problem was complicated by the fact that, although without exception cracking of the nature described was noted only when local fine aggregate had been used, there were numerous instances where the apparently same local aggregate performed in an entirely normal and satisfactory manner.

Immediately north of the pavement failure in Montery County is a section of pavement, constructed at least six years earlier, in which fine aggregate from the Salinas River was used, but which is still (1940) in excellent condition and shows no evidence of excessive expansion or cracking.

Development of Test Procedure

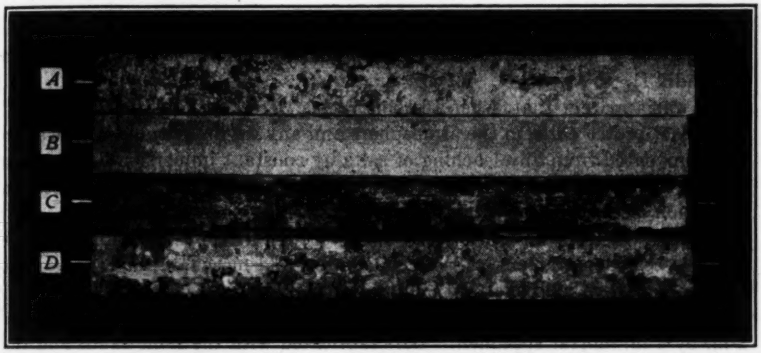
Upon conclusive evidence that the local sand used in the Bradley pavement, constructed in 1936–1937, had played an active part in the failure, a laboratory study was undertaken to determine, if possible, the cause or causes of the trouble and the reason for the inconsistencies that had been noted not only in the locality under immediate investigation, but likewise in all of the coast counties from Monterey to and including the northwesterly part of Los Angeles County.

The first step was to make up mortar and concrete bars of the local (Oro Fino) and the imported (Coyote) fine and coarse aggregates, and then subject some of these bars to continual wetting, some to continual dry exposure, under normal laboratory temperature and humidity conditions, and some to alternate wetting and drying. In one series, after initial curing for seven days, the specimens were dried for three days in an oven at 150° F and then soaked in water at 70° F for four days, the complete cycle taking one week. Another set was dried for two days in the oven at 150° F and soaked seven days in water at 160° F, the complete cycle requiring nine days.

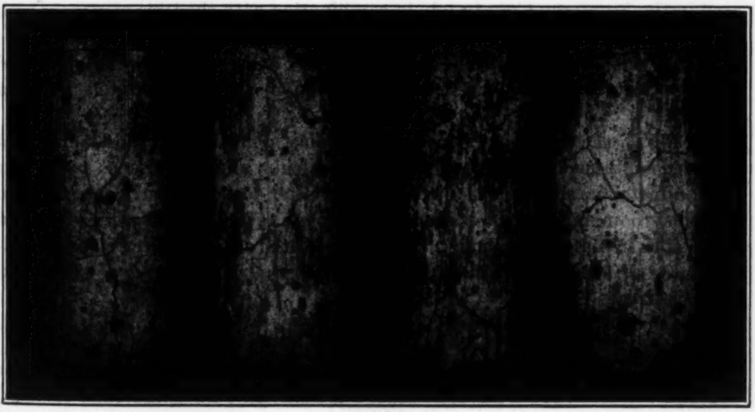
Under none of these curing methods was any excessive expansion observable, even up to more than one year, regardless of the source or nature of the sand, except in the case of a coarse aggregate comprising 100% shale. In that case the expansion was obviously due to a physical expansion of the shale which, when present in large or concentrated quantities, had the effect, ultimately, of rupturing the concrete, but, when present in the normal percentages found in the aggregate under suspicion, had no measurable deleterious effects for the period under observation. In the case of the coarse aggregate with 100% shale, failure occurred on the fifty-first cycle of wetting and drying, at which time the expansion was 0.193%.

AN ACCIDENTAL DISCOVERY

In the meantime, however, upon removing the cover from a 2-in. by 4-in. mortar cylinder which had been cast and retained in a tin container for one year, the specimen was observed to be covered with blotches fringed with a white efflorescence (subsequently analyzed as sodium carbonate), and in a short time the entire specimen became covered with cracks similar to those shown in Fig. 2(*b*) and also to the crazing noted in the pavement and other structures in the area under investigation. A similar condition will be noted in



(*a*) Relative Length of 1-in. by 1-in. by 10-in. Mortar Bars (Mix 1 : 3) Cured for Four Months Under Various Conditions



(*b*) Mortar Specimens (Mix 1 : 2) After Curing Seven Months in Sealed Containers

FIG. 2.—CONDITION OF LABORATORY SPECIMENS AFTER CURING IN AIR, WATER, AND SEALED CONTAINERS

the case of the mortar bars in Fig. 2(*a*). These specimens are identified, by letters, as follows:

Specimen (see Fig. 2(*a*))	Curing method	Expansion after four months, in millionths of an in. per in.
A	Sealed container	+7,310
B	Air	−1,350
C	Water	+ 40
D	Sealed container	+7,230

All bars contain the same quantity of high-alkali cement (1.14%) and a neutral aggregate to which was added 10% of the deleterious mineral No. 28039 (see Appendix I).

It was apparent that, when test specimens were kept in sealed containers, or at least protected from the atmosphere and any drying out, but at the same time prevented from any leaching of salts by constant immersion or alternate wetting and drying, a chemical reaction was going on which caused an excessive expansion of the mortar, with ultimate failure.

A series of tests was then started on 1-in. by 1-in. by 10-in. mortar bars cured in sealed containers, as well as in water, and measured for expansion at different ages. Experience with hundreds of specimens, subsequently fabricated, has invariably checked the results accidently noted in the case of the 2-in. by 4-in. mortar specimen. Bars fabricated with the same sands and the same cement have invariably followed the same expansion pattern.

The local Oro Fino fine aggregate (sand No. 4, Appendix II, and Fig. 3) used in the Monterey County job, in combination with the type of cement used in the work, always shows excessive expansion in a few months (considerable even at twenty-eight days); but the imported (Coyote) sand (No. 20) with the same cement has shown negligible expansion in periods exceeding eighteen months.

In Fig. 3, the specimens were of a 1 : 3 plastic mortar mix, and were cured in sealed containers. The C_3A-content (tricalcium aluminate) does not appear to be a factor in the expansion reactions. Later tests on specimens stored in the moist room, but protected from excess moisture, indicate the same expansion reaction as in sealed containers. However, for the sake of uniformity and convenience, all specimens, other than those constantly wet or dry, were cured in airtight cans.

CURING PROCEDURE

Immediately following fabrication, the test bars are cured twenty-four hours in the moist room under standard conditions. They are then removed from the molds, identified by marking with an indelible pencil, measured, and immediately placed in the containers.

The containers used are regular 6-in. by 12-in. tin cylinder molds with the joints soldered to prevent loss of moisture. The slip cover is probably sufficiently tight to seal the specimens without any other precautions, but if there is any doubt a strip of adhesive tape is wrapped around the joint.

Only enough free water (30 cc to 50 cc) is placed in the bottom of the container to insure keeping the air humid. The specimen rests on the ½-in. monel metal gage point, and therefore the mortar of the bar is not in direct contact with the water.

Eighteen 1-in. by 1-in. by 10-in. specimens (a day's run) are usually stored in one container. The containers are stored under ordinary room temperature, no special effort being made to keep the temperature constant. The specimens are removed from time to time for measurement and then immediately returned to the containers for further curing and later tests. If rusted badly, the containers are replaced.

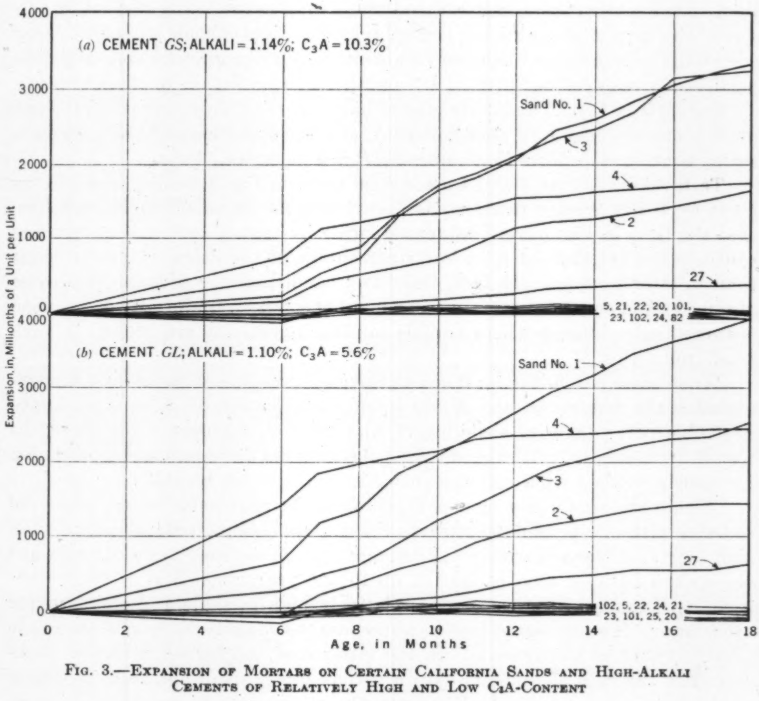


FIG. 3.—EXPANSION OF MORTARS ON CERTAIN CALIFORNIA SANDS AND HIGH-ALKALI CEMENTS OF RELATIVELY HIGH AND LOW C_3A-CONTENT

CEMENT

Other concrete structures in this area, in which the same type of local sand but a different cement had been used, developed no distress up to five or six years at least. This fact gave rise to the suspicion that the expansion resulted from a chemical reaction between certain ingredients in the aggregate and some ingredients in the cement. Alkali in the cement in the form of the sodium and potassium oxides was suspected and, as the cement used on the Bradley job contained approximately 1.14% total alkalis, the tests were repeated with another cement low in alkali (0.45%), with definite results, in that there was little, if any, expansion with the low-alkali cement in combination with the local (Oro Fino) sand which had shown so much expansion with the 1.14% alkali cement. The tests have been repeated many times, not only with the two aforementioned cements, but with other California cements of intermediate alkali content and sands from within and without the coast area.

The resultant expansion has almost invariably been proportional to the alkali content of the cement, whenever used in combination with aggregates containing minerals of the deleterious type found in the area under invesitgation. On the other hand, mortars containing commercial sands originating outside of this area, and containing negligible percentages of shale and chert, being essentially of quartz and feldspar fragments with some granitic and sandstone particles, have developed little, if any expansion, even with high alkali cements.

The data in Figs. 3 and 4 are offered in support of this observation, the mix in each case being a 1 : 3 plastic mortar, and the specimens all being cured in sealed containers. Note that cement *HP* is a puzzolanic type.

Tests on sands Nos. 2 and 4 made after those in Fig. 3 showed expansion as great as, if not greater than, sands Nos. 1 and 3. It would seem, therefore, that the tests in Fig. 3 were influenced either by lack of sufficient moisture to continue the reaction, or by a lower percentage of the deleterious ingredients than in later samples. In fact, these two conditions are probably the cause of some lack of consistency in the tests on other sands, as uniformity of sampling is exceedingly difficult where trouble-causing ingredients are present in such small quantities.

When sand No. 5, Fig. 3, failed to develop excessive expansion, a mineralogical study was made, and it was found that this sample of sand contained negligible percentages of shale, chert, and impure limestone. Therefore, the results are consistent with the nature of the material and confirm the conclusion previously reached regarding the probable source of the trouble.

Within the area under investigation, all of the aggregates from commercial sources, with one possible exception, contain appreciable percentages of shale and chert. All sands with small percentages, or entirely free, of shale and chert show little, if any, expansion up to one year, regardless of the cement used. All sands in the coast area relatively high in shale and chert, on the other hand, develop expansions in a few months roughly in proportion to the alkali content of the cement. In the latter case, negligible expansion is observed in the case of cements with less than 0.5% alkali and high expansion in the case of the 1.14% alkali cement, the other cements ranging in between roughly in proportion to the alkali content (see Fig. 4). Some inconsistencies are noted, but not of such magnitude that they cannot be accounted for by variations in the aggregate.

It is obvious, therefore, that in the presence of certain minerals an otherwise sound but high-alkali cement is a contributing factor to the excessive expansion and subsequent failure of a concrete structure. Under certain conditions this expansion may not be sufficient to disrupt the structure and may cease as soon as the reaction has been completed in any particular cement-

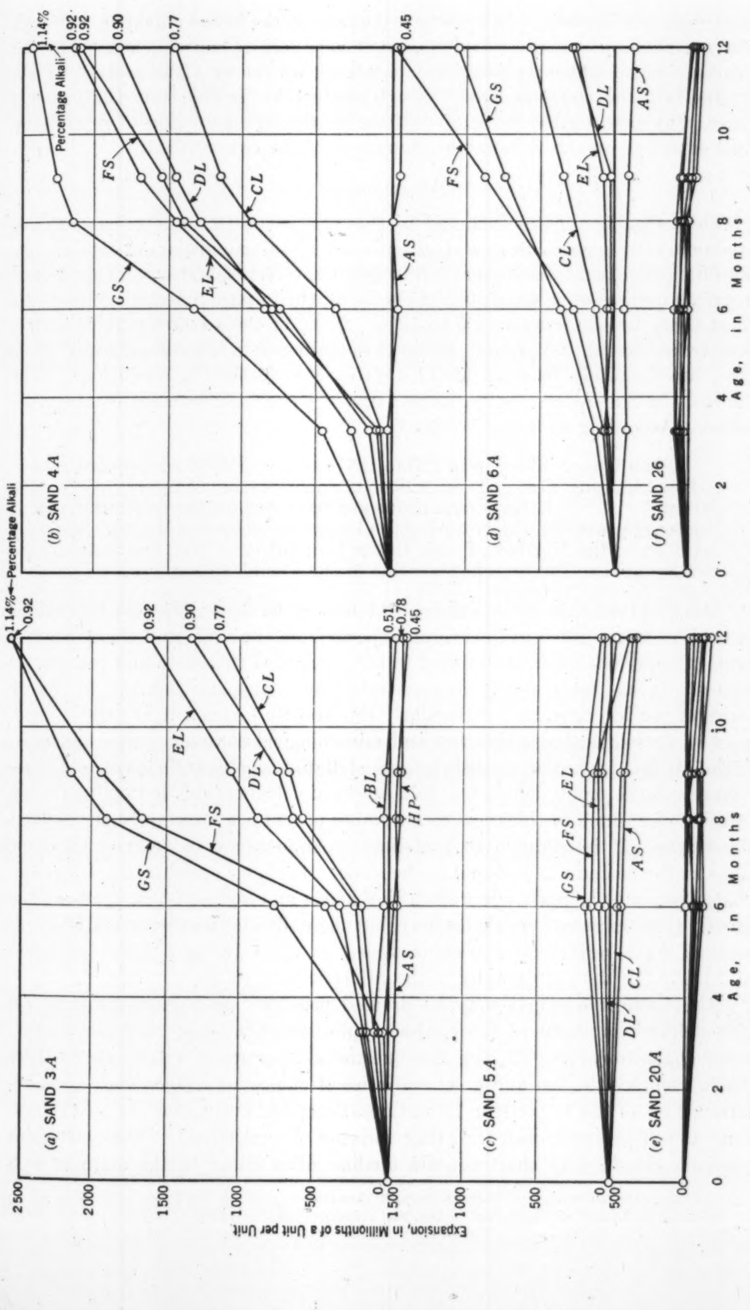

FIG. 4.—EXPANSION OF SAND-CEMENT MORTARS AS INFLUENCED BY THE TYPE OF SAND AND THE ALKALI CONTENT OF THE CEMENT

aggregate combination. In other cases, however, the initial cracking, although above normal but not excessive, may have very serious consequences when the structure is subsequently subjected to attack by sea or alkali waters which, seeping into the concrete mass through fine cracks formed from the primary cause, may take up the work of destruction through corrosion of reinforcing steel or attack on the vulnerable compounds of the cement itself.

AGGREGATES

The coast aggregates included in this study consist of mineral particles predominantly granitic in character with some quartz-feldspar, sandstone, impure limestone, shale, and chert. The granite, quartz-feldspar, and sandstone usually comprise more than 90% of the total; the impure limestone, shale, and chert comprise the remaining 5 to 10%. None of the adverse reactions have been traced to the first group. Some of the minerals in the second group, however, are definitely reactive under appropriate weathering conditions. The minerals in this latter group originate in the Upper Miocene sedimentary deposits. According to Ralph D. Reed,[3]

> "The Upper Miocene in California was a period of widespread seas in which deposition of organic siliceous shale of the Monterey type took place * * *. Whatever conditions are necessary for the deposition of this material prevailed widely during the Upper Miocene from Lower California at least to the Northern Coast Range province and from the San Joaquin Valley area to the present shoreline of the Pacific Ocean."

Many of the types of shale and chert found in the Upper Miocene formations of California are different in several respects from the shale and chert of other geological periods commonly found in other parts of this state and the United States. It has been clearly demonstrated by geologists that the Monterey series of the Miocene, and particularly the Modelo formation, is unique in regard to petrological classification and mineralogical content. Although most of the Modelo formation consists largely of diatomaceous, tuffaceous, and other siliceous shales, many lenses and thin layers of calcareous shale ranging from a fraction of an inch in thickness to a number of feet are intermixed throughout the strata. It is common to find lime, opaline silica, or some chalcedonic silica as the cementing material in the shale. In many cases opaline silica and chalcedony are the main minerals in thin lenses and layers. The opaline silica greatly predominates over chalcedony, but these silicified bands, layers, and concretions have nevertheless been classified as chert by geologists and other authorities on the petrography of the Miocene formations.

The California cherts may be divided into two main classifications: (1) The deleterious cherts of the opaline types, which may or may not contain some chalcedony; and (2) the less questionable group of quartzose particles which includes the red and green varieties of chalcedonic silica such as radiolarian chert of the Franciscan formations, described and named by A. C. Lawson,[4] as well as jasper and the other varieties of chalcedony. The deleterious particles classified as chert contain opaline silica either in the main or as a

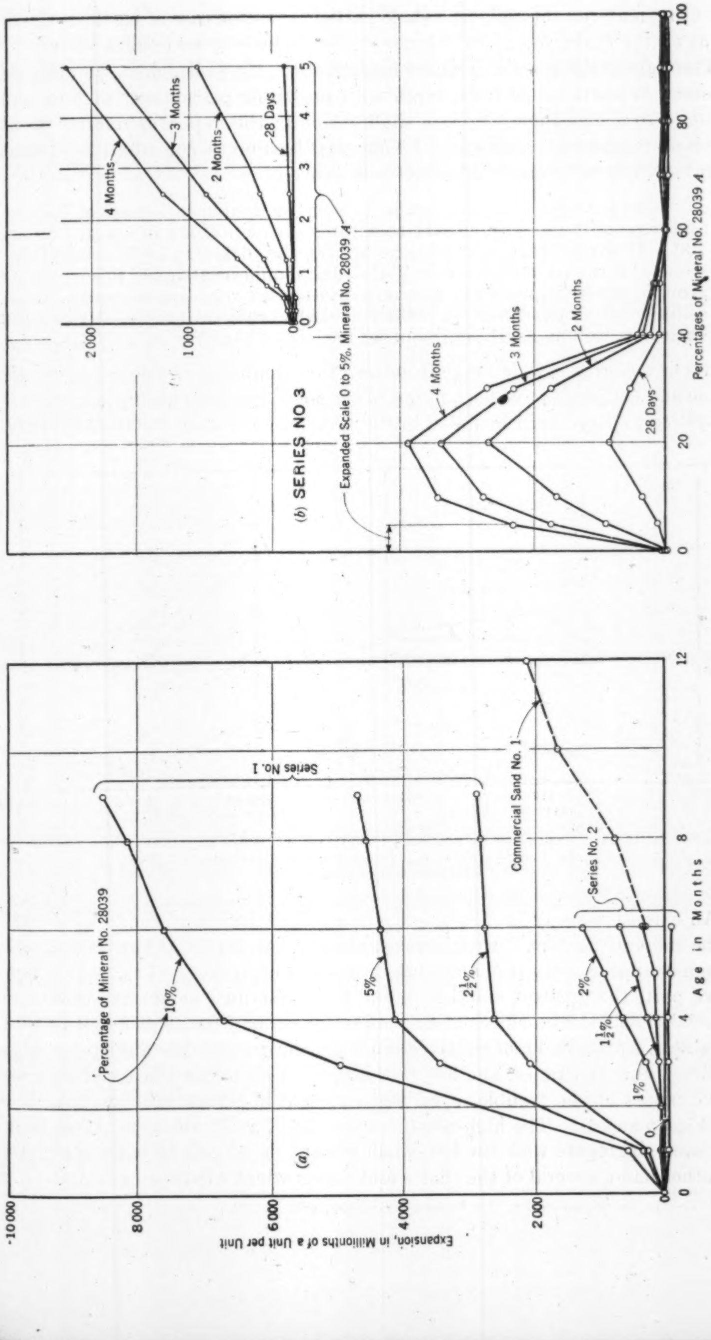

FIG. 5.—COMPARATIVE EXPANSION OF MORTARS CONTAINING SAND NO. 21, IN RELATION TO AGE AND PERCENTAGE OF MINERAL NOS. 28039 AND 28039 A

cementing material throughout a shale particle. In the case of particles classified as cherty shale, some of the laminæ contain little or no opaline silica.

Throughout the coast area under investigation, the shale, chert, and impure limestone deposits range from types with negligible percentages of lime and magnesia to a high-lime magnesia shale which in this report is referred to as "siliceous magnesian limestone." This classification is consistent with that given by William Twenhoffel,[5] who states that:

> "The per cent of calcium carbonate or the double carbonate of calcium and magnesium in sedimentary rock ranges from nothing to approximately 100. If the per cent equals or exceeds 50, the rock may be termed a limestone. If the per cent is below 50 the rock should be assigned to some other group. There is, however, no sharp division between limestones and other sedimentary rocks; they grade without sharp break into the sandstones and shales, as well as nearly every other variety of rock."

Rocks covering a wide range from zero to a comparatively high percentage of lime and magnesia have been found in the coast area, and a sufficient number of these rocks have been included in the present study to cover the field fully.

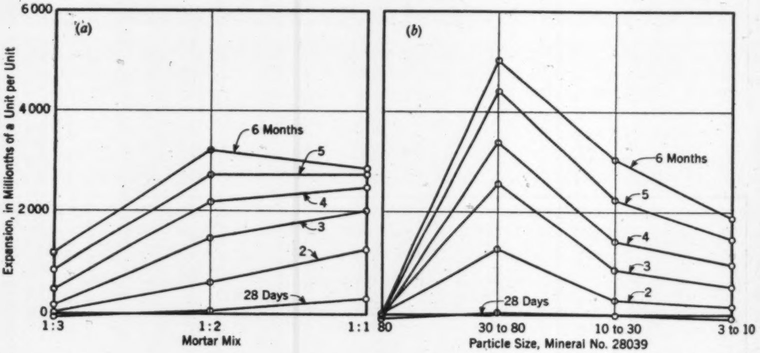

FIG. 6.—COMPARATIVE EXPANSION OF MORTARS CONTAINING SAND NO. 21, IN RELATION TO MORTAR MIX AND PARTICLE SIZE, THE PERCENTAGE OF MINERAL NO. 28039 REMAINING CONSTANT AT 5%

An extensive study has been made in an effort to isolate the "bad actors" in the mineral content. Considerable success has attended this effort. Although it appears very probable that some form of hydrous silica plays a very active part, the greatest reaction in the tests described herein has been with material classified as a siliceous magnesian limestone (Nos. 28039 and 28039*A* in Table 4, Appendix I), of relatively high specific gravity, low absorption, high sodium sulfate resistance, and low rattler loss. This mineral is one of the most active causes of the trouble, even when present in percentages less than 1.00 (see Figs. 5 and 6). The high-alkali cement *GS* (Fig. 3) was used throughout. The same aggregate with the low-alkali cement developed no expansion. On the other hand, several of the shales and cherts which expanded moderately in water showed negligible expansion in sealed containers, even with a high-alkali cement (see Table 1), as contrasted with the siliceous magnesian limestone (No. 28039), which developed no expansion when cured in water but high expansion in sealed containers. It has not been determined if the reaction in the case of this impure limestone is due entirely to some form of silica or in part to the magnesium carbonate. If it is due in any part to the magnesium carbonate, the probable chemical reactions in this respect are as follows:

[a] See Appendix I; all these specimens were cured in sealed containers.

The sodium oxide in the cement hydrates to form sodium hydroxide. The sodium hydroxide, in turn, probably reacts with at least some form of the magnesium carbonate in the siliceous magnesian limestone to form magnesium hydroxide and sodium carbonate; thus:

$$\mathrm{Mg\,CO_3} + 2\,\mathrm{Na\,OH} \rightarrow \mathrm{Mg(OH)_2} + \mathrm{Na_2CO_3} \ldots\ldots\ldots\ldots (1)$$

The sodium carbonate ultimately crystallizes with seven to ten molecules of water, with an increase in volume, and thus causes expansion of considerable magnitude, resulting in stresses sufficient to rupture the concrete. The approximate volume change may be computed theoretically from Eq. 1, assuming the following specific gravities:

Description	Specific gravity
Magnesium carbonate in the rock	3.037
Sodium hydroxide	2.130
Magnesian hydroxide	2.300
Sodium carbonate including 10 molecules of H_2O	1.460

If the molecular weight of the reacting components and the end products are divided by the specific gravities, the following respective volumes are obtained:

$$\left.\begin{array}{l} \mathrm{Mg\ CO_3} = \dfrac{\text{Molecular weight}}{\text{Specific gravity}} = \dfrac{84.33}{3.037} = 27.7 \\ \quad + \\ 2\ \mathrm{Na\ OH} = \dfrac{80.016}{2.13} = 37.6 \end{array}\right\} 65.3 \text{ (Combined volume of reacting components)}$$

reacts to form:

$$\left.\begin{array}{l} \mathrm{Mg(OH)_2} = \dfrac{58.336}{2.3} = 25.36 \\ \quad + \\ \mathrm{Na_2CO_3,\ 10\ H_2O} = \dfrac{286.17}{1.46} = 196.00 \end{array}\right\} 221.36 \text{ (Combined volume of reaction products)}$$

or an increase in volume of 239%.

To check the accuracy of this assumption, tests were made to determine the action of sodium hydroxide upon various materials that might be present in the aggregate, such as magnesium carbonate, calcite, dolomite, etc., as well as on the siliceous magnesian limestone.

The method used was to subject the substance under observation to the action of a normal sodium hydroxide solution for seventy-two hours, excluding the possibility of contamination by atmospheric carbon dioxide. A portion of the clear liquid was titrated with normal hydrochloric acid using methyl orange as an indicator. A second volume equal to that used in the methyl orange titration was treated with barium chloride solution to precipitate the carbonates and then titrated with normal hydrochloric acid with phenolphthalein as the indicator. The difference between the volumes of acid used in these determinations was computed to sodium carbonate.

Treated in this manner a sample of:

(*a*) Standard calcite yielded only a trace of sodium carbonate as Na_2CO_3;
(*b*) Bakers calcium carbonate likewise yielded only a trace;
(*c*) Dolomite with 7.1% Mg O yielded 1.06% Na_2CO_3;
(*d*) Technical hydrated magnesium carbonate yielded 51.00% Na_2CO_3; and
(*e*) The siliceous magnesian limestone with 15.5% Mg O yielded 8.65% Na_2CO_3.

All material was crushed to pass an 80-mesh screen before test.

These results indicated that sodium hydroxide reacts with certain forms of magnesium carbonate, but not with carbonate of lime. It appears that some similar reaction occurs in the case of at least some of the hydrous silicates. Although some early expansion due to physical causes may be expected from some of the shales, and therefore the percentage of such shales should be held to a reasonable minimum (controlled by the sodium or magnesium sulfate test), nevertheless, when held to comparatively low limits, the expansive force may not be sufficient to cause rupture except in the nature of popouts when particles are close to the surface. This conclusion is confirmed by observation of numerous structures which, except for surface popouts, show no distress over a period of years even if the aggregate contains a relatively high percentage of many of the types of shale found in the area under investigation. With some cherts and shales, however, in addition to the siliceous magnesian limestone, a chemical reaction of a decidedly destructive nature always takes place in the presence of a high-alkali cement.

An astonishing development was the effect of a very small percentage of the high lime-magnesia rock. As will be seen by reference to Fig. 5(*a*), as low as 1.00% of this mineral caused considerable expansion in six months, the expansion in that period being almost identical with the expansion mortars of sand No. 1 in the same period of time, indicating that sand No. 1 contains not more than 1.00% of deleterious particles but that even this low percentage is objectionable.

The particle size of this mineral also has an important bearing on the result. It was thought that, by crushing the deleterious particles to pass 200-mesh completely, an accelerated reaction might be had. The reverse was the case, as specimens fabricated with −80-mesh particles developed no expansion in sealed containers, whereas the −30-mesh to +80-mesh particle specimens showed the greatest expansion (see Fig. 6(*b*)). Therefore, it appears that the reaction between the reactive ingredient in the aggregate and the alkali in the cement, when the aggregate is in a finely divided state, is either dissipated throughout the mass in such a way as to cause no high expansive forces or the reaction is largely over before the concrete attains permanent set. One theory is that the expansion is taken up in the interstices and by the gel, thus reducing the measurable manifestation of the reaction to negligible proportions.

MERRIMAN ALKALINITY AND FREE ALKALI TEST

The Merriman test[6] for alkalinity and free alkali was applied to the cements, but it was found that this test was not always consistent with the results. One cement, relatively low in the Merriman test, but with high alkali as determined by chemical analysis, developed high expansion; and its action, therefore, was consistent with the total alkali as determined from the chemical analysis rather than with the percentage of soluble alkali as determined by the Merriman test. Another cement with a high Merriman test, but low in alkali as determined by the chemical analysis, gave low expansion results. The reason for the discrepancy appears to be that the soluble portions of some cements go into solution much more slowly than others. The conclusion has been reached, therefore, that the Merriman test procedure, in its present form at least, is not suitable for a proper classification of cements in the order of the reactions encountered in the California tests.

EXTENT OF TESTS

Tests have been made on fine aggregate from all of the commercial sources within the region affected and from several sources outside of this area for comparison purposes; they have been made also on most of the commercial cements manufactured in California ranging in alkali content from less than 0.50% to approximately 1.14% (Table 5, Appendix III).

---

[6] Specifications for Cement, Board of Water Supply, City of New York.

As previously stated, negligible expansion developed with sands from outside the affected area. With one exception, all of the local sands showed high expansion in proportion to the alkali content of the cement. With the exception of the one sand, all of the samples contained from 5% to 10% of shale, chert, and the siliceous magnesian limestone. The sample of sand (sand No. 5) from the one deposit which failed to react was subsequently analyzed and found to contain only a very small percentage of the deleterious particles.

Numerous combinations have been made of aggregate from all commercial deposits and cement from most of the California mills. For check purposes, the study has been expanded to include, also, several cements from other parts of the United States.

Following a visit to the laboratory, when he was in California during the summer of 1939, the late Thaddeus Merriman, M. Am. Soc. C. E., who was much interested in the study, forwarded a sample of low-alkali cement (0.47%) from a Lehigh Valley plant (cement *N* in Table 5, Appendix III); and Ira Paul of the New York State Highway Department furnished a sample of 0.64% alkali cement from a New York plant (cement *R*). Through F. V. Reagel of the Missouri State Highway Department and W. E. Gibson, Assoc. M. Am. Soc. C. E., of Kansas, cements were secured similar to those used in pavements in Missouri and Kansas (cements *M* and *O*). These out-of-state cements have all been tested in combination with the Oro Fino and Coyote sands.

The expansion reactions have paralleled the reactions of the California brands. Cement *M* with a high-alkali content (0.83%) has developed excessive expansion with the Oro Fino sand (4,010 millionths of a unit per unit in fourteen months) and negligible expansion with the Coyote sand, whereas cements *N*, *O*, and *R*, comparatively low in alkali, have developed little if any expansion with either the Oro Fino or Coyote sands.

More than 3,000 1-in. by 1-in. by 10-in. mortar specimens of all combinations were fabricated and tested for expansion under different curing methods. The present status of knowledge of the subject was only arrived at through following numerous leads, some of which led into blind alleys and others of which were productive of results pointing the way and suggesting additional tests or lines of investigation.

Series I.—This series was started in May, 1938, and included only the two sands used on the Bradley job. Several coarse aggregates were used, including chert, shale, granite, and an altered dacite.

The cements in this first series were of the brand used in the Bradley job (a high-alkali cement) and in addition a low-alkali cement from another mill. The test specimens consisted of 2-in. by 2-in. by 11¼-in. bars of six-sack concrete, using 50% sand and 50% coarse aggregate, and the maximum size was ¾ in. One set of bars was cured in water, one set in air, and other sets alternately soaked and dried at air and water temperatures ranging from 70° F to 160° F. These tests produced no results of value, even up to one year, and at no time duplicated field experience with the local fine aggregate and job cement.

All specimens cured in water showed a slight expansion in the earlier period, but by 200 days all showed shrinkage from the peak length. At one year all specimens were shorter than the original length with the exception of the shale coarse aggregate specimens (ledge shale from Oro Fino Canyon), which showed a slight expansion (0.009%).

All specimens cured in air at laboratory temperature showed shrinkages ranging from 0.1% to 0.3%, but no cracking. In the alternately wet and dry group, there was shrinkage or negligible expansion with the exception of the coarse aggregate specimen of 100% shale which, by the fifty-first cycle, had expanded 0.193% and failed by cracking.

Series IA.—Shortly after Series I was started, supplementary specimens of the same size were placed under similar test, using aggregates from various spots in the Oro Fino deposit, and also from other commercial sources throughout the district between Monterey and Los Angeles counties. Again the results were negative.

Series II.—After Series I and IA had been under way approximately three months, the condition of the 2-in. by 4-in. mortar specimens cured in a sealed container was observed, and a new series was immediately started, the specimens in this series being fabricated in September and October, 1938. Because of the expense and labor involved in fabricating and measuring concrete specimens, and because it was apparent from an inspection of the mortar specimen cured in the sealed container that the fine aggregate was considerably more reactive, at early stages at least, than the coarse aggregate, Series II consisted of fine-aggregate mortar specimens only, and the specimens in all subsequent series, except one, were mortar specimens. At the start, six 1-in. by 1-in. by 10-in. 1 : 3 mortar bars were fabricated from each mix for curing under different conditions, and the results reported are the average of several specimens. As the 1 : 2 mortars were found much more reactive, all later specimens were fabricated from this mix.

Sands from fourteen sources were included in Series II—five from commercial sources throughout the affected area; seven from outside sources, free of shale and chert; and in addition a crushed diorite and a crushed quartz. With little information at that time relative to the most probable source of the trouble, and to ascertain if the situation could be corrected by the use of a low C_3A cement, two types of the brand of cement used on the Bradley job were included: (1) The job cement with 10.3% C_3A and 1.14% alkali, and (2) a modified cement from the same mill containing 5.6% C_3A and 1.10% alkali. To hold the amount of testing to a minimum, no other cements were included in Series II.

The mixes were put up in duplicate, one set with the high-alkali and comparatively high C_3A, and the other with the high-alkali and comparatively low C_3A cement. A uniform water-cement ratio (0.94) was used, the slump varying $1\frac{3}{4}$ in. to $2\frac{1}{8}$ in. with the natural sands, 1 in. to $1\frac{1}{4}$ in. for sands having rock chips in the coarser sizes, and $\frac{5}{8}$ in. to $1\frac{1}{4}$ in. for the crushed quartz and diorite. Some of the specimens were cured continuously in water, some in air, some alternately wet and dry, and some in sealed containers in the presence of a slight amount of free water.

As no material reaction was expected short of six months, the sealed containers were not opened or the specimens measured until six months had elapsed. The reaction was found to be so extensive by this time (Fig. 3) that in all subsequent series the measurements were started at earlier periods. After measuring, the specimens were returned to the sealed containers for further curing and measurement at subsequent test periods, usually monthly. At six months all of the sands from the shale-chert infected area, except one, showed considerable expansion. The exception was the sand which was subsequently found to be low in shale and chert.

All of the sands from outside the infected area, except one (all of which have a good construction history), showed either only a slight expansion or a shrinkage at six months. This relative condition has persisted throughout the entire test period to date. The expansion of the one exception (No. 27 in Fig. 3) was not especially high, but, as it was decidedly out of line with the others, a thorough study is being made (1940) to ascertain the cause.

Mortar cylinders (2 in. by 4 in.) for compression tests, fabricated from the same mixes as the bars and cured in water, developed equal strengths up to one year for the poor and the good sands. Later specimens cured in sealed containers showed a gradual falling off in strength with age whenever the infected sands were used.

Series III.—As soon as Series II was well under way and time permitted, a third series was started similar to Series II, but including a number of other California brands of cement ranging from low to high alkali. In addition to the bars, 2-in. by 4-in. mortar cylinders were cast and cured in sealed containers for breaking at twenty-eight days, six months, and one, two, and five years.

As in the previous series, all bars cured continuously in water expanded slightly at first and then began to shrink. The first expansion measurements of the specimens cured in sealed containers were made at one hundred days. Even at that period, considerable expansion was noted in the case of the infected sands.

Series IV.—Having determined definitely from Series II and III that certain sands were reactive, the next step was to determine, if possible, which mineral ingredient or ingredients in the sands were the source of the trouble. Since all minerals except the shale and chert had been removed from suspicion by previous tests on selected sands, four suspected minerals were selected from the infected area, including a diatomaceous shale (No. 28037); a chert (No. 28038); and a calcareous shale (No. 28039), later classified as a siliceous magnesian limestone (Table 4, Appendix I). These shales and cherts were crushed to pass a No. 3 screen and were combined in various percentages with a neutral sand (No. 21) from the Russian River, north of San Francisco Bay.

This series was later expanded to include a serpentine found in the coast area, a calcareous shale (No. 19374) with approximately 6% Ca O but low magnesia, a siliceous chert (No. 19375), and two opaline cherty shales (Nos. 28045 and 28046). An opal and an opalized chert were likewise included to determine the effect of an opaline silica. Crushed limestone was used in other specimens.

The conclusion from this test was that the principal ingredient in the sand contributing to the abnormal volume change was the "siliceous magnesian limestone" and that probably the magnesia in the form of $Mg\ CO_3$ in this rock was one of the active reagents with the sodium hydroxide from the sodium oxide in the cement. However, excessive expansion was not confined to the specimens of No. 28039 but was likewise noted, although to a lesser degree, with the laminated calcareous shale No. 19374, and the opaline cherty shales Nos. 28045 and 28046 (Table 4, Appendix I).

The early tests in this series were made with 2.5%, 5%, and 10% additions to the Russian River sand. As evidence accumulated that excessive expansion occurred with even as low as 2½% of No. 28039, the series was expanded to include specimens with lower percentages ranging down to as low as 0.10% (see Fig. 5(*a*)).

OTHER TESTS

Later test series have included observations to determine the effect of:

(1) Age of cement;

(2) Washing soluble salts out of the cement, treating the aggregate with this resultant liquor, and then testing for expansion;

(3) Admixtures such as pumicite, celite, ground Ottawa sand, calcium chloride, and Vinsol resin;

(4) Treating the sand with sodium hydroxide and dilute hydrochloric acid;

(5) Varying the quantity of cement, using 1 : 3, 1 : 2, and 1 : 1 mortar mixes; and

(6) Methods of accelerating reaction by heating so as to reduce the time of test.

Most of these later tests have not been conducted long enough to produce conclusive data of value. Apparently, however, the test cannot be accelerated by heat, by the autoclave, or by pulverizing the deleterious materials, but can be accelerated by using 1 : 2 mortar mixes instead of 1 : 3 and adding from 5% to 20% of the reactive minerals crushed and screened to the size range, a −30-mesh to +80-mesh size.

The addition of a puzzolanic material seems to be effective, as 25% pumicite substituted for an equivalent weight of high-alkali cement reduced the expansion to a negligible amount at early periods. Part of the reduction may have been due to the lower percentage of total alkali in the combined mix. Ground Ottawa sand, however, was much less reactive and calcium chloride had little effect (see Fig. 7). The reaction with the puzzolanic-type cement included in Series II (*HP* in Fig. 4) was likewise considerably less than with other standard cements of the same or less alkali content. Vinsol resin appears effective to a certain extent.

Treating the Oro Fino sand with water mixed with, and then leached from, a high-alkali cement, or with a solution of sodium hydroxide, apparently stops any subsequent reaction; but treating with a hydrochloric acid solution is ineffective. This would indicate that it may be some form of silicate rather than carbonate which causes the trouble.

CONCRETE TESTS

With the exception of Series I and IA, all of the tests described were made on mortar specimens. A later series consisted of 6-in. by 6-in. by 30-in. specimens of six-sack concrete, using different combinations of good and bad coarse and fine aggregates. Specimens of each mix were cured, sealed in water, and were kept continuously dry at laboratory humidity and temperature. This test has been in progress too short a time, however, to produce information of value.

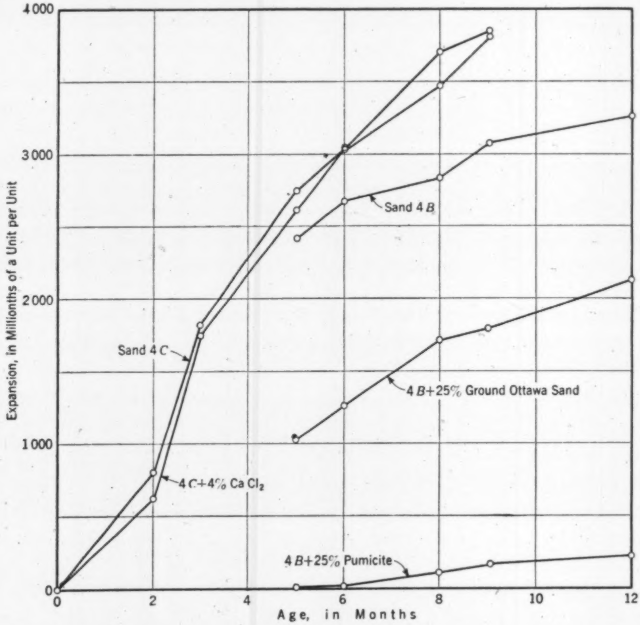

Fig. 7.—Effect of Various Admixtures on the Expansion of a High-Alkali Cement and Reactive Sand Mortar (1 : 3 Mix)

Shale and Chert Popouts

Although the laboratory investigations described herein conclusively demonstrate a very destructive chemical reaction between a high-alkali cement and some ingredient in the siliceous magnesian limestones, nevertheless one cannot overlook the fact that some chemical action is also taking place in the presence of some types of the low lime-magnesian shales and cherts, as evidenced by the data shown in Table 1, as well as by a study of the extensive popouts observed in numerous structures, including pavements, bridges, and buildings where shale or chert particles are invariably found at the base of the popouts, frequently accompanied by a soft viscous substance analyzed as a silica gel with some form of sodium silicate. Figs. 8(*a*) and 8(*b*) are views of large popouts from the basement of the old Times Building in Los Angeles. Fig. 8(*a*) is a part of a 5-in. popout showing at: (*a*) Sodium silicate gel; (*b*) an intermediate zone of partly altered shale; and (*c*) apparently unaltered rock. The chemical analyses of these samples, given in Table 2, were necessarily made on very small specimens and may therefore be inaccurate in some details. Fig. 8(*b*) shows altered and unaltered parts of the mineral that caused the popout.

The aforementioned silica gel frequently has been observed exuding from cracks or pores in the face of concrete structures in which aggregates and cements similar to those under investigation had been used. This type of gel has also been found throughout the cores and pieces of concrete examined from all of the failed pavements and structures. In some cases a number of aggregate particles had entirely altered to gel, so that it often swelled out above a freshly cut surface of a concrete specimen. In many cases the reaction has only partly progressed into particles identified as siliceous shales or cherts of a type relatively free from lime and magnesium carbonates. Although the gel has usually been found in a plastic state in fresh popouts, and in specimens cut from beyond the exposed surfaces of the concrete pavements and structures, it hardens readily and shrinks when dried on exposure to the air.

A detailed examination was made of approximately 200 popout and core specimens removed from the affected buildings, sea walls, bridges, and pavements over an area extending from Los Angeles on the south to the northern part of the Salinas Valley. As defined by Allan H. Nicol, mineral technologist for the State Division of Highways, each popout particle had associated with it a considerable amount of optically isotropic material of very low index of refraction. This material was identified as opaline silica with complex sodium silicates and was found to have indexes ranging from 1.41 to 1.54. This substance, which was slightly plastic before drying, is hereafter referred to as "gel." It was found that the index of refraction of the dried gel increased with the color. The clear, glassy variety had indexes ranging from 1.41 to 1.47.

FIG. 8.—TYPICAL SHALE POPOUTS

The yellow and pale brown types showed values from 1.46 to 1.49, whereas with the brown to dark brown types the values ranged from 1.47 to 1.54.

Microchemical tests showed that the type of gel with a low refractive index was a nearly pure opaline silica, relatively free from sodium, magnesium, aluminum, calcium, and iron salts, whereas the yellow, amber, and brown varieties, which predominated in many specimens, contained increasing percentages of silicates and other compounds of these and other elements. The presence of these compounds, together with a variable content of adsorbed water, undoubtedly could account for the variable refractive indexes.

Most of this gel is fluorescent under ultraviolet light. A strong fluorescence was observed in the expansion bars and mortar cylinders which carried various percentages of No. 28039 (siliceous magnesian limestone; see Appendix I). These specimens had been subjected to the sealed curing test. The fluorescence in this case is due to gel derived from the particles of No. 28039 in the aggregate, as the rock in its original unaltered condition does not fluoresce.

The gel-like material associated with these specimens contains opaline silica, with varying amounts of sodium, magnesium, aluminum, calcium, and iron compounds. All of the gel examined on popouts, and in the cores and broken concrete from the various sources, shows similarity of optical properties and chemical composition.

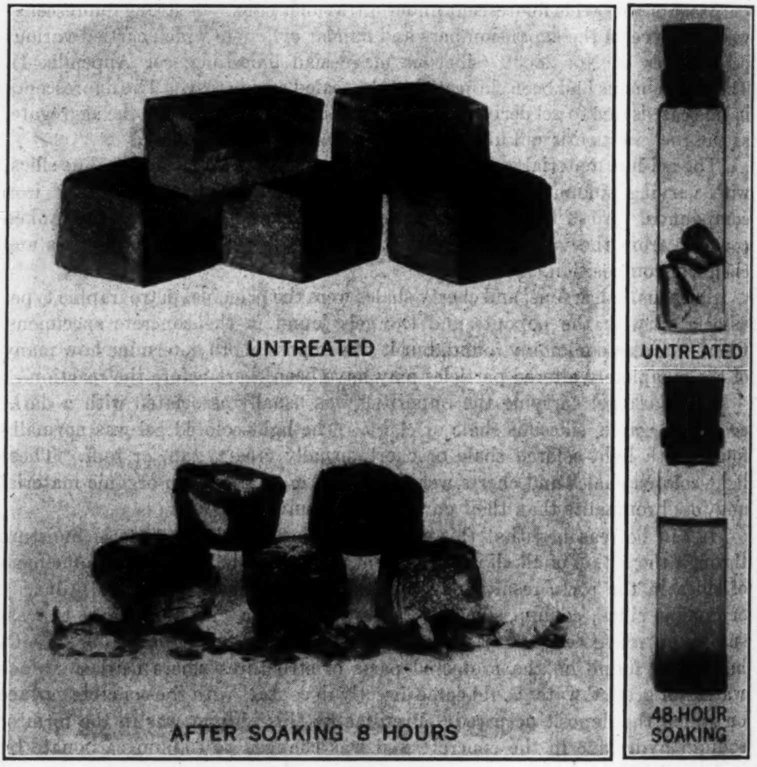
Siliceous, calcareous, and cherty shales were the principal petrographic types associated with the popouts and the gels found in the concrete specimens. Chert was also commonly found, but it was impossible to determine how many of the completely altered particles may have been chert before the reaction.

The dark gel carrying the impurities was usually associated with a dark-colored, organic, siliceous shale or chert. The light-colored gel was normally found with light-colored shale or chert, usually cream, tan, or buff. These light-colored shales and cherts were generally more free from organic material and fossil remnants than their dark-colored equivalents.

It can be reasoned that this substance forms in the presence of moisture through the action of alkali in the cement or possibly in the rock on some form of silica in the rock, resulting in a gel-like end product consisting primarily of opaline silica, sodium silicates, and water. As a partial proof of this assumption, white deposits or incrustations containing more than 50% Na_2CO_3 have been found on the protected parts of structures where neither surface water nor ground water could come directly in contact with the concrete surface on which the deposit occurred. Presumably this sodium was in the form of sodium hydroxide in the concrete and was changed to sodium carbonate by carbon dioxide derived from the air.

Following this reasoning, mineralogy has well established the fact that hydrous forms of silica, such as opaline, are readily dissolved in either sodium or potassium hydroxide solutions, and also that these forms of silica are found in abundance throughout some of the Miocene formations in the area under discussion. All siliceous shales and cherts, therefore, are subject to question, in connection with the chemical reaction resulting in the gel substance. Extensive tests show that many types of shale and chert found in the gravel deposits are readily dissolved and disintegrated by soaking in a 10% solution of sodium hydroxide. In Fig. 9 the effects of soaking are shown for two materials—specimens cut from ledge rock, and ½-in. shale and chert particles from stream-bed gravel deposits.

Although these tests show only that the gel type of chemical action accompanying popouts and expansion failures can be approximately duplicated in the laboratory by the use of a sodium hydroxide (Na OH) solution, additional tests indicate that a similar action occurs when these types of aggregate are soaked in the mixing water from high-alkali cements. The chemical composition of water containing alkali, leached from a low-alkali (0.45%) and a high-alkali (1.14%) cement, is shown in Table 3, together with the change in each solution, after digesting for 120 hr at 200° F with Oro Fino sand containing about 9% of chert and shale particles. It is significant that the water from the



(*a*) Specimens Cut from Ledge Rock

(*b*) Stream-Bed Gravel

FIG. 9.—EFFECT OF A 10% SODIUM HYDROXIDE SOLUTION (AT 70° F) ON SOME TYPES OF SILICEOUS (CHERTY) SHALE AND CHERT FROM THE CALIFORNIA MIOCENE FORMATIONS

high-alkali cement dissolved approximately ten times more silica during the treatment than the water from the low-alkali cement.

Figs. 8(*c*) and 8(*d*) show two typical popouts of the type accompanied by relatively large deposits of gel. It will be noted from Table 2 that these shale particles have chemical compositions somewhat similar to No. 28042 (Table 4, Appendix I), particularly in regard to lime, magnesia, and alkali, although the shale in Figs. 8(*a*) and 8(*b*) is very much harder than that in Figs. 8(*c*) and 8(*d*), or the soft shale represented by No. 28042. Even if the gel type of reaction accompanies many popouts and other expansion failures observed in the field and also can be accounted for, at least theoretically, when a high-alkali cement is used, the volume change and the exact source of the stress causing the popouts and accompanying the reaction require further investigation.

CONCLUSION

The tests described herein justify the following conclusions:

1. Certain mineral constituents in concrete aggregates contribute to expansion of concrete and sometimes develop stresses of such magnitude as to cause failure.

2. Some shales expand excessively when saturated with water or when they are alternately wet and dry and, therefore, the percentage of such material should be kept to a practical minimum. This action, however, appears to be physical and of much less intensity than a chemical reaction with other minerals.

3. Excessive expansion, sufficient to rupture a concrete mass, may occur when certain minerals are present. The reaction in this case is chemical, and evidence indicates that it always takes place with the siliceous magnesian lime rocks found in the aggregates from the Upper Miocene sedimentary deposits of the state and frequently in the presence of some of the low-magnesia, low-lime shales and cherts.

4. The chemical reaction producing excessive expansion apparently occurs only when the portland cement component contains an appreciable percentage of alkali in the form of sodium and potassium oxides. It is of an intensity proportional to the percentage of such oxides, apparently being of such low order as to be negligible when the alkali content is less than 0.6%.

ACKNOWLEDGMENTS

The investigations and tests described in this paper were conducted as a research project of the California Division of Highways, of which State Highway Engineer Charles H. Purcell, Assoc. M. Am. Soc. C. E., is chief. The writer is indebted to the following members of his staff, all of whom have contributed valuable suggestions: Lester Meder, assistant physical testing engineer, for having first observed the accelerated expansion of specimens cured in sealed containers and for subsequent direction of the fabrication and measurement of test specimens and intelligent analysis of results; G. H. P. Lichthardt, chief chemist, for the direction of all chemical analyses and the development of the theory of the probable reactions; O. J. Porter, senior physical testing engineer and head of the Aggregate and Soils Department, and his assistant, Mr. Nicol, for their contribution to the geological and aggregate classification and discussion, identification of the mineral constituents, and suggestions as to probable reactions. In the field District Engineers L. H. Gibson, District V, San Luis Obispo, and S. V. Cortelyou, M. Am. Soc. C. E., District VII, Los Angeles, afforded wholehearted cooperation.

APPENDIX I

MINERAL IDENTIFICATION

The chemical analysis and physical properties of a few of the Miocene shales, cherts, and impure limestones, found in the coast area between Monterey and Los Angeles, Calif., are given in Table 4. Each sample is identified by a laboratory test number that identifies the following detailed description of each one:

No. 19374—Laminated Calcareous Shale:

Groundmass an impalpable mixture of clay, opaline silica, and sericite, carrying abundant fragments of quartz, orthoclase, chalcedony, and calcite, with some marcasite. Organic matter and fossil relics, including foraminifera and diatoms, are found occasionally as stringy accumulations parallel with the laminæ. The chalcedony occurs chiefly as fragmental grains, with an occasional veinlet. A few small clay lenses were observed without any appreciable embedded mineral grains of sufficient size to be identified. The laminations in this rock are quite high in clay and opaline silica, and carry the thickest layers of organic matter and fossils. This could explain the ease with which this material splits apart.

No. 19375—(Chalcedonic) Cherty Shale:

Predominant evidence of chalcedonic replacement of the shaly portions of this rock. The groundmass is predominantly chalcedony of the flamboyant type, with some areas not entirely replaced. Sizable fragments of recognizable minerals are lacking. Organic matter, low in content, occurs in layers that tend to parallel the bedding. The entire specimen is pierced throughout by chalcedony veinlets. Quartz and feldspar fragments are lacking. Opaline silica not observed in this material. Fossils absent.

[a] Combined water and organic matter. [b] Los Angeles Rattler Test.

No. 28037—Diatomaceous Shale (Soft Siliceous Type):

Carries a few fragments of plagioclase and quartz. Groundmass consists chiefly of diatoms and other opaline material, together with clay, some mica (probably sericite), and a variable amount of organic matter. Groundmass is quite uniform.

No. 28038—Chert:

Opaline material, with some organic matter, and a few fine chalcedony fragments constitute the groundmass of this speciman. The groundmass is pierced throughout the entire length of the slide by a series of fine chalcedony veinlets that average about 0.15 mm in width. These veinlets are all more or less parallel with each other and are apparently conformable with the bedding. They also parallel the heavy layers of organic matter. Abundant evidence of chalcedonic replacement throughout groundmass. "Canals" or veinlets are in portions partly opaline. No fossils or diatoms were noticed. Chalcedony of veinlets is of flamboyant type and carries minute opaque inclusions, possibly marcasite. Many canals or veinlets not entirely sealed from wall to wall by opaline cement, leaving innumerable fissures and openings.

No. 28039—Siliceous Magnesian Limestone:

A groundmass composed principally of chalcedony, opal, dolomite, and calcite. The dolomite occurs as rhombohedrons; calcite shows excellent twinning lamellæ; the chalcedony is flamboyant and shows aggregate polarization under *X* nicols. A few diatoms present in the groundmass, many showing replacement by calcite, dolomite, or chalcedony. Irregular patches of organic matter, concentrated near the chalcedony.

No. 28042—Soft Shale (Santa Margarita Formation):

Quartz and other mineral grains are very abundant in this material (over 25% of groundmass). Groundmass carries abundant organic matter and finely disseminated marcasite. No evidence of siliceous replacement. No diatoms or other micro-fossils observed. Cracks and fissures numerous. Cement of groundmass chiefly clay. No evidence of recrystallization—hence, material is probably quite soft and friable. Average size of grains approximately 0.039 mm. Consist principally of quartz, with some plagioclase and actinolite. Quartz has inclusions, possibly rutile. Organic matter strung out parallel to laminæ. This sample also carries a considerable amount of an anisotropic, pleochroic mineral (index greater than balsam) found in popouts.

No. 28045—Opaline Cherty Shale:

This rock shows strong similarity to No. 19374 and to No. 28046, under low-power magnification. It is of the same geological age as No. 19374 and No. 28046, as evidenced by the foraminifera and other fossils, which show partial chalcedonic replacement. The groundmass appears to be an intimate mixture of chiefly opaline silica with a small amount of diagenetic glauconite and clayey portions, with traces of organic matter. The latter is of fairly uniform distribution throughout the slide. Embedded in this groundmass are abundant coarse detrital grains of quartz, orthoclase, and plagioclase. Numerous feldspars appear partly glauconitized. Chalcedony is not very abundant in the groundmass, except as a replacement of the fossils. No free calcite or dolomite as fragments or veins was observed. This material differs from No. 19374 by a lower calcite-dolomite content, and by a higher amount of detrital quartz and feldspars, as well as a more uniform distribution of the organic matter.

No. 28046—Opaline Cherty Shale:

This rock is of the same geological age as No. 19374 and No. 28045 and strongly resembles them. The following differences, however, are noteworthy: In No. 28046 the detrital quartz and feldspar content is lower, and these grains are smaller; spherules of chalcedony are fairly abundant in the groundmass; glauconite and organic matter are more plentiful than in No. 28045 and occur in concentrated form parallel with the laminæ; although the groundmass is composed chiefly of opaline silica, it nevertheless appears partly pleochroic under high power and indicates the presence of intermixed diagenetic minerals (formed after deposition). No free dolomite or calcite was observed in this material, and what lime content is found on chemical analysis will be due in large part to the fossils and the detrital plagioclase grains. Due to concentration of organic matter and clay in definite layers, this rock is more laminated than No. 28045, and the evident lack of opaline replacement along these laminæ suggests the easy cleavability of this material.

No. 30704—(Dark) Opaline Chert:

Dark brown stringy accumulations of organic matter parallel the bedding, which is frequently distorted. An occasional quartz or orthoclase fragment is enclosed by opaline groundmass. Sample carries a few channels of brecciated material, cemented by opaline veinlets and clay. The quartz and orthoclase are the only recognizable anisotropic minerals observed in this material. Matrix predominantly opaline silica with some undistinguishable clay minerals. Material shows no evidence of chalcedonic replacements, and no fossils.

APPENDIX II

SAND IDENTIFICATION

Group I.—In this group rock fragments consist chiefly of granitic rock and sandstone with less than 15% quartzite, rhyolite, andesite, siltstone, and limestone, and from 4% to 15% shale and chert. The mineral grains consist chiefly of quartz and feldspar, with less than 10% of pyroxene, amphibole, mica, magnetite, hematite, limonite, serpentine, and calcite. Sands Nos. 1 to 6 in this group were secured from the following places:

Sand No.	Source
1	Santa Clara River at Saticoy, Ventura County
2	Sisquoc River at Sisquoc, Santa Barbara County
3	Piru Creek at Santa Clara River, Ventura County
4	Oro Fino, tributary to Salinas River, Monterey County
5	Bank adjacent to Salinas River at Atascadero, San Luis Obispo County
6	Salinas River at Templeton, San Luis Obispo County.

Group II.—Rock fragments in Group II consist chiefly of granitic rock and gneiss in Southern California, and of graywacke (sandstone) in Northern California, with less than 10% of basalt, andesite, quartzite, and jasper and usually less than 1% of shale and chert. Mineral grains in Group II are similar to Group I. Sands Nos. 20 to 24 in this group were found in:

Sand No.	Source
20	Coyote Creek, Santa Clara County
21	Russian River, Healdsburg, Sonoma County
22	Livermore Valley, Alameda County
23	Near Olympia, Santa Cruz County
24	Roscoe, San Fernando Valley, Los Angeles County
25	Irwindale, San Gabriel Valley, Los Angeles County
26	Monrovia, San Gabriel Valley, Los Angeles County
27	San Joaquin River at Friant, Fresno County

Group III.—The sands in Group III were made by crushing ledge rock to the desired gradation. Sands Nos. 101 and 102 in this group were found in:

Sand No.	Source
101	Crushed hornblende diorite, Logan, San Benito County
102	Crushed quartz, Jackson, Calaveras County.

APPENDIX III

CEMENT CLASSIFICATION

The cements used in the investigation were analyzed as shown in Table 5.

TABLE 5.—CEMENT ANALYSES

In the identifying letters given in the first column, the first letter refers to the brand and the second letter to the type of cement, as follows:

S = Standard cement; in some cases the standard product contains less than 8% of C_3A and therefore might also be classified as a low or moderately low C_3A cement.
L = Cement having less than 8% C_3A and complying with American Association of State Highway Officials Specification M-60-38 as distinguished from the standard product of the same manufacturer with higher C_3A content.
A = Low-heat type "*A*."
P = Portland-puzzolan; insoluble, 15.44; all other cements less than 0.85% insoluble; cements *M*, *N*, *O*, and *R* are from mills outside California.

DISCUSSION

R. W. Carlson,[7] Assoc. M. Am. Soc. C. E. (by letter).—The disclosure of excessive expansion of concrete due to chemical reaction between cement and aggregate has opened a vast new field of concrete research. The importance may be tremendous, depending upon just how much bad concrete is attributable to this cause. A scattering of aggregates that are susceptible to reaction with alkalis doubtless will be found in all parts of the country.

If recurrence of cement-aggregate expansion can be prevented, the average quality of concrete structures should be raised appreciably. Recurrence of this type of concrete expansion probably can be prevented with least hardship to cement and aggregate producers when the following questions are answered:

1. Is the trouble due only to the formation of an alkali carbonate, only to the formation of an alkali silicate, or both?
2. Are the alkalis of sodium and potassium, which are usually lumped together in analysis, equally harmful?
3. Is it possible that the combination of moderate-alkali cements with the susceptible aggregates will produce expansion in correspondingly longer time?
4. Conversely, is it possible that the combination of high-alkali cements with moderately good aggregates will ultimately produce trouble?
5. Is the alkali carbonate likely to be formed by carbonation of the alkalis in aggregates, especially those like crushed feldspar containing a considerable amount of alkali?
6. Is it possible that concretes containing good aggregates but cements of high-alkali content are likely to develop alkali carbonates, and subsequently shrink excessively due to drying?
7. Are the alkalis in the cement equally harmful whether free or combined, either as sulfates, aluminates, or otherwise?

The great need, of course, is for an accelerated test to which questionable combinations of cement and aggregate can be subjected. Due to the slowness of the reaction, doubtful aggregates or cements cannot be proved soon enough merely by making up common specimens and observing their expansion. In some cases, the potential expansion might not develop for a year or more. Therefore, some sort of reliable accelerated test needs to be developed that will give the result in a shorter time. At present, it is indicated that certain sizes of aggregate are more harmful than others, also that certain proportions of cement to aggregate are more sensitive. Undoubtedly, temperature is also a factor. Some combination of conditions may be found that will give an indication of the long-time expansion in a few weeks. It is hardly to be expected that any type of autoclave test applied for only a few hours will be reliable.

Bailey Tremper,[8] Esq. (by letter).—The physical consequences that may result from chemical reactions between high-alkali cements and certain mineral constituents of aggregates have been presented convincingly in this paper. The author's disclosures serve to focus attention on concrete in other localities where the outward appearance of internal expansion is similar to that illustrated in Fig. 1.

[7] Associate Prof., Civ. Eng., Mass. Inst. Tech., Cambridge, Mass.

[8] Materials Engr., Dept. of Highways, State of Washington, Olympia, Wash.

In 1935, H. S. Mattimore and G. A. Rahn, Jr.,[9] Assoc. Members, Am. Soc. C. E., reported on the condition of some experimental concrete test walls that had been exposed to weather in Pennsylvania and were then 4½ years old. Two cements and two fine aggregates were used in the concrete. The alkali content of the cements was as follows:

Chemical	Brand A	Brand B
Na_2O	0.43	0.24
K_2O	0.57	0.37
	1.00	0.61

There was not much difference in the composition of the two cements in other respects.

According to the scheme of rating used, all of the specimens made with brand B cement were rated as 70% intact or better. The ratings for specimens made with brand A cement were from 0 to 80%, averaging 51% and 75%, respectively, for the two sands.

In the State of Washington there are a few examples of concrete exhibiting patterns of open cracks while other concrete made with aggregates from the same sources is in excellent condition. The defects are connected definitely with the source, and probably with the alkali content, of the cements. In one instance the aggregate used in the defective concrete was almost entirely igneous in origin.

These occurrences give rise to the uncomfortable suspicion that deleterious expansion may result from the use of high-alkali cement with a variety of aggregates that is very much more extensive than the sedimentary group described by the author.

Mr. Stanton's physical test, consisting of the measurement of length changes of 1 by 10-in. mortar bars, seems to have served very well in distinguishing between good and bad combinations of cement and aggregate in the locality in which he has worked. It is not known, however, that the test will serve equally well with other types of aggregate. It is unfortunate, moreover, that several months at least are required to obtain significant results.

These considerations point to the desirability of knowing more concerning the chemical nature of the reactions involved. When this information is available it should be possible to devise a more rapid method of eliminating suspicion from satisfactory aggregates.

Mr. Stanton points to two types of chemical reactions as possible causes of expansion. The first is a reaction between sodium hydroxide and the magnesium carbonate occurring in the siliceous magnesian limestone. The second is a reaction between the alkalis and silica in the aggregate.

The first reaction does not appear to the writer to be the basic cause of expansion for the following reasons:

---

[9] "Research on Concrete Disintegration," by H. S. Mattimore and G. A. Rahn, Jr., *Proceedings*, A. S. T. M., Vol. 35, 1935, p. 410.

(1) Expansions were observed with aggregates containing magnesia in relatively small amounts.

(2) Although the paper does not report the separate percentages of sodium oxide and potassium oxide in the cements involved, it is logical to assume that they were present in varying ratios. The observed expansions were in good agreement with the total alkali content of the cements. This indicates that sodium and potassium compounds were equally active. The latter does not give the theoretical increase in volume indicated for the sodium-magnesium reaction.

(3) Calcium hydroxide, always present in relatively large amounts in hardened concrete, should prevent the formation of sodium or potassium carbonates.

The reaction involving silica in the aggregate, as illustrated in Table 3, seems to be a more valid explanation of the expansion. Rocks that show puzzolanic action when finely ground are generally soluble in part in alkali solutions. Alumina as well as silica may be dissolved. If such a reaction is the cause of expansion in concrete, then one might expect rocks such as rhyolite and andesite, particularly when formed by explosive volcanic action, to be troublesome with high-alkali cements.

In the consideration of such a reaction, the effect of dissolved calcium hydroxide cannot be ignored. Nearly all calcium salts are less soluble than the corresponding sodium or potassium salts. Therefore, the final products would be expected to be calcium silicates or aluminates with the alkalis converted back into the hydroxide form and available for additional attack upon the minerals. If the alkalis play a catalytic rôle of this nature, their potency in relatively small percentages may be more readily comprehended.

Reactions of this kind would continue in the presence of moisture until stopped by exhaustion of the active minerals, exhaustion of the calcium hydroxide, the accumulation of high pressures within the concrete, or the formation of reaction products in amounts sufficient to form a barrier against the migration of the reacting constituents.

If reactions of this kind are the true cause of expansion, further studies must take into consideration the change in solubility of calcium hydroxide in varying concentrations of sodium and potassium hydroxides, the effect of temperature on solubilities, the density and permeability of the concrete, and its capability to resist the pressure built up by the reaction products. It is hoped that Mr. Stanton's studies will progress to the point that the chemical phases can be discussed more fully.

It is worthy of emphasis that it was only with aggregates from a relatively small area in the State of California that deleterious effects were found through the use of high-alkali cements. D. G. Miller and P. W. Manson[10] have determined the alkali contents of 106 commercial cements from 74 mills. Their analyses, therefore, should represent a typical cross section of cement as produced in the United States. Of the 106 cements, more than one half contained alkalis (computed as Na_2O) of more than 0.6%, the maximum set by Mr. Stanton for freedom from deleterious expansion. If an aggregate has been used previously with cements from several mills, it is probable that in at least one instance the cement was high in alkali. Examination of concrete in service, then, should form a basis for estimating the probable effects on proposed construction of that aggregate with high-alkali cement even though the alkali content of previous cements is not known.

[10] "Tests of 106 Commercial Cements for Sulfate Resistance," by D. G. Miller and P. W. Manson, *Proceedings*, A. S. T. M., Vol. 40 (1940).

HUBERT WOODS,[11] ESQ. (by letter).—Unquestionably, this paper provides, for the first time, an adequate explanation of a number of baffling cases of concrete deterioration that have occurred in the coastal region of California. It also provides new incentive for a more comprehensive study of aggregates in their relation to cement composition. There is great need for further studies on the chemical nature of the expansive reaction between certain natural minerals and the alkalis in cements. Only when this reaction is well understood can intelligent steps be taken to forestall or prevent it.

It would be as unreasonable to conclude that all aggregates will react expansively with alkalis in cement as to conclude that only those aggregates peculiar to the coastal area of California will do so. The widespread satisfactory behavior of concrete, in general, attests the fact that such troubles are not omnipresent, and where local aggregates and cements have had a long record of satisfactory performance there is no reason for alarm. On the other hand, with aggregate from a new source, without adequate history of performance, a thorough study is justified, and there is great need of a rapid test by which such aggregates may be judged with respect to possible expansive reaction with alkali.

In cases where the only aggregates economically available are likely to give trouble through reaction with alkalis in cement, it might be concluded that a simple solution is to put a limit on the alkali content of cement. As a matter of fact, at present that is about all that can be done; but it is not a satisfactory final solution. It is not economically desirable. All cements made in the United States contain more or less alkali, not by intent but by reason of the fact that nature has put alkali-containing minerals in practically all clays and shales used in cement making. The alkalis are partly, but not wholly, volatilized in the rotary kilns. In order to reduce the alkalis in his cement, the manufacturer may have to use other raw materials containing less of the alkali minerals, and these may be very difficult to find and very expensive to use. It would be highly desirable to find some inexpensive means, perhaps by additions to the cement, whereby the expansive reaction would be circumvented, and a diligent search for such means would seem to be essential.

N. T. STADTFELD,[12] M. AM. SOC. C. E. (by letter).—In this paper Mr. Stanton has made a valuable contribution, based on a painstaking investigation. He eliminated all other possible factors to tie in definitely the disintegration of concretes containing certain aggregates with the alkali content of the portland cement used.

---

[11] Chf. Chemist, Riverside Cement Co., Riverside, Calif.

[12] Div. Engr., Board of Water Supply, New York, N. Y.

Although they are present in small quantity, the alkalis, nevertheless, have been under suspicion for a number of years. In 1929 the late Thaddeus Merriman,[13] M. Am. Soc. C. E., gave the results of an extensive investigation, which had led him to conclude that the rate of formation of the hydration products obtained when water is added to cement is dependent on the alkalinity of the solution. Within a certain zone of alkalinity, hydration is slow and orderly; but alkalinities either above or below this range were found to increase the rate of hydration. Thus the addition of calcium chloride to the mixing water, which lowers the alkalinity, will accelerate the hardening process. Similarly, the addition of sodium hydroxide, which increases the alkalinity, not only speeds up the hardening process but increases the maximum hydration temperature, as measured by a calorimeter in which a cement paste is hardening. After several years of investigation and numerous tests on the sulfate-resistant cement used in the tunnels and spillway of the Fort Peck (Mont.) Dam, Mr. Merriman finally embodied a restriction on the soluble alkali content in the specifications for portland cement of the Board of Water Supply (BWS) of the City of New York.[6] Cement to the extent of three million barrels made at 10 plants, complying with these specifications, has now been delivered to the various sections of the Delaware aqueduct. The principle involved in restricting the alkali content to obtain a uniform rate of hydration and to protect men against alkali burns when they work the wet concrete is different from the principle involved in restricting alkali content because of the deleterious effect on the concrete when used in conjunction with certain aggregates. Nevertheless, the fact remains that a well-defined beginning has been made to produce, consistently, a portland cement of a low-alkali type; and therefore, experience gained during four years of procedure may be of interest.

It is true that, whereas the BWS specifications confine their restrictions to water-soluble alkalis, the author uses the total alkali content, computed as sodium oxide (Na_2O), as the criterion of fitness. In his investigation these two did not always keep pace with one another, but records from plants producing BWS cement do show a close correlation. In addition, some records from plants not making BWS cement, which were made available to the writer, also show substantial correlation. In every case, cement passing BWS specifications would have been under the 0.5% Na_2O limitation, and cement failing in one would have failed in the other.

Table 6 gives the results of a series of tests run at one of the plants which consistently meet the BWS specifications. The raw mix was kept constant and, as the temperature was lowered, samples were removed and alkali determinations made. Although no accurate record of the temperatures was made, the samples were arranged in accordance with descending temperature.

It is apparent that potassium can be more readily eliminated by temperature increases than sodium; this was to be expected as potassium compounds volatilize at lower temperatures. Note the decrease in potassium content from 0.79% to 0.26% and the decrease in sodium content from 0.29% to 0.16%, a ratio of more than 3 to 1 for the potassium to a ratio of less than 2 to 1 for the sodium. Also note that, as the author's limit of 0.5% (total alkalis) is approached, the titration value of 3.5 for the BWS specifications is similarly reached. The method of determination is described in the specifications, as follows:

---

Computed as Na_2O	0.38	0.42	0.41	0.41	0.53	0.49	0.76	0.65	0.91	0.95

[a] Sample 4 is a duplicate of Sample 3; and Sample 6 is a duplicate of Sample 5. [b] Merriman method.
[c] J. Lawrence Smith method (see Scott's "Standard Methods of Chemical Analysis," 5th Ed., 1939, p. 1612).

> "The alkalinity of the cement shall not be greater than 3.8 and its content of free alkali shall not exceed 3.5. These characteristics shall be determined as follows: Weigh out 800 grams of cement and put into an enameled saucepan with 500 c.c. of distilled water. Stir frequently for two hours, then filter through large folded filter paper for 10 minutes. If filtrate is not clear, refilter. Titrate 25 c.c. of the filtrate with N/2 HCl, using methyl orange as the indicator. The number of c.c. of acid required to neutralize the filtrate to the methyl orange end point is the measure of the alkalinity.
>
> "The free alkali content of the cement shall be determined as follows: Measure out 100 c.c. of the filtrate obtained in the alkalinity test of the preceding paragraph into a small beaker, and add 30 to 35 c.c. of a saturated filtered solution of $Ba(OH)_2$. Let stand, filter and wash with H_2O. Pass CO_2 into the filtrate for five minutes. Let stand, filter and wash the precipitate with H_2O. Heat to boiling and, if a precipitate forms, filter it out. Then boil the total filtrate plus wash water down to about 50 c.c., filter it and make it up to 100 c.c. with distilled water. Now take 25 c.c. of the solution and titrate it with N/2 HCl in the presence of methyl orange. The number of c.c. of the acid required to neutralize the 25 c.c. to the end point of the methyl orange is the measure of the free alkali content. Both of these tests are to be made at room temperature."

Close correlation holds true at other plants meeting the specifications. The opinion may be ventured that this is due to the fact that in all cases the so-called "flue dust" is discarded. "Flue dust" is the fine material blown from the rear end of a rotary kiln and caught under waste-heat boilers, in precipitators, or by other means. In many cases it is fed back to the raw mix and sometimes to the finished cement. In the former instance it builds up the alkali content, occasionally to such an extent that even with high temperatures it becomes impossible to clinker the mix properly, thus causing waste in fuel and lowering of quality. In the latter case it tends to increase the alkali content of the cement and mainly the non-water soluble alkali content.

Had the paper included such items in the history of the clinker as burning-zone temperature, speed of kiln rotation, subsequent treatment of the clinker, and a notation as to the disposition of the "flue dust," additional and valuable deductions might have been made.

A plea is made here for placing restrictions on water-soluble alkalis rather than on the total alkalis, because the determination of the former is extremely simple and excellent checks are obtained between laboratories, whereas determination of the latter is laborious (3½ days for an experienced chemist) and checking between laboratories is difficult.

Regardless of the form which the restrictions on alkalis may take, however, some additional burden is likely to be placed on producers, as disintegration of parts of the Parker Dam[14] in southern Arizona has been traced recently to the destructive action of the alkalis in the portland cement on a hydrous silica occurring in the aggregate, an aggregate which had passed all known tests for durability. A trend may well be expected toward the incorporation of low alkali content in future specifications for cement as a safeguard against possible disintegration. With this in mind a review of some of the difficulties encountered in manufacturing such cement may be of value.

All BWS cement is made from well-burned clinker assured by:

(1) Insistence on continuous high temperature (about 2,700° F) in the burning zone of the kiln, as recorded by pyrometers placed outside and in front of the kilns;

(2) Insistence on regularity of kiln rotations coordinated with the occasional rise and fall of the temperature; and

(3) Insistence on satisfactory performance in the "sugar test" which indicates the degree of completion with which the various constituents in the clinker have been combined.

The BWS test for sugar solubility is described in the specifications as follows:

> "The sugar solubility of the cement shall not be greater than 8.0 to the phenolphthalein end point, nor greater than 10.0 to the final clear point. These values shall be determined as follows: A sample of about 100 grams of the cement is passed through the 200-mesh screen and put into a glass bottle closed with a rubber stopper. From this bottle 15 grams are then weighed out and placed into a Nessler tube containing 100 c.c. of a 15-percent. solution of cane sugar in distilled water (commercial granulated sugar such as 'Jack Frost'); this solution shall not be more than three days old. The tube and its contents are then quickly shaken by hand and placed on a wheel revolving about 60 times per minute. At the end of about 1 hour and 50 minutes the mixture is poured into a filter paper and funnel and allowed to filter for ten minutes when the beaker containing the filtrate is removed. (In case the filtration time of 10 minutes is too short to produce a volume of filtrate of 30 c.c., it may be lengthened by shortening the time of shaking, but the total time from the putting of the sample into the solution to the end of the filtration must be exactly 2 hours.) Twenty-five c.c. of the filtrate is now titrated with N/2 HCl in the presence of phenolphthalein and the number of c.c. of

---

[14] See minutes of December 6, 1940, meeting of Committee C-1 on cement, A.S.T.M., p. 5.

> acid to the end point is the first measure of the sugar solubility. At this stage of the test, in the case of a thoroughly burned cement which has been kept dry, the solution will be practically clear and only traces of ferric oxide and alumina will be in suspension. In the case of an underburned cement, or one which has been exposed to moisture, the solution will be heavily clouded and the end point must be approached slowly and with caution. When so performed, the phenolphthalein end point can be definitely determined, as the color changes from light pink to yellow. The titration is then continued until the solution is crystal clear and nothing remains in suspension. The total number of c.c. of acid from the beginning of the titration to this final clear point is the second measure of the sugar solubility. This test shall be made at room temperature. In addition to disclosing the quality of the cement as above stated, this test further indicates the character of the hydration products which will be realized in the completed concrete."

In most cases adherence to principles (1) to (3) resulted in a cement of satisfactory alkali content. However, it was found in a few of the plants that with proper burning and low sugar-test results the alkali content was higher than allowed by the specifications. After some experimentation it developed that, where potassium was present, shortening of the burning flame and consequently impinging it on the hot clinker bed would drive off this element. This could be noted through blue glasses, which showed up the unmistakable purple hue of potassium vapors.

Where even this technique was insufficiently effective, probably due to the presence of larger proportions of sodium (which, as previously mentioned, does not respond as well as potassium), addition up to 0.5% by weight of calcium chloride was made to the raw mix, which changed some of the alkalis, in whatever form present, to alkali chlorides. These volatilize easily and appear to be driven off completely, as none of the resultant cement showed any trace of chlorides, but did show a large reduction in alkali content.

To summarize, therefore, with present knowledge based on four years of experience, the following is suggested for the consistent production of cement low in alkali content:

(*a*) Discard all "flue dust" and incidentally save on fuel;

(*b*) Install pyrometers and kiln-rotation recorders and note the alkali content with varying burning temperatures;

(*c*) Experiment with length of flame in the burning zone; and

(*d*) As a last resort, add calcium chloride up to 0.5% by weight to the raw mix.

In conclusion it may be stated that, although the disintegration of concrete, as found by the author and in the Parker Dam, may well be due to the action of alkalis in cement on localized aggregates not generally encountered, the limitation on the alkali content should be encouraged in any case for additional safeguard and the production of a decidedly better product, as outlined in the first part of this discussion.

W. C. HANNA,[15] ESQ. (by letter).—That very reactive aggregates exist in certain districts of California has been known for many years. The occasional defective concrete constructions made with these aggregates have probably contained cements of all brands used within the state, and this includes cements manufactured in foreign countries.

As early as 1934, the company with which the writer is connected investigated the case given by Mr. Stanton in Fig. 1(*d*) (a building completed about 1931), recognized the abnormal condition, and decided to determine the cause. The cement used in the construction was of most excellent quality, sound in every respect, and with both the manufacturer's tests and the independent inspection of a well-known commercial laboratory to prove the quality. A study was started at once and the company assigned Ira C. Bechtold (later, Portland Cement Association Fellowship, National Bureau of Standards) to devote considerable time to the problem.

Inspection of concrete cores from this structure revealed the gel formation which evidently had caused the cracks. From the study of the concrete it was possible to trace the bad aggregate to its source and to collect specimens of it for laboratory study. Photographs of the concrete showing the gel formation, together with Mr. Bechtold's findings, were exhibited to a number of organizations and individuals who were interested in the matter. This discussion is based on the resultant report.

Examination of the concrete disclosed that it contained many particles that were evidently foreign to the remainder of the aggregate material. These particles ranged in color from a dark brown to a light tan or buff. They were quite hard, but brittle, when dry and intact. They were sometimes cracked and frequently disintegrated and contracted in the center. Practically all such particles showed a hard, shiny shell, and in some cases small spheres were noted near them which appeared to be hard and white but brittle when dry. These particles varied in size from very small grains to pieces about $\frac{1}{4}$ in. by $\frac{1}{4}$ in.

To this point all specimens were kept dry. Then they were immersed in water for a period of three days, after which they were removed, allowed to dry at room temperature for three days, and then again immersed in water. After twenty-four hours in water the foreign particles became very soft and began to disintegrate; and from many of them a definite formation of gel occurred, in some cases in a quantity almost equal to the volume of the original particle. The envelope around many particles became wet and soft but did not expand appreciably. The aforementioned spheres also softened. Some of the particles which showed marked disintegration before wetting did not form large amounts of gel. In one case a specimen from a core developed a large amount of gel from an area that became cracked as the piece remained wet; and finally a small piece of concrete was forced away by the gel.

Some cracks in concrete specimens from cores were found to pass entirely through the specimen. In several such cases it was found that gel was being squeezed out of the crack, sometimes in several spots along the crack. Where there was a crack it was always found that there was at least one particle developing gel within it.

---

[15] Chf. Chemist and Chemical Engr., California Portland Cement Co., Colton, Calif.

An attempt was made to determine the chemical nature of the gelatinous material being formed from the particles under consideration. It was almost impossible to secure the pure gel material for test purposes because, in the process of formation, it always became contaminated with cement and small fragments of aggregate. Furthermore, it is to be expected that this type of gel would absorb calcium hydroxide and other material from the water around it. However, the following approximate analysis was obtained on a small portion of relatively clean gel scraped from the specimen: SiO_2, 41%; Al_2O_3, 11%; CaO, 33%; and H_2O, 17%.

Mr. Bechtold expressed an opinion that reaction of the calcium hydroxide freed from the cement by water is involved in the formation of this gel. The gel formation appears to be irreversible. Evidently, the gel progressively swells after it is first formed, but fortunately, after once being dried and contracted, it will not swell again when brought into contact with water. This point on the irreversibility of this reaction is important. It indicates that during the life history of a given piece of concrete construction there is a gradual slowing up of the reaction between calcium hydroxide and the reactive aggregate. In the early stages this reaction may be severe enough to cause cracking and "pop outs," but after a period of several years, depending on how reactive the aggregate happens to be, the disruptive reactions will have spent themselves.

Further research reported in 1936 indicated that volume changes and the extent of cracking evidenced in the ordinary laboratory specimens were not indicative of the intensive destructive forces that appeared to be responsible for the failures in question. Laboratory specimens will not indicate the same extent of change observed in the field. The expansive force of the gel can derange the particles of concrete so much that readjustment to the former position is impossible. When such readjustment is forced by shrinkage under drying conditions, the deranged particles may act as wedges to force the cracks open.

The shales vary tremendously in activity. They have not been found to be active to water alone to the extent of forming gel, although disintegration has been observed. In saturated limewater many of them produce large quantities of gel. In some cases the gel produced has been estimated to have a volume of 6 to 8 times that of the shale producing it. Other specimens of apparently the same material produce little gel and some show no sign of activity. Concentrations of even less than 10% of shale could produce stresses that would exceed the tensile strength of the strongest concrete.

At least a part of the bad aggregates in the aforementioned structure produced gel with limewater which, of course, is found in all normal concrete. There was a sufficient amount of such aggregate in the concrete to account for the damage. The gel formed in the concrete did not indicate that the alkalis of sodium and potassium were necessary for the reaction.

Mr. Stanton's bad aggregate is not the same as those detected in the aforementioned structure. It seems to resist the limewater but is readily attacked by a 10% solution of either K_2SO_4 or K OH. It was of interest to note that the reaction with these potassium compounds was more severe than with the corresponding sodium compounds.

The Stanton test, using sealed containers, is a valuable one for estimating the relative activity of certain California aggregates. For the present, the test should be classed as specific, because the writer has records of aggregates which have proved to be unsatisfactory in the field but which failed to show any excessive expansion when subjected to a Stanton test lasting several months. Mr. Stanton was admittedly dealing with a bad aggregate as revealed both in field work and by his unique laboratory test. All users of concrete should recognize his contribution in developing a test that is easily made and that certainly reveals doubtful quality of the aggregate he was testing.

Mr. Stanton has indicated that expansions he has encountered may be due in part to a reaction between $MgCO_3$ and Na OH. It is indicated that $Na_2CO_3 \cdot 10\,H_2O$ is a product of this reaction and that, due to the addition of ten molecules of water to the Na_2CO_3, an enormous increase in volume results. This in turn has a disruptive effect on the concrete. The writer is convinced that this possible reaction does not explain the expansion effects encountered by Mr. Stanton. From a practical standpoint, it is known that dolomitic limestone or magnesian limestone, when free of reactive siliceous material, is classed as one of the best of aggregates. Many widely distributed concrete structures, thirty or forty years old and containing dolomitic limestone as aggregate, are in excellent condition. It seems logical to conclude that the magnesian limestone part of this bad aggregate is not at fault. Some instability of the siliceous phase of this aggregate may be the cause of the failures reported by Mr. Stanton.

A close study of the paper will reveal a sincere attempt to establish the limitations of concrete made from portland cement, aggregate, and water. A clear conception of the function and limitation of each ingredient entering into concrete is essential.

Portland cement is very reactive chemically, and must be so to be useful. The compound composition of cement is complex, and the reactions taking place upon hydration are involved. The products of reaction are basic in character. The basic compounds may react within the cement composition itself or with some added material such as reactive aggregate. Aggregates that are reactive to portland cement compounds enter the field of puzzolanic materials. Some materials that may be definitely classed as poor and unsound aggregates, upon being interground with portland cement, will produce a sound and high-quality puzzolanic cement. In some respects there is a relation between the reaction products of portland cement and the reaction products from unsound aggregates. Both are active chemically and yield complex calcium silicates. Placing a relatively large particle of reactive aggregate within a concrete structure is always dangerous. The reactivity of the piece of aggregate may persist for an indefinite period, and there is always danger of failure of concrete, if the destructive forces set up are sufficient to overcome the inherent strength of the concrete structure. Construction engineers should attempt to approach the ideal in formulating concrete; that is, they should use a high quality portland cement plus a properly graded inert aggregate. This thought, of course, is not a new one; but it is worth repeating.

The record of failure as reported by Mr. Stanton is conclusive and indicates that constructive work toward improvement must be done by all concerned. The cement manufacturer should be required to produce the best quality of cement consistent with available raw materials. Great care should be taken as to the quality of aggregate, and the governing factors are relative inertness, high inherent strength, proper size distribution, and reasonable availability to the construction site. Further constructive work must be done in the field of physical and chemical testing of cements and aggregates. It is difficult to devise practical tests of this kind, but the work should be continued until satisfactory engineering tests are developed.

The field of better design for concrete structures should not be overlooked. There is still plenty of room for improvement in the design of concrete structures. Another study of a more fundamental nature involves a better knowledge of the chemistry of cement compounds. Considerable is known of the function of the recognized oxides in cement, such as silica, iron oxide, alumina, lime, magnesia, and sulfuric anhydride. Small amounts of other materials such as titanium dioxide, phosphorus compounds, and alkalis are present in all commercial cements. The effect of these incidental materials should be the subject of further study.

The chemical form of the sodium and potassium compounds present in cement is not known. There is evidence that potassium in cement often occurs as K_2SO_4. The possibility of complex calcium-sodium silicates should not be overlooked; nor should the alkalis in the aggregates be forgotten. The writer has made many Stanton tests in which 1% sodium or potassium hydroxide was deliberately added to the normal portland cement used in the test. In general, the addition of active alkali appeared to lower, or had little effect on, the degree of expansion.

The time has not come to establish a definite specification limit for alkali in portland cement. Considerable difficulty has been encountered in obtaining check results on alkali determinations. The writer has seen a great discrepancy in results on check samples submitted to representative laboratories. Considerable cooperative work is being done on standardizing the methods for estimating sodium and potassium oxides in portland cement. In the future, chemists probably will be able to estimate these compounds with reasonable certainty, but for the present they are inclined to allow considerable tolerance in any estimate of alkalis.

Out of the maze of discussion that has resulted from the commendable work of Mr. Stanton and others on alkali in portland cement, much good will result. Every one seems to be "alkali conscious," and the writer considers the current agitation as a "one track" proposition. All factors that can lead to unsound concrete should be investigated carefully. Cement manufacturers will do their utmost to cooperate with every one interested in the fabrication of better concrete structures.

J. C. Witt,[16] M. Am. Soc. C. E. (by letter).—In his very interesting paper Mr. Stanton presents some field and laboratory data on the expansion of concrete. On the basis of fact and assumption he points out relations that may exist between the two groups of phenomena. However, some statements are made with a "q.e.d.-ness," or finality, which the data do not justify. Reference to a few points will be sufficient to make this clear.

Under the heading "Earlier Failures" this statement appears:

> "Although the sulfates in sea water undoubtedly contributed to the serious deterioration of the sea walls, it was obvious that this deterioration was accelerated by the infiltration of sea water through cracks resulting from excessive expansion occasioned by other causes."

The deterioration of concrete exposed to sulfate solutions has been observed all over the world. It has not been restricted to cements or aggregates of any particular composition, nor to any combination of the two. The reason is not apparent why the deterioration of the sea walls mentioned in the paper is due primarily to the nature of the cement and aggregate present—the sea water simply being a contributing agent.

In the laboratory, specimens containing cements relatively high in alkali compounds and certain fine aggregates were subjected to storage conditions involving a wide range of moisture and temperature. After more than a year no excessive expansion was observed. Accidentally it was found that expansion could be obtained easily by placing specimens in sealed containers. This procedure does not represent the type of exposure to which most concrete is subjected.

The following statement is quoted from the author's discussion of Table 1:

> "It has not been determined if the reaction in the case of this impure limestone is due entirely to some form of silica or in part to the magnesium carbonate. If it is due in any part to the magnesium carbonate, the probable chemical reactions in this respect are * * *."

This is followed by a computation (Eq. 1) indicating that, when magnesium carbonate and sodium hydroxide react, the products are magnesium hydroxide and sodium carbonate (with ten molecules of water of crystallization), accompanied by an increase in volume of 239%. Apparently this is the basis for such statements in the "Conclusion" as: "Certain mineral constituents in concrete aggregates contribute to expansion of concrete and sometimes develop stresses of such magnitude as to cause failure," and "The chemical reaction producing excessive expansion apparently occurs only when the portland cement component contains an appreciable percentage of alkali in the form of sodium and potassium oxides."

Here are a few of the comments that could be made:

(*a*) The volume of the water of crystallization is not included in the "combined volume of reacting compounds." In conformity with the author's nomenclature, this volume is 180.16. It is equivalent to 276% of the combined volume of the listed reacting compounds and to 80% of the reaction products.

---

[16] Technical Director, Marquette Cement Mfg. Co., Chicago, Ill.

(*b*) There is a series of hydrous sodium carbonates. There is no basis for assuming that $Na_2CO_3 \cdot 10\,H_2O$ alone would crystallize from solution—the only manner in which any member of the series is formed. A crystal containing a given number of molecules of water does not develop directly into a crystal containing more water. Re-solution and recrystallization are necessary. The compound $Na_2CO_3 \cdot 10\,H_2O$ is unstable—losing water when in contact with air.

(*c*) If crystallization occurs when the cement paste is plastic, no cracking of a specimen would be expected. After the cement has hardened, very little water is available in the interior of a specimen stored in a sealed container. At the surface some water is available, but crystallization here would not cause cracks of any importance.

Following Eq. 1 this statement appears with reference to the volume increase computations: "To check the accuracy of this assumption, tests were made to determine the action of sodium hydroxide upon the various materials that might be present in the aggregate, * * *." Several substances were treated with a large excess of normal sodium hydroxide solution. The conditions differed greatly from the other tests described in the paper, and the results do not serve to check any of the assumptions.

R. F. Blanks,[17] M. Am. Soc. C. E. (by letter).—The far-reaching discovery, reported by Mr. Stanton, that reactions between alkalis in cement and some mineral constituents of aggregates explain certain cases of concrete expansion, cracking, and disintegration is not surprising. Since about 1930, there has been a growing suspicion that the minor compounds in cement (including alkalis) might have a greater influence on the quality of cement and the resulting concrete than was generally realized. The incredible part, in the light of developments since Mr. Stanton's discovery, is that it has taken engineers and investigators so long to arrive at this explanation.

The Constituent Materials in Concrete.—During recent years the quality of portland cement has been improved notably, and this has been reflected in specification requirements. Limitations on various compounds that have been found to be objectionable in portland cement have been imposed, and in some cases manufacturing methods and procedure have been limited by specification requirements. Free lime, magnesia, alumina, and, in special cases, iron, have been subjected to varying degrees of restriction. During the past few months (1941) the alkalis of sodium and potassium have likewise been limited in some special cases. However, far too little is yet known regarding the true constitution of portland cement, in what forms the various compounds really exist, or what reactions are actually involved in the hydration processes.

It cannot be said that even comparable progress has been made in the specification and use of aggregate materials. The popular conception that aggregates are merely inert filler materials and that most all rocks, with a few exceptions, will make good concrete still persists. However, as P. H. Bates has indicated,[18] all aggregate materials are subject to chemical reaction in concrete and the real problem is whether or not they are adversely reactive. Mr. Bates also pointed out that the compounds of calcium, as well as of sodium and potassium, should not be overlooked in searching for the solutions to the alkali-aggregate reaction problems. Present criteria by which the suitability of aggregates for use in concrete is judged are woefully inadequate, and basic information for intelligent guidance is almost entirely lacking.

[17] Senior Engr. (Civ.), Bureau of Reclamation, Denver, Colo.

[18] *Proceedings*, Conferences on Problems Related to Alkalies in Cement and Their Effect on Aggregates and Concretes, Bureau of Reclamation, February, 1941, p. 20.

In the light of the aforementioned conditions, it is again not surprising that, since Mr. Stanton's discovery, many cases of concrete disintegration similar to those that he described have been revealed. Concrete structures either known to be or strongly suspected of suffering from alkali-aggregate reactions are now under observation in other parts of California, and in Arizona, New Mexico, Washington, Idaho, Oregon, Nebraska, Canada, Iowa, Virginia, and Pennsylvania. The list of aggregates known to be reactive in the presence of alkalis includes materials having such descriptive terms as andesitic, rhyolitic, felsitic, granitic, slaty, schistose, impure limestones, and others as yet unidentified, in addition to the shale, chert, and siliceous limestone reported by Mr. Stanton.

Preventive Measures.—The predominating question in the minds of all who are concerned with the alkali-aggregate reaction problems, of course, is "How can future cases of such concrete disintegration be avoided?" From the cement manufacturer's viewpoint, alkali-reactive aggregates should be excluded from use. He substantiates his position by stating that most of the concrete in existence is rendering satisfactory service even though high-alkali cement was used in much of that concrete. Concrete investigators emphasize that there is, as yet, no certain method of determining what combination of cement and aggregate might be expected to cause trouble under various service conditions. Furthermore, the occurrence of alkali-reactive aggregates is not a condition peculiar to any one locality but is apparently widespread.

The engineer and builder, in some cases, finds himself in a quandary. For most ordinary concrete work, particularly where aggregates with long service records in combination with a relatively high-alkali cement are available, the problems probably need to occasion little concern, except an uneasy realization that alkalis in cement are not desirable constituents. For large, important, and costly works there is, for the moment, only one available expedient—the imposition of the lowest practicable limit on the alkali content of the cement. Whether this expedient affords adequate protection in all cases, whether some aggregates should be condemned for use in concrete, or whether there are other more effective corrective measures whereby the destructive chemical reactions can be neutralized yet remains to be determined.

Comparison of Mr. Stanton's Findings with Those of the Bureau of Reclamation at Parker Dam.—The Parker Dam case has been discussed in detail in the technical press.[19,20] It is sufficient to state here that Parker Dam was completed in 1938, and, after less than two years of service, random-pattern cracking (Fig. 10) and internal expansion of the concrete developed on an extensive

[20] "Cracking in Concrete Due to Expansive Reaction Between Aggregate and High-Alkali Cement As Evidenced in Parker Dam," by H. S. Meissner, Assoc. M. Am. Soc. C. E., *Journal*, A. C. I., April, 1941.

scale. As high-alkali cement was used in the construction of Parker Dam, the possibility of alkali-aggregate reactions, similar to those described by Mr. Stanton, was immediately investigated by means of his 1 : 3 mortar-bar expansion test at 70° F. The results obtained from such tests at six months (Fig. 11(*a*)) show about the same expansion for the Parker sand, Grand Coulee sand, and the local Denver sand from the Platte River (approximately 300 millionths) with a cement containing 1.13% total alkalis. In comparison with Fig. 4, this might be interpreted as meaning that all the aforementioned sands are mildly reactive in combination with a high-alkali cement. On the other hand, the foregoing results might be interpreted as meaning that none of these sands are reactive, the recorded uniform expansions being due simply to increased moisture content of the mortar bars.

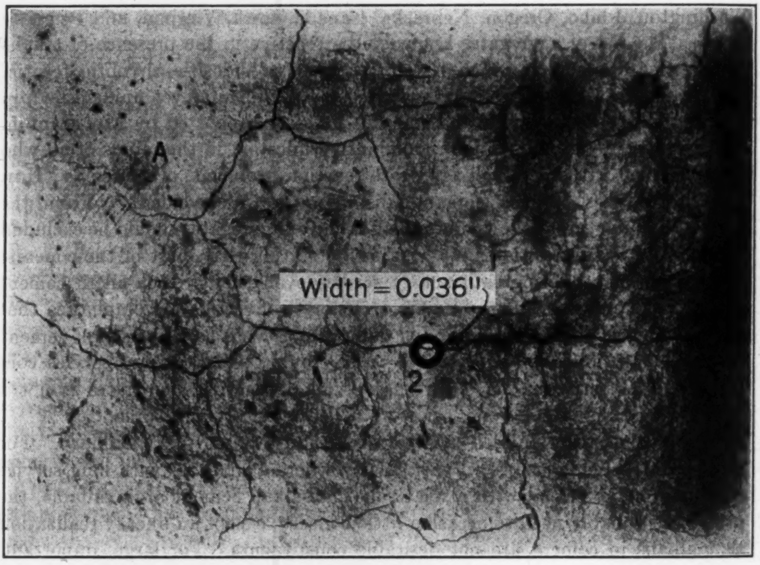

FIG. 10.—TYPICAL RANDOM-PATTERN CRACKING OF THE PARKER DAM SURFACE CONCRETE AS A RESULT OF INTERNAL EXPANSION

Conclusive evidence to explain the condition of the Parker Dam concrete was not obtained until cores were drilled. When the Parker concrete cores were stored in the presence of moisture, a gel-like ooze appeared on their surfaces and also was found in the small cavities and voids within the concrete mass (see Fig. 12). Upon drying, this gel became a hard whitish deposit similar to that described by Mr. Stanton. Chemical analysis of the gel revealed it to be essentially sodium silicate. Further investigation showed that the gel-like substance was apparently a reaction product between the alkalis in the cement and as yet unidentified mineral constituents carried by small percentages of andesitic and rhyolitic aggregate particles in the Parker gravel (see Fig. 13).

Whereas it is inferred from Mr. Stanton's paper that only the sand in the California aggregates carried alkali-reactive materials, 6-in. cobbles have been found undergoing chemical alteration in the Parker concrete.

After the reactive aggregates in the Parker gravel were identified by means of the concrete-core studies, samples of the andesite rocks were hand picked and the material subjected to tests corresponding to those shown in Fig. 6(*b*) for siliceous limestone. The comparative responses of a 10% crushed Parker andesite and the 5% siliceous magnesian California limestone (as reported by Mr. Stanton) to the mortar-bar expansion test at 70° F are shown in Figs. 14(*b*) and 14(*a*), respectively.

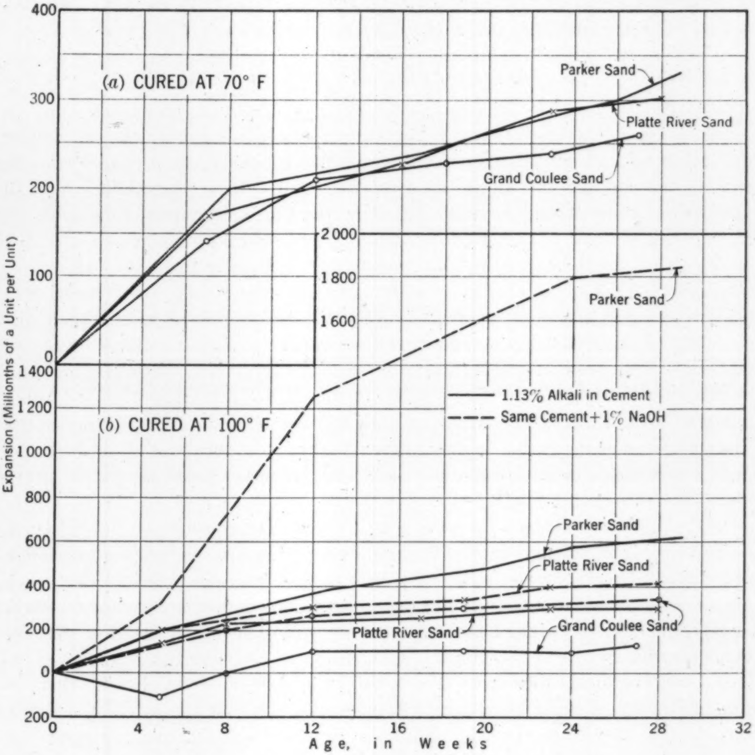

FIG. 11.—1 : 3 MORTAR BARS CURED IN SEALED CONTAINERS

In an effort to develop an accelerated test for detecting alkali-reactive aggregates, the mortar-bar test was conducted at 100° F with a cement containing 1.13% alkalis and also with the same cement to which had been added 1% of Na OH. The results from these tests are shown in Fig. 11(*b*). Again, the correct interpretation of these results is not very clear. However, the differences in the expansions obtained with and without the addition of Na OH are believed to be significant. A close comparison of the data shown in Fig. 11(*b*) with those represented in Fig. 11(*a*) also indicates some inconsistencies.

The most significant fact developed by Mr. Stanton's investigations, corroborated by those conducted by the Bureau of Reclamation, is that "bad" aggregates apparently make "good" concrete in combination with cements containing less than 0.60% total alkalis. The question immediately arises: "Is an aggregate that is reactive in the presence of a high-alkali cement 'bad' or is the high-alkali cement 'bad'?" This is an important question that has not as yet been answered satisfactorily.

For concrete work in those areas where alkali-reactive aggregates are known to occur, the California Highway Department has limited the alkali content of cement to 0.60%. The Bureau of Reclamation has imposed such a limit on cements being used in current large concrete works. Practically all of the natural sand and gravel aggregates available in the Western States contain varying percentages of andesitic, rhyolitic, and felsitic materials. Not all particles of andesite and rhyolite found in the Parker concrete show evidence of chemical alteration and, likewise, examples of felsite in concrete containing high-alkali cement have been observed to be chemically inactive. However, methods for predetermining when such materials may or may not be reactive in the presence of excessive quantities of alkalis in cement have not been discovered. It is reasonably certain that the reactive minerals in these aggregate materials are products of alteration, and the intensive petrographic and microscopic investigations of aggregates, cements, and concretes that are being initiated should clarify the situation. In this connection, a comparison of the findings from the present investigations with the experiences described[21] by J. C. Pearson and G. F. Loughlin in 1923 with feldspar aggregates should prove extremely interesting.

Effect of Environmental Conditions on Concrete Deterioration at Parker Dam.—The drying conditions in the Parker Dam region are very severe, although observations on concrete structures in the arid regions indicate that such exposure is not particularly trying to concrete or conducive to unusual crack development. At Parker Dam, the cracking is most severe in the more massive concrete members and the abutment blocks at or near the roadway elevation. The cracking diminishes from the top of the dam downward, and there is practically no cracking at or near water levels. Also, at the top of the superstructure in the relatively thin wall, floor, and roof slabs of the gate-operating house, the cracking is insignificant.

For varying depths, to 30 ft, 10-in. by 20-in. cores have been drilled from the top of the spillway crest. The strength and Young's modulus values obtained with these cores are much higher than those previously reported[19] for cores taken at higher elevations. The average strength of the more recent 10-in. cores is 4,750 lb per sq in.; modulus, 3,375,000 lb per sq in.; and Poisson's ratio, 0.16. However, the recent cores from all depths profusely develop the characteristic exuding deposit of sodium silicate when stored in the presence of moisture. The gel-like deposit is found in the small pores within the concrete

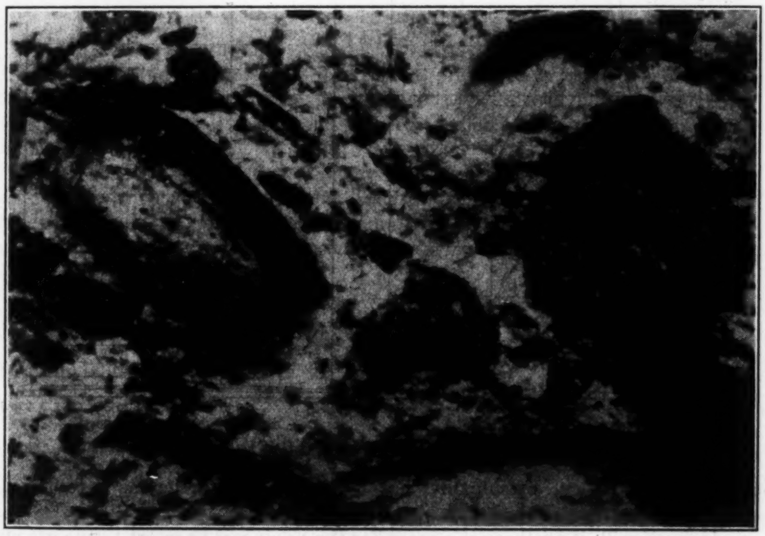

FIG. 13.—ANDESITIC AGGREGATE PARTICLES IN PARKER DAM CONCRETE ALTERED BY CHEMICAL REACTION WITH ALKALIES IN THE CEMENT

mass, and evidence of chemical attack upon particles of andesite and rhyolite aggregate can be seen—all as revealed by the earlier cores. The cementing matrix does not show the same degree of dissociation as previously observed, as might be expected from the higher strengths obtained with the later cores.

Improved Quality of Low-Alkali Cement.—The experiences of the Bureau of Reclamation in changing from relatively high-alkali cements to those of low alkali have developed interesting comparisons. The change from high to low alkalis with attendant improvement in other qualities has been made possible for certain Reclamation work through the splendid cooperation of the cement manufacturers in developing practical production methods. In most cases the alkali content has been reduced by controlling the selection and processing of raw materials and by increased burning temperatures. The combination of raw materials required for producing low-alkali cement results in a final product that is considerably higher in total silicates (C_2S and C_3S), with attendant lower C_4AF and C_3A, and the cement is more thoroughly burned. The typical examples in Table 7 illustrate the improved composition as a result of reducing the alkali content of certain low-heat cements. The sum of C_2S and C_3S (which is sometimes considered as one measure of the potential cementing value of a given cement) has been increased about 10%. In addition, the cementing efficiency, presumably, has been increased further as a result of higher burning temperatures.

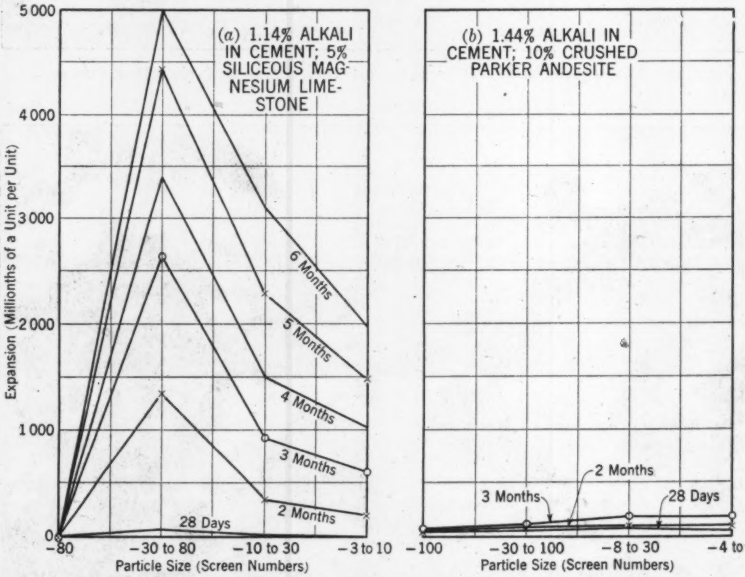

Fig. 14.—Reaction of Aggregates to the Mortar-Bar Expansion Test at 70° F

In some mills it has been necessary for the producers to resort to the use of calcium chloride or other expedients in addition to raw-material selection in reducing the alkali content of their cement below the 0.60% limit. Calcium chloride apparently will effect a reduction in alkalis of at least 0.3% to 0.4%, depending upon manufacturing conditions. When it has been used, no evidence of chlorides has been found in the finished cement. In one case a heat-treating process of the clinker efficiently reduces the alkali content about 0.3%. In addition, the 7-day strength of this cement is increased 25%, for the same theoretical composition and fineness, by the heat treatment.

Experience to date indicates that the increased cost of producing cement that meets the 0.60% alkali limit may vary from practically nothing to 20 cents per bbl, depending upon the individual mill conditions.

TABLE 7.—EFFECT OF REDUCING THE ALKALI CONTENT OF CEMENT (PERCENTAGES)

Constituent	MILL A		MILL B		MILL C	
	Normal alkali	Low alkali	Normal alkali	Low alkali	Normal alkali	Low alkali
C_4AF	15	9	12	7	16	14
C_3A	6	5	6	6	6	4
C_2S	43	49	48	52	46	45
C_3S	29	32	29	30	25	32
Alkalis	1.2	0.4	0.9	0.4	1.3	0.4

Conclusion.—The engineering profession, the cement and aggregate industries, and the users of concrete are all indebted to Mr. Stanton. Without question, his discovery will ultimately lead to far-reaching improvement in concrete and better understanding of its ingredient materials.

J. MacNeil Turnbull,[22] Assoc. M. Am. Soc. C. E. (by letter).—Investigations and tests of great interest are presented in this paper and, by demonstrating one effect of the presence of the alkalis in portland cement, the importance of these minor and hitherto neglected constituents has been emphasized.

F. M. Lea and C. H. Desch[23] have given the percentage of the total alkali content of various types of portland cement that are dissolved on shaking the cement in water for forty-eight hours. The amounts of the alkalis that can go into solution under these conditions exhibit a wide range of values—20% to 85%.

R. H. Bogue[24] has given some of the possible compounds that the alkalis may form in portland cement.

The writer believes that the percentage of soluble alkalis depends upon the proportion of the alkalis which are combined with the cement in stable compounds. Any excess greater than this will be present in a free, or easily liberated, state, and available for extraction by water or reaction with any chemically active substance in the aggregate.

During 1936 the writer investigated the increase in the caustic alkalinity of water in contact with hardened concrete. He had hoped to be able to remove a considerable proportion of the alkalis from the cement by washing it in water before addition to the aggregate. This was done by adding the cement to three and one half times its weight of water and keeping the mixture well stirred for a period of 30 min or longer. The cement was allowed to settle and the free water decanted, the surplus, greater than the water-cement ratio desired, being removed by centrifuging. The wash water was filtered and submitted to chemical analysis. Table 8 gives the composition of this wash water after washing 1,400 g of cement with 4,900 ml of tap water for 30 min; 4,275 ml of water were recovered, leaving a water-cement ratio of 0.45 by weight in the cement paste.

TABLE 8.—CHEMICAL COMPOSITION OF WASH WATER FROM A MEDIUM-ALKALI CEMENT

In Parts per Million

Cl	CO_3	OH	SO_4	$Si\,O_2$	Ca	Mg	Na	K	NO_3
21	15	984	1,325	2.0	1,444	0.4	19	492	trace

The cement used was cement *C* of Table 9, from which it will be seen that this cement contains considerably more potash than soda. The principal compounds dissolved out of the cement appear to be calcium sulfate, calcium hydroxide, and potassium hydroxide.

TABLE 9.—PERCENTAGE OF ALKALI IN PORTLAND CEMENT

Cement	Na_2O	K_2O	Total alkali[a]
A (low-heat)	0.11	0.23	0.26
B (low-heat)	0.64	1.22	1.44
C (standard)	0.14	0.78	0.65
D (standard)	0.70	0.40	0.96
E (standard)	0.98	0.55	1.34

[a] Calculated as Na_2O.

Tests of hardened cement mortar, 1 : 2.2 by weight, in the form of a pipe lining ⅜ in. thick, 3¼ in. internal diameter, 12 in. long, made of cement *C*, with and without washing, confirm the analysis given in Table 8. After hardening, the pipes were filled with tap water and left standing for a period of seven days. The water was then removed and replaced with fresh water, and left for a further period of seven days. The composition of this water is given in Table 10.

The washing of cements *A* and *D*, Table 10, had no effect in reducing the caustic alkalinity, but cement *C* was considerably improved. Cements *B* and *E* were not tested but, due to their very high alkali content, are included in Table 9 as a matter of interest.

Although the soda cannot be washed out of the cement itself, it can be leached out of the hardened cement mortar or removed by washing the cement for longer than the normal period of final set. L. Forsén[25] mentions that the alkali appears as free hydroxide as soon as the gypsum or any other calcium salt is consumed by the aluminates.

---

[25] "The Chemistry of Retarders and Accelerators," by L. Forsén, *Proceedings of the Symposium on the Chemistry of Cements*, Stockholm, 1938, p. 301.

The writer suggests that these differences between the behavior of the sodium and potassium hydroxides in unhardened and hardened cement may explain the lack of coordination between the author's results and the Merriman test.

TABLE 10.—CHEMICAL COMPOSITION OF TAP WATER AFTER CONTACT WITH CEMENT MORTAR FOR SEVEN DAYS (AVERAGE OF TWO SUCCESSIVE PERIODS)

In Parts per Million

Cement	Prior treatment of cement	Age, in weeks[a]	Cl	CO_3	OH	SO_4	SiO_2	Ca	Mg	Na	K	NaOH[b]	Remarks

[a] Age of lining at test. [b] Caustic alkalinity computed as sodium hydroxide. [c] Caustic alkalinity due largely to calcium hydroxide. [d] Caustic alkalinity due largely to potassium hydroxide. [e] Potassium hydroxide reduced 58%. [f] Chemical composition not determined. [g] Washed for 1.5 hr. [h] No reduction of caustic alkalinity. [i] As HCO_3.

The results of the author's tests with finely ground siliceous magnesian limestone No. 28039 suggest that the use of this material as an admixture (apparently by inducing a rapid reaction with the alkalis in the cement) may prevent any subsequent reaction with the chemically active material in the aggregate.

Acknowledgment is made to D. Avery and V. G. Anderson, industrial, research and analytical chemists, for the chemical analyses.

ROBERT A. KINZIE, JR.,[26] ESQ. (by letter).—The results of Mr. Stanton's work, and his interpretation of the results, were both interesting. Since the test method was new, the writer was mainly interested in the problems of reproducing the results, and to this end he secured aggregates from the same source.

The work was arranged so that the effect of the sand, method of curing, and the alkali in the cement could be determined. Mr. Stanton's tests showed that a portland-puzzolan cement which he tested had a much smaller expansion than would be predicted from its alkali content. This cement was included in the writer's series.

The bars in this series of tests were made according to the method given by Mr. Stanton; that is, they were cured in four ways:

(1) Wet............Immersed in water.
(2) Moist...........Cured in sealed cans, over but not touching a layer of water on the bottom of the can.

---

[26] Supt., Santa Cruz Portland Cement Co., Davenport, Calif.

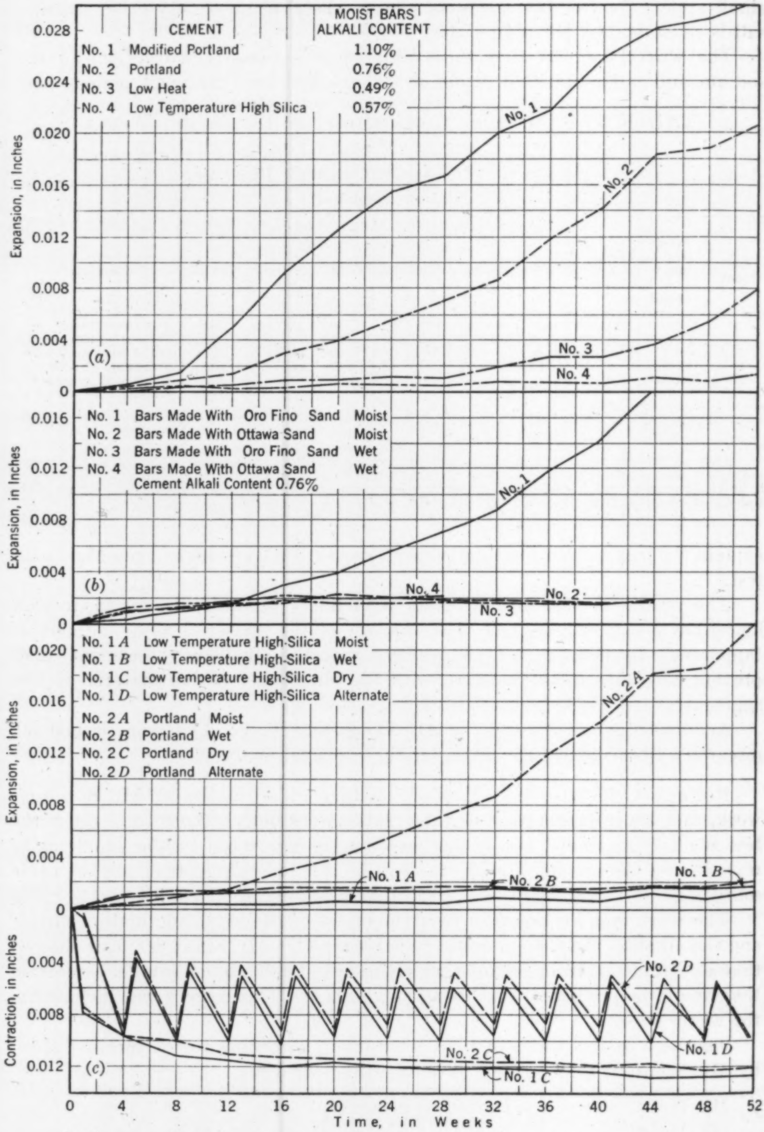

FIG. 15.—REPRODUCTION OF THE STANTON TESTS (ORO FINO SAND, GROUP I, NO. 4)

(3) Alternate........One week immersed in water and then dried in air at 70° F for three weeks. The relative humidity was not closely controlled, but was about 60%.

(4) Dry............Kept in air at 70° F and a relative humidity of about 60%.

Portland cements, made to Government specifications, were used, with the exception of the low-temperature high-silica cement, which was a portland-puzzolan cement. The results of the writer's tests may be summarized as follows:

A test on bars made with Oro Fino sand (Group I, No. 4) was designed to show the effect of alkali in the cement in relation to this sand. Therefore, three cements of different alkali content were selected.

The portland-puzzolan cement was included to check Mr. Stanton's results. The curves in Fig. 15(*a*) show that with "moist curing" the expansion of the mortar made with Oro Fino sand increased with increased alkali content of the cement. The portland-puzzolan cement had a much lower expansion than would be expected from its alkali content.

The curves in Fig. 15(*b*) were drawn to show that the expansion is caused by a combination of "moist curing" and Oro Fino sand. The cement is the same as cement No. 2 in Fig. 15(*a*). With "wet curing" there was an initial expansion of some magnitude in all cases and then a much slower change. For both types of curing the Ottawa sand bars behaved normally.

The curves in Fig. 15(*c*) were included as a further check on the results of Mr. Stanton. The cements were low-temperature high-silica, the same as cement No. 4, Fig. 15(*a*), and the portland cement was the same as cement No. 2, Fig. 15(*a*). The bars were cured in four ways to determine whether the method of curing was the main factor in the expansion and to check further the behavior of the low-temperature high-silica cement. All of the bars were made with Oro Fino sand.

This series of tests showed that the method of testing developed by Mr. Stanton's laboratory will give results that can be checked by other laboratories.

THOMAS E. STANTON,[27] M. AM. SOC. C. E. (by letter).—Considerable "water has gone over the dam" since this paper was first published in December, 1940. The presentation and data as of that date were based on laboratory tests and field studies conducted during a period of approximately eighteen months, an entirely too short time for the development of much of the data that have subsequently come to light (as of August, 1941). The subsequent developments, however, do not change the original conclusions in any material respect, but have served, rather, to confirm them and, in addition, indicate the possible answer to several as yet unsolved or at least only partly answered problems.

In closing the discussion on this important topic, the writer desires to express his appreciation to those who have so kindly participated, and likewise to repeat his grateful acknowledgment of the assistance of the members of his staff, without which most of the valuable data presented would have been unavailable. Many valuable suggestions have been made and it is hoped that the information presented in the paper and in the subsequent discussion will be of value in either solving some important problems relative to Portland cement concrete or pointing the way to further studies.

---

[27] Materials and Research Engr., State Div. of Highways, Sacramento, Calif.

Parker Dam.—Interest in the subject has been accentuated by the findings of the U. S. Bureau of Reclamation that the severe cracking that developed in 1940 in parts of the Parker Dam on the Colorado River can be traced to a reaction between the cement and aggregate. The story of the Parker Dam is treated fully in the discussion by Mr. Blanks.[19,20] The Bureau has since started a very extensive and thorough nationwide investigation in cooperation with cement manufacturers.

A. S. T. M. Activities.—P. H. Bates, chairman of Committee C-1 of the American Society for Testing Materials (A. S. T. M.), has appointed a working committee on the "Effects of Alkalies in Portland Cement on the Durability of Concrete," of which Mr. Blanks is chairman and the writer a member.

Further Bradley Pavement Developments.—It will be recalled that the early (1.5 years) failure of the pavement north of Bradley, Monterey County, Calif., was confined to the sections in which the local (Oro Fino) sand had been used, and that the other sections in which Oro Fino coarse aggregate and imported (Coyote) sand had been used had, to the date of the original report, failed to show appreciable distress.

Two years later (spring, 1941) the Oro Fino coarse aggregate-Coyote fine aggregate sections had begun to show some distress, thereby indicating that under conditions similar to the California experience the reactive particles in the coarse aggregate may be expected to cause trouble ultimately, although apparently at a somewhat slower rate, and possibly to an ultimate less degree, than fine aggregate of a similar composition. This conclusion is checked by subsequent laboratory tests on coarse and fine aggregate containing reactive particles.

TABLE 11.—MINERAL COMPOSITION AND REACTION CHARACTERISTICS OF DIFFERENT MINERALS SIMILAR TO THE CONSTITUENTS OF ROCK NO. 28039

Mineral	Approximate percentage in rock No. 28039	Percentage in bar	Age in months	Expansion units
Chalcedony	15	10	12	60
Opal Type 1	12	2.5	6	9,920
Opal Type 2	1	10.0	10	11,490
Limonite	1	5	10	30
Glauconite	1	5	6	10
Dolomite	10	10	6	10
Calcite	60	10	12	50
Combined[a]	100	10	12	7,470

[a] Sample including all minerals.

Reactive Properties of Opal.—The probable rôle of the hydrous silicates was fully discussed in the paper. It was pointed out that a sodium silicate gel was at the base of most, if not all, of the popouts and was also found throughout broken sections of concrete as well as exuding on the surface through pores and cracks.

However, in the early tests, specimens containing 10% of either opal or the highly opalized chert No. 28038 had failed to develop excessive expansion, whereas excess expansion was invariably encountered with the same percentage of the siliceous magnesian limestone No. 28039. This experience led to the effort to develop a formula based on a possible reaction between magnesium carbonate and sodium hydroxide.

The next step was to make chemical and petrographic analyses of the siliceous magnesian limestone No. 28039 to determine its mineralogical composition and then to make up expansion bars of each mineral component singly and in combination in the relative percentages found in nature. Table 11 shows the results of this study.

Although the combined synthetic sample was made up of the relative percentages found in No. 28039 and 10% of this combination added to a neutral sand, the tests on each mineral separately were not at the relative percentages found in the original rock but in some cases in higher percentages, the main purpose of the tests being to reveal the probable reaction characteristics of each mineral when present in a sufficiently large percentage.

At the same time, however, excessive expansion has been observed even with much smaller percentages: 1% of Type 2 opal expanded 1,310 units in eight months and 5% of the same mineral expanded 10,250 units, or 1.025%, in the same period of time. From this study it was determined that in the California experience the opal constituent was at the base of most, if not all, of the trouble, and, therefore, the original study of the rôle of soluble silica in the form of opal was resumed.

It was then found that the reason little, if any, reaction was originally developed with the highly opalized material was that the mixture had been overdosed. If the entire coarse or fine aggregate is composed of opaline particles, there is no undue expansion, but when present in what might be called a "pessimum" amount, which appears to be substantially less than 10% or 15% of the total aggregate, a high expansion may be expected in the presence of a high-alkali cement. Table 12 shows the expansion results with a number of rocks, all of which contain opal in varying amounts.

TABLE 12.—Relative Degree of Expansion Induced by 2½%, 5%, and 10% of Different Reactive Rocks Added to a Neutral Sand-High-Alkali Cement Mortar

(1-In. by 1-In. by 10-In. Mortar Specimens; Mix 1 : 2; Age at Time of Measurement, Six Months)

Percentage added to a neutral sand	Rock No.

	Expansion in Millionths of an Inch per Inch									
2.5	+220	+12,580	+6,310	+7,470	+3,850	+2,910	+320	+11,040	+4,850	+9,920
5.0	+1,150	....	+5,520	+5,460	+5,390	+4,160	+730	+8,490	+4,460	+8,820
10.0	+180	+110	+3,650	+210	+8,420	+7,470	+260	+130	+1,910	+1,740

[a] Only a small quantity of this rock available at time of fabrication of specimens. Analysis shows it to be similar to No. 28038. [b] Opal from dredger dumps on American River near Auburn, Calif.

In the case of the California aggregates the quantity of deleterious particles required for maximum expansion appears to be related both to the opal content and to the type of opal or hydrous silicate. There is definite evidence that opal with high water content is more soluble and reacts quicker than opal with low water content. Much work needs to be done along this line, however.

Further attention is called to the low percentage of opal required for maximum results, as well as the remarkably low percentage (in some cases less than 0.5%) which produces excessive expansion in a relatively short time (Table 13). This would appear to be conclusive evidence that, when expansion does not occur in the field until after a year or more, the percentage of deleterious material may be as low as 0.75% and possibly even less.

Test results available by July, 1940, led to the conclusion that, since little, if any, measurable expansion was observed with deleterious particles below 80-mesh or 100-mesh size, the reason for the falling off in expansion as the percentage of such particles was increased beyond a certain percentage might be an accelerated reaction between the cement and finely dispersed mineral particles.

TABLE 13.—SHOWING EXPANSION EFFECT OF DIFFERENT PERCENTAGES OF TWO HIGHLY REACTIVE ROCKS[a]

[a] Rock particles substituted in percentages shown for an equivalent percentage of neutral Russian River sand. [b] Opal secured from dredger dump on the American River near Sacramento, Calif. [c] Rock No. 28038 has been identified as one of the constituents of Oro Fino sand and was secured from ledge deposits found in Monterey County.

Although the underlying cause may be that originally suspected, later tests show that neutralization also occurs in the presence of excess percentages of coarser particles from which all finer particles have been removed. From this it would appear that, for maximum reaction, there is a relation between the amount of reactive mineral in any unit area and the alkali in the cement, and that, when the area of such a mineral available for reaction with a given amount of alkali exceeds a certain amount, the magnitude of the reaction products at the locus of each particle may be insufficient to cause excessive expansion and rupture.

The power of the disruptive action is well illustrated in Fig. 16. In this case a mortar bar, 1 in. by 1 in. by 10 in., was fabricated from a high-alkali cement and an all limestone fine aggregate to determine the reaction, if any, between limestone and the cement. All specimens in this series showed no expansion except one which developed the cracks shown in Fig. 16. Upon breaking this specimen along the line of the transverse crack, it was found that a small piece of reactive mineral had inadvertently been included, and that, although this foreign mineral particle was only about 1.0% of the cross section of the 1-in. by 1-in. bar, the reaction had sufficient force to cause rupture.

Type of Mineral Aggregate.—In so far as the early reactions are concerned, the source of the California troubles was definitely defined as resulting from some mineral in the 5% to 15% shale and chert portion of the aggregate, the bulk of the remaining 85% to 95% consisting of unreactive granitic rock, sandstone, quartzite, rhyolite, andesite, siltstone, and limestone.

The subsequent identification of the trouble with certain chert aggregates led to a suspicion in some quarters against all types of chert. It now appears probable that only those cherts which contain soluble silica of the opaline type are definitely reactive and that other cherts may be absolved of any suspicion in so far as any present evidence based on California experience is concerned. At the same time it has not yet been proved that all opaline cherts are equally reactive. It may be that only the highly soluble types are to be feared and then only when the percentage of solubility exceeds a certain amount. There is ample field for further investigation along this line.

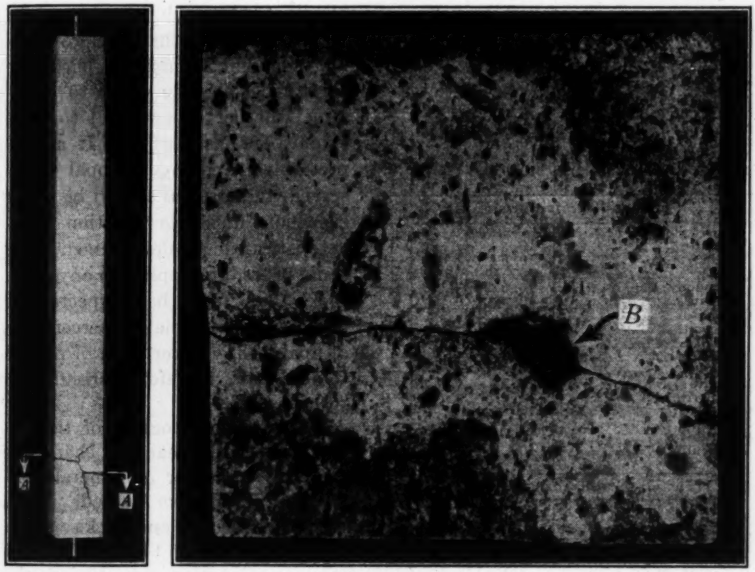

FIG. 16.—RUPTURING EFFECT OF A SMALL PARTICLE OF REACTIVE MINERAL ACCIDENTALLY INCLUDED IN A NEUTRAL LIMESTONE FINE AGGREGATE, HIGH-ALKALI CEMENT MORTAR (SECTION *A–A* SHOWS REACTIVE PARTICLE INCLUSION AT *B*)

Mr. Twenhoffel states[28] that "Opaline or amorphous silica is wanting or extremely rare in Mesozoic and older flints and cherts, but may be found in those of the Tertiary and later.”

[a] Percentage substituted for an equivalent percentage of neutral sand.

[b] This percentage was found to be the most reactive.

[c] Expansion not believed to be due to cement-alkali reaction.

Any type of aggregate that contains opal may be reactive. However, due to the prevalence of opaline cherts and cherty shales in the Tertiary formations west of the Rocky Mountains, the West is more likely to experience this difficulty than the East, so far as cherts in general are concerned.

It is evident, therefore, that all cherts, as such, should not be blacklisted, but that, before passing judgment against any particular chert, it is first in order to determine whether or not, and to what extent, opal is present. If an appreciable percentage of opal is observed, the mineral should be under suspicion until its reaction characteristics can be determined. The same procedure applies to any other rock that may be suspected of containing appreciable percentages of opal or any other form of readily soluble and, therefore, presumably reactive silica.

During the progress of this investigation the reaction characteristics of a number of minerals and rocks at 70° F were studied. A list of these minerals and rocks will be found in Table 14. Tests were made on mortar bars using the high-alkali cement, *GS*, combined with the percentages of mineral indicated in figures after the name. The material under investigation was added in the indicated percentages to a neutral sand.

The reactivity was determined by measuring the expansion characteristics of mortar bars of high-alkali cement, non-reactive sand, and variable percentages of materials under investigation. Test specimens were stored and tested at 70° F. As will be noted, chalcedony, as well as a number of other minerals of the type tested, is not reactive, at least in a short period of time.

All fluorescence observations on minerals in Table 14 apply strictly to samples tested with equipment in the laboratory of the California Division of Highways. Other specimens of the same mineral species from different localities may show different fluorescence results. In all of the California series, storage and tests were at a normal laboratory temperature of approximately 70° F. Prof. Roy F. Carlson and others have been able to get expansion at 110° F and 150° F not obtainable at 70° F.

TABLE 15.—EXPANSION OR SHRINKAGE OF CONCRETE SPECIMENS OF ORO FINO AND COYOTE AGGREGATES CURED IN WATER, IN SEALED CONTAINERS, AND IN AIR

(Age, Twenty-one Months; Expansion in Millionths of an Inch per Inch)

Autoclave Tests on Feldspars and Other Materials.—Inasmuch as several investigators have questioned feldspar as a mineral constituent, some studies were made to determine the effect on various unaltered feldspars and other petrographic types of aggregates when immersed in normal Na_2CO_3 and Na OH solutions after a method similar to that used by E. A. Stevenson.[29] The material tested included: (1) Three different types of opal, (2) Parker Dam andesite, (3) siliceous magnesian limestone No. 28039, (4) orthoclase, (5) microcline, (6) oligoclase, (7) andesine, and (8) labradorite. (Feldspars 4, 5, 6, 7, and 8 were obtained from Ward's Natural Science Establishment, Rochester, N. Y.)

The specimens submerged in the test solution were sealed in an autoclave at a pressure of approximately 300 lb per sq in., temperature 430° F, for six days. Results indicated the ready solubility of the opal and of parts of the siliceous magnesian limestone No. 28039, but the feldspars and the Parker andesite were practically unaffected by this treatment.

---

[29] *Journal of Geology*, 1916, Vol. 24, p. 180.

Curing in Sealed Containers Not Necessary with Large Concrete Specimens.—The discovery that excessive expansion of mortar specimens occurred only when cured in sealed containers defined the test procedure requisite to a determination of the reactions between the fine aggregate and the cement. Hundreds of mortar-bar tests conducted during this study have confirmed the necessity for the sealed container or some equivalent method of storage for this size specimen.

Recent developments, however, demonstrate just as conclusively that, in the case of concrete specimens of 6-in. cross section, it is not necessary to cure in sealed containers, and that, in fact, the greatest reaction may be developed when such specimens are constantly immersed in water.

Tables 15 and 16 are illustrative of this development. It will be noted in Table 16 that some of the 6-in. by 12-in. cylinders and 6-in. by 6-in. by 34-in. beams composed of Oro Fino fine aggregate, stored continuously in water, developed excessive expansion and lowered strength in eighteen months, whereas the companion 2-in. by 2-in. by 10-in. concrete specimens, using aggregates from $\frac{3}{4}$-in. and smaller failed to develop expansion when stored in water twenty-one months, but have developed considerable expansion in sealed containers (Table 15). There would appear, therefore, to be a critical size of specimen below which the reaction will not take place unless the specimen is stored in a sealed container or in some other way in which the moisture can be controlled properly.

Concrete Tests.—Under the heading "Concrete Tests," reference was made in the paper to the 6-in. by 6-in. by 34-in. specimens of six-sack concrete, using different combinations of non-reactive and reactive coarse and fine aggregates, the specimens of each mix being cured under three conditions—(*a*) sealed, (*b*) in water, (*c*) exposed to air,—at laboratory temperature (approximately 70° F) and humidity. Similarly, 6-in. by 12-in. cylinder specimens were treated for compression strength tests.

The following mixes were used: (1) Oro Fino fine and coarse aggregate; (2) Oro Fino fine aggregate, Coyote coarse; (3) Coyote fine aggregate, Oro Fino coarse; and (4) Coyote fine and coarse aggregate.

Two sets of specimens were made—one with the high-alkali cement *GS*, and the other with the low-alkali cement *AS*. The test had been in progress too short a time when the report was closed to produce information of value. The writer now reports the situation as of one year later (1941).

The specimens were fabricated in September, 1939. At one year, no appreciable expansion had taken place in any of the specimens, regardless of the method of cure. When next inspected, at eighteen months, a very marked expansion had taken place in the Oro Fino fine and coarse aggregate specimens stored in water, and some expansion in similar mixes covered with a watertight wrapping. Table 15 shows the expansion at twenty-one months for all concrete specimens in this series.

TABLE 16.—Condition of Concrete Beam and Cylinder Specimens After Storage in Water for Eighteen Months

(*a*) 6-In. by 6-In. by 34-In. Beam

21 months[a]	4,220	0	....	....
28 days[b]	....	....	4,030	4,590
18 months[b]	....	....	2,440	5,800

[a] Expansion in millionths of an inch per inch. [b] Compressive strength, in pounds per square inch.

Attention is called particularly to the fact that little, if any, expansion and no cracking were noted at twelve months, whereas very marked expansion and deterioration took place in some specimens between twelve months and eighteen months, thus paralleling the Bradley job experience in which the same aggregates and cement were used, and where excessive expansion became apparent between twelve and eighteen months after construction.

Tests to Determine Aggregate Characteristics.—The only known suitable tests to determine the reactive characteristics of aggregates conclusively have been long-time expansion tests of mortar and concrete specimens, although petrographic analyses are of valuable assistance in furnishing rapid advance information relative to the presence of mineral inclusions that may be reactive.

Unfortunately, when the percentage of reactive mineral is small, several years may be required before the reaction becomes apparent. Attention has turned, therefore, to a study of accelerated methods of determining the probable reaction characteristics of an aggregate by chemical analysis and other means.

Chemical analyses of the white crust and efflorescences taken from the surface of disintegrated concrete usually indicate a rather high content of Na_2CO_3. Working on the assumption that the sodium is probably present originally in the concrete as hydroxide (later converted to the carbonate on exposure to air), studies of aggregate solubility in Na OH solutions were made in California studies as far back as 1936.

From 1936 to 1938 more than 500 specimens, representing various types of shale, chert, and other questionable aggregate particles were individually soaked in a 10% Na OH solution, in airtight containers, at ordinary laboratory temperature. Results of this early work showed the ready solubility of certain types of shales and cherts.

On further study, it was discovered that these shales, cherts, and particles of each solubility were high in opaline or hydrous silica content. It was felt, therefore, that this type of aggregate should be objectionable in the presence of any alkalis likely to be encountered in the concrete, whether contributed by ground water, mixing water, or the cement.

A further investigation was started in the early part of 1937 to determine the solvent action of Na OH solution on certain commercial concrete sands of the State of California. The purpose of this later investigation was to find, if possible, a better testing device than the present A. S. T. M. Sodium Sulfate Soundness Test, for those sands known to contain shale and chert of a deleterious nature.

After much experimentation, the method finally selected as showing the most promise consisted of grinding 50 g of each sand to pass the 100-mesh sieve, soaking in a 10% Na OH solution for fifteen hours at a temperature of 210° F, then determining the amount of dissolved carbonate by titration, and assuming the remainder as silicate. Results, however, showed generally as much solvent action on certain sands of apparent durability as on sands known to contain deleterious particles. Therefore, as the results were inconsistent and inconclusive, no further investigation along this line was made until June, 1939.

In June, 1939, after the Bradley pavement failure investigation was started, chemical analyses were made on solutions from treating Oro Fino and Coyote sand, respectively, in (*a*) tap water, (*b*) low-alkali cement leaching water, and (*c*) high-alkali cement leaching water. Again it was noted that the non-reactive Coyote sand was nearly as soluble as the reactive Oro Fino.

When the more recent developments demonstrated that in all probability soluble silica of an opaline nature was "at the root" of the California trouble, a new series of solubility tests was started, using a weaker sodium hydroxide solution and a less severe procedure, on the theory that, as opal may be more soluble than other silica minerals, a procedure might be developed under which the opal could be dissolved more rapidly than other minerals, thereby enabling comparative determinations to be made.

The results of this later study have, to date (September, 1941) been disappointing and it is somewhat doubtful if the sodium hydroxide solubility test is sufficiently selective to be dependable in the case of aggregates containing quite small but at the same time objectionable percentages of reactive minerals. The study is being continued, however, in the hope that a satisfactory and dependable procedure can be developed.

Fluorescence.—Studies have been continued to ascertain, if possible, the nature and significance of the fluorescence observed and described in the paper, in the hope that an effective and reliable aid might be developed for detecting reactive aggregates. The results of this study have been none too encouraging, as the observations are too frequently inconsistent.

Efforts have been made to compare the amount of observed fluorescence of both reactive and non-reactive rock particles in concrete. Results indicate that, although the gel is fluorescent in most cases where expansion occurs through cement-aggregate reactions, there is likewise a noticeable fluorescence in samples where no reaction has taken place. In many cases fluorescent rims are observed surrounding durable aggregates. Many non-reactive mineral grains that fluoresced in the sand sample continue to fluoresce after the sand has been incorporated in concrete cylinders, so that it is difficult to distinguish between the non-reactive and the reactive particles. In addition, not all reactive particles show fluorescence after several months in the sealed curing test.

The observations in connection with this work were made with a standard commercial type of mercury-vapor lamp with built-in filter. Since the ultraviolet radiation characteristics of the many commercial lamps now available undoubtedly vary with the type and manufacturer, and since no other type of lamp was available for use in the experiments, it is not possible to say, at this time, what results would have been obtained from these same samples if different ultraviolet equipment, having different wave-length ranges and different filters, had been used.

It is possible that, for certain gels and reactive rims, as well as for the reactive aggregates themselves, different lamps may show decidedly different fluorescence effects. It is likewise very probable that many types of aggregates now known to be reactive, but which have not shown fluorescence under the mercury-vapor lamp used in the test, may fluoresce under a higher or lower wave length. Additional work needs to be done in this field (see Table 14 for fluorescent reactive and non-reactive materials).

Modulus of Elasticity by Means of Sonic Vibrations.—Considerable progress has been made during recent years in the development of equipment and procedure for determining modulus of elasticity by means of sonic vibrations.[30] Suggestions were made in several quarters that it might be possible to determine the effects of the expansive reaction between cements and aggregates more readily and at an earlier date by means of sonic vibrations than through expansion measurements.

A number of investigators are now studying this phase, including the Research Department of the Portland Cement Association, the Bureau of Reclamation, the Washington State Highway Department, the Riverside Cement Company, and undoubtedly many others, as well as the California Division of Highways.

[a] Opal from dredger dumps near Roseville, Calif.

[b] The first two columns (1 and 7) are in days.

The results of some of the California studies are shown in Table 17. The measurements shown were made first on the specimens immediately upon removal from the molds and thereafter at weekly intervals. Each value is the average of measurements made on four sides of three bars in each set, or a total of twelve determinations.

All of the tests were made on specimens without end gage plugs. A duplicate set of specimens was made with end plugs for expansion determinations. Modulus tests on the bars with end plugs were somewhat erratic and therefore are not shown in this table.

---

[30] "Measuring Young's Modulus of Elasticity by Means of Sonic Vibrations," by T. C. Powers, *Proceedings*, A. S. T. M., Vol. 38, Pt. II, 1938, p. 460.

The control specimens were made from a neutral sand and high-alkali cement. These control specimens have shown a steady increase in modulus, whereas all specimens containing variable added percentages of reactive mineral in the form of opal reached a peak modulus in not more than three weeks and then a retrogression in direct relation to the expansion characteristics. However, although the modulus decreases as expansion develops, the decrease at early ages is not appreciable except in the case of a high expansion. The expansion measurements are more marked, and it appears doubtful, therefore, if the sonic method will be found more satisfactory than direct expansion measurements.

Also, as most commercial fine aggregates contain substantially less deleterious particles than the synthetic sands reported in Table 17, a longer time before the reaction becomes detectable by the sonic method may be anticipated with reactive commercial sands. Commercial sands have not been tested long enough to produce information of any value.

Correctives.—The study of correctives has been continued with little practical success to date. At first it was thought that if the sodium hydrate could be converted to a chloride the sodium (or potassium) chloride might be harmless. However, such apparently is not the case. Calcium, ferric, and aluminum chloride have all been added to the mixing water, but none have proved effective in reducing the expansion. In fact, in most cases the expansion has been considerably increased.

Other possible correctives have included diatomaceous earth, resins, and sodium alginate but none of these materials has proved sufficiently effective in reducing expansion to warrant their use. Likewise, magnesium carbonate was added to react with the sodium hydroxide, but without success.

The writer's attention was called to work done in which sodium sulfate was added to cement to increase its alkali (sulfate) resistance.[31] However, a 4% addition of anhydrous sodium sulfate had the effect of increasing instead of decreasing the expansion, even with the low-alkali cement *AS*, to such an extent that, although this cement is non-reactive under normal conditions, the expansion in twenty-eight days in the presence of the sodium sulfate was even greater than in the case of the high-alkali cement *GS*.

In this short period the *AS* cement specimens expanded 3,800 units and the *GS* cement specimens 2,640 units per unit. The specimens were of a 1 : 2 mix made with Russian River sand to which had been added 2.5% opal.

Aluminum powder has proved effective in stopping the expansion. When 0.05% by weight of the cement was added, the high-alkali cement bars have shown no expansion up to four months, but the mortar was so fluffed by the expulsion of gas that this method is not considered suitable for construction purposes.

Silica or Puzzolanic Admixtures.—As reported in the paper, the high-silica or puzzolanic type cement HP (Fig. 4) had developed very little expansion in twelve months although the cement contained 0.78% alkali. At the end of twenty-eight months the same specimens show even a slight shrinkage, whereas specimens containing normal cement CL with 0.77% alkali have continued to expand, reaching 3,600 units or 0.36% at twenty-eight months.

---

[31] *Industrial and Engineering Chemistry*, Industrial Ed., Vol. 33, No. 5, May, 1941, p. 692.

This fact gave encouragement to the enlargement of this series to include all California commercial puzzolanic type cements and likewise to include a series of blends of the high-alkali cement *GS* to which had been added, or for a part of which had been substituted, a percentage of certain silica admixtures.

These studies have not progressed sufficiently to be considered conclusive, but they have developed one interesting fact: When the siliceous material is added without reducing the cement content, little benefit is noticed. The expansion is reduced effectively only when the siliceous material is substituted for an equivalent amount of cement. This is revealed in Table 18.

Comments on Discussions.—Having brought all test data up to date, it is possible to comment on the discussions of the original paper.

Professor Carlson propounded several questions. The answers to some of these are at least partly known and some are definitely in the process of determination. The solution of others may be long deferred but offer a definite goal for the interested researcher.

The trouble is not due entirely, if at all, to the formation of an alkali carbonate but undoubtedly also in major part, if not entirely, to the formation of an alkali silicate. No further evidence has been developed either to sustain or to disprove the original suggestion that an alkali carbonate might be one of the contributing factors.

Such tests as are available indicate that the alkalis of sodium and potassium are equally objectionable, but this phase is to be explored thoroughly as a part of the program instigated and being conducted by the Reclamation Bureau.

Although it may be that a combination of moderate-alkali cements with susceptible aggregates may produce expansion in correspondingly longer times, the results of at least twenty-four-month tests with high percentages of No. 28039, and shorter periods in the case of other reactive minerals, indicate that this is highly improbable, at least for any commercial aggregates studied where the percentage of offending mineral is as low as that present in the California aggregates.

It was found, however, that, if a high percentage of a relatively low-alkali cement is used with a highly reactive aggregate, expansion may occur, probably due to the presence of a high total alkali content. In illustration, cement *AS* with 0.45% alkali, which showed no expansion in eighteen months in the 1 : 3 and 1 : 2 mortars, shows a definite expansion (2,210 units) in eighteen months in the 1 : 1 mix with no expansion of the same mix at eight months.

Tests up to thirty-three months do not indicate that certain combinations of high-alkali cement and non-reactive aggregate will ever cause trouble, although it is admitted that longer tests may upset this conclusion.

There is no answer at present to the inquiry as to the possibility of the formation of alkali carbonate through the carbonation of the alkalis in aggregates, especially those like crushed feldspar containing a considerable amount of alkali; nor to the last two questions raised by Mr. Carlson. This is a fertile field for study.

Mr. Woods has well stated the problems facing the cement manufacturers in reducing the alkalis in cement. It would undoubtedly be an ideal solution if some inexpensive addition to the cement to circumvent the expansive reaction could be found. Such a solution may be found in the nature of a silica admixture that will not only nullify the expansive reaction, but likewise result in a less expensive product. In this respect the data shown in Table 18 are of interest.

Mr. Stadtfeld makes a plea for placing restrictions on water-soluble alkalis rather than on total alkalis and a further plea for the Merriman free alkali test and a limit of 3.5% free alkali under this test. As stated in the paper, under the heading "Merriman Alkalinity and Free Alkali Test," it was found that in the case of the California cements this test is not always consistent with results and, therefore, is not a suitable test as a substitute for total alkalis as determined by chemical analyses. This phase of the subject was discussed with Mr. Merriman when he visited the Laboratory of the California Division of Highways in July, 1939, just prior to his untimely death. After leaving Sacramento, Mr. Merriman wrote the writer as follows:

> "Just a word to say how much I enjoyed my visit of Saturday and how instructive it was. You are on the track and close to the goal of demonstrating that all cements do not always act alike. To me it was inspiring

to see what you have done. Far too few ever look beyond the obvious because they are blind even before they start.

"The literature is full of results attained by the use of unknown materials which are assumed to act alike under all conditions and in all locations. Their history and origin are never known! Is that engineering?"

It may be that, as Mr. Stadtfeld states, the Merriman alkalinity and free alkali tests are suitable quality tests under average conditions, but it is evident that they do not fully satisfy the situation covered by this paper and, on the other hand, may be too severe for universal application.

It is possible that, under certain circumstances, the destructive action taking place in concrete may be one of base exchange involving the calcium in solution, the alkali, alumina, and the silica, somewhat in the manner suggested by Mr. Tremper. If this should be the case, the alkali would be replaced and liberated by the calcium and then could combine with the silica.

Search of available literature yielded no information regarding the expansion, if any, which occurs when the reaction $Na_2OH + Si\,O_2$ takes place. Probably the lack of data is due to the large number of possible combinations of alkali and silica, the majority of which are noncrystalline or colloidal.

Although it is true that large amounts of calcium hydroxide result from the hydration of cement, only a small part of it is in solution and available for chemical reaction.

The solubility of calcium hydroxide at several temperatures is as follows:

1 g of calcium hydroxide is soluble in—

(cc of water)	(Degrees centigrade)
540	0
630	25
1,300	100

As there is not enough water present in concrete to dissolve all of the calcium hydroxide formed, it is not necessary that sufficient sodium carbonate be present to combine with all of the lime hydrate to form the carbonate before the sodium carbonate can crystallize as stated in Mr. Tremper's discussion.

It must be understood that the possibility of the reactions—magnesium carbonate plus sodium hydroxide yielding magnesium hydroxide plus sodium carbonate ($Mg\,CO_3 + 2\,Na\,OH \rightarrow Mg(OH)_2 + Na_2CO_3$); sodium hydroxide plus silica ($Na_2O + Si\,O_2$); or any other chemical activity—is visualized as taking place only at the points of contact of the reactive aggregate and the sodium hydroxide from the cement and not throughout the entire mass of the concrete. This localizes the reaction and further reduces the amount of calcium hydroxide available for the calcium carbonate reaction to which reference has been made.

Mr. Tremper's suggestion that the Na OH acts in a roving commission rather than becoming fixed as a silicate is interesting and a possible situation, but would be more probable if the $Ca(OH)_2$ were more soluble or if there were more free water available.

Mr. Hanna, in his comments, differentiates between the sodium and potassium hydroxide. It was found, in a limited series of tests in which Na OH and K OH were added to the mixing water, that the addition of either accelerated and increased the expansion of the specimens up to a certain percentage addition. Additions above this amount retarded and decreased the action. The writer's work was done on a synthetic sand, made by adding No. 28039 to a neutral sand. Data published by the Bureau of Reclamation show that an increase of Na OH beyond the amount added by the writer accelerates the action with Parker andesite. It is probable that there is a different "pessimum" amount of alkali for various minerals, just as there is a different "pessimum" amount of different minerals for a given alkali content.

The same study indicated that there is very little difference in the effect of the K OH and the Na OH when they are used in equimolar amounts. The molecular weight of sodium hydroxide is 40, whereas that of potassium hydroxide is 56. If the bases are used in that proportion, or equimolar, they react very similarly.

Mr. Blanks lists many materials which he states are known to be reactive. It should not be concluded that all materials of the types listed, such as andesite, rhyolite, felsite, and granite are, of necessity, reactive in all cases, or even at any time reactive just because they are of the types noted, but rather that when reactive it may be because they contain a sufficient percentage of reactive soluble silica of the opaline type.

It is unfortunate if the paper was so worded as to justify the inference of Mr. Blanks that only the sand in the California aggregates carried alkali-reactive materials, as such, of course, is not the case. The rôle of the coarse aggregates has been fully covered in the earlier part of this discussion and need not be repeated. Mr. Blanks has submitted a very valuable contribution to the discussion on this subject.

It is gratifying to note the extent to which Mr. Kinzie, reproduces the results secured in the California studies described in this paper. As previously stated, it is apparent that one highly potential corrective procedure is through the use of suitable puzzolanic admixtures, and this phase merits thorough exploration.

Summary.—In summarizing developments since the paper was published in *Proceedings*, it is interesting to note the extent to which different investigators are now tracing some of their hitherto unexplained concrete failures to a reaction between alkali in the cement and the aggregate.

There is still considerable to be learned relative to the mineral ingredient or ingredients at the base of the trouble, but in the California case, at least, the evidence points conclusively to the opaline types of rocks as contributing at least a major part. Experiences of others, however, indicate rather definitely that opal may not be the only reactive mineral. It is possible that any form of silica that is readily soluble in Na OH may in time contribute to undue expansion, although the writer's tests to date, at normal temperature, do not indicate any excessive expansion in the case of non-opaline rocks.

The maximum amount of alkali that can be tolerated is still a matter for future determination. The California tests indicate that with the California aggregates and California standard cements little concern need be felt if the alkali content is kept below 0.6%, but whether this is universally true, or even locally over a greater period of years than covered by the present series of tests, can only be determined by future developments. At the same time, however, there is considerable ground for hope that some corrective will be found that will afford ample protection in any doubtful cases.

The nationwide investigations now being made by the Bureau of Reclamation will be a most valuable contribution to the study and it is hoped that the Bureau will make the data collected available to the profession at large.

AN INVESTIGATION OF STEEL RIGID FRAMES

BY INGE LYSE,[1] M. AM. SOC. C. E., AND W. E. BLACK,[2]
JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. C. J. POSEY, W. J. ENEY, LAMOTTE GROVER, WILLIAM R. OSGOOD, M. HIRSCHTHAL, JAROSLAV J. POLIVKA, A. C. BARROW, AND W. E. BLACK.

SYNOPSIS

Tests on two riveted-steel, rigid-frame models (scale, 4 to 1) are described in this paper. In one frame, the knee sections were approximately square, having a sharp reentrant angle at the inner corner. The other frame had a large circular fillet at the inside corner of the knee. The frames were tested chiefly as two-hinged structures under working loads.

In general, the structural behavior of the two rigid frames was in accordance with conventional theory. At the knees of both frames, however, the normal stress distribution departed markedly from the usual straight-line relationship. In the square knee, a concentration of stress existed at the inner corner but was found to be of minor importance. In the curved knee, compressive stresses in the flange of the curved fillet were considerably greater than those computed by either the straight-beam or the curved-beam theories. Furthermore, a transverse variation of the stress in the outstanding legs of the curved flange angles increased the high compressive stresses in the curved knee. On the basis of the test results, recommendations for the analysis and design of each type of rigid frame have been made and are presented herewith.

INTRODUCTION

During the decade 1925–1935 there was a growing appreciation of the many structural and esthetic advantages of the rigid-frame type of construction, particularly as applied to short-span bridges. However, due to the lack of available information regarding the stress distribution in this type of structure, especially at the knee section, the steel rigid frame has been viewed with some concern by many engineers.

NOTE.—Published in November, 1940, *Proceedings*.

[1] Prof., Reinforced Concrete and Solid Bridges, Inst. of Technology, Trondheim, Norway; formerly Research Prof. of Eng. Materials, Lehigh Univ., Bethlehem, Pa.

[2] Instr., Dept. of Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.; formerly Am. Inst. of Steel Construction Research Fellow in immediate charge of the Rigid Frame Investigation, Lehigh Univ., Bethlehem, Pa.

In order to remedy this situation, the American Institute of Steel Construction (A. I. S. C.) initiated two experimental investigations of the structural behavior of steel rigid frames. One was conducted on rigid-frame knee sections by the National Bureau of Standards at Washington, D. C.;[3,4,5] and the second investigation, which is presented for discussion in this paper, was conducted on complete one-quarter size models, and was made possible by the establishment of a cooperative research fellowship by the A. I. S. C. and Lehigh University at the Fritz Engineering Laboratory, Bethlehem, Pa.

In the investigation conducted at the National Bureau of Standards, the primary purpose was to determine the stress distribution at the knee section. At Lehigh University, two complete rigid-frame models were tested to secure a check upon the stress distribution obtained by the testing of knee specimens only, and also to permit the observation of other important data regarding the frame as a whole. The focal point of interest was the knee section, although such subjects as movement of foundations and accuracy of conventional methods of analysis and design were also studied.

TEST PROGRAM

The investigation was planned with the view of studying the behavior of the frames when hinged at the supports. The test program was laid out with the following objectives in mind:

A. Determination of stress distribution in the knee section (1—principal stresses and maximum shears, 2—normal stresses and shears on arbitrary sections);

B. Effect of the stress distribution in the knee upon the behavior of the frames as a whole (1—on horizontal reaction, 2—on stresses away from the knee, and 3—on deflections);

C. Effect of simulated foundation slippage (1—on horizontal reaction, 2—on stresses away from the knee, and 3—on deflections);

D. Determination of restraint provided by flat-plate base;

E. Comparison between experimental data and calculated results.

TEST SPECIMENS

In order to compare the results of this investigation with similar tests at the National Bureau of Standards,[3,4,5] the shapes of the knee sections of the two model frames were made respectively similar to two of the specimens tested at the Bureau.

The chief point of difference between the two models was the shape of the knee. One, referred to as the square-knee frame, had a sharp reentrant angle of slightly more than 90° at the inside corner of the knee; whereas the other, designated as the curved-knee frame, had a large circular fillet at the inside of the knee. The details of the two frames are shown in Fig. 1. The method

FIG. 1.—DETAILS OF MODEL FRAMES (SCALE RATIO, 4 : 1)

of fabricating the square knee, showing that the web does not extend through the vertical section at the inside corner of the knee, is illustrated in Fig. 2. The size of the models was chosen to fit the testing machine available, and the applied loads were designed to produce permissible working stresses in the models.

The square-knee frame (Fig. 1(*a*)) was considered to be reduced from an imaginary prototype with a clear span of 72 ft and was designed as the middle one of three such frames spaced 15 ft apart, with framed floor beams and stringers supporting a 36-ft roadway with an H-20 loading. The linear dimensions of the model were one fourth and the cross-sectional areas approximately one sixteenth of those of the prototype. The curved-knee frame (Fig. 1(*b*)) was later designed for the same conditions.

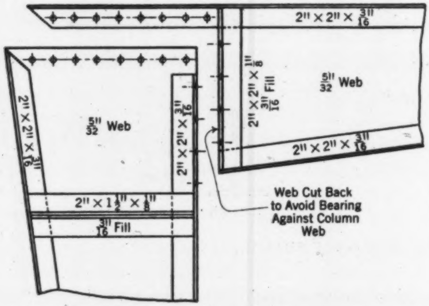

FIG. 2.—FABRICATION DETAILS OF A SQUARE-KNEE FRAME

Due to the small size of the frames, it was considered advisable to have them fabricated at a plant equipped for small-scale iron work rather than at an ordinary structural shop. The square-knee frame was fabricated by the Bethlehem Fence Works, in Bethlehem, and the curved-knee frame by the Allentown Iron Works, in Allentown, Pa.

In general, the workmanship of the two frames was satisfactory. Over-all dimensions and depths of the sections were sufficiently accurate to permit use of the nominal values in all but a few instances. One objectionable feature was found, however, in the square-knee frame. At the intersection of the compression flanges at both knees, where tight bearing should be obtained, small gaps existed. It was considered advisable to fill these gaps with shims that were tackwelded in place, but which produced tight bearing only along the

outstanding legs of the girder flange angles. Thus, a loose fit was eliminated at the expense of a concentration of stress at the bearing. Tensile properties of the material in the two frames are given in Table 1.

TEST METHODS AND OBSERVED DATA

Loading Apparatus.—The frames were tested in a 300,000-lb machine having a 21-ft beam which provided an excellent base on which to set the 18-ft models. The load was transferred from the movable head of the testing machine to two fixed load points on the frames by a system of bars and loading beams, as illustrated in Fig. 3, on the square-knee frame.

The horizontal reaction was resisted by a $\frac{3}{4}$-in. round bar extending between the two column bases in all tests. To allow adjustment of the reaction and the span length of the frame, the ends of the tie bar were threaded and fitted with nuts. Rollers under one of the column bases insured that only a negligible amount of friction might affect the horizontal reaction. The tie-bar attachment and rollers are shown in Figs. 3 and 4.

In order to prevent lateral buckling or twisting of the flexible horizontal girder, trussed frames were built up from the testing machine at midspan, and just inside the inner face of each column, as shown in Fig. 3. The frame had a tendency to bear against all of these lateral supports under load; but only at the

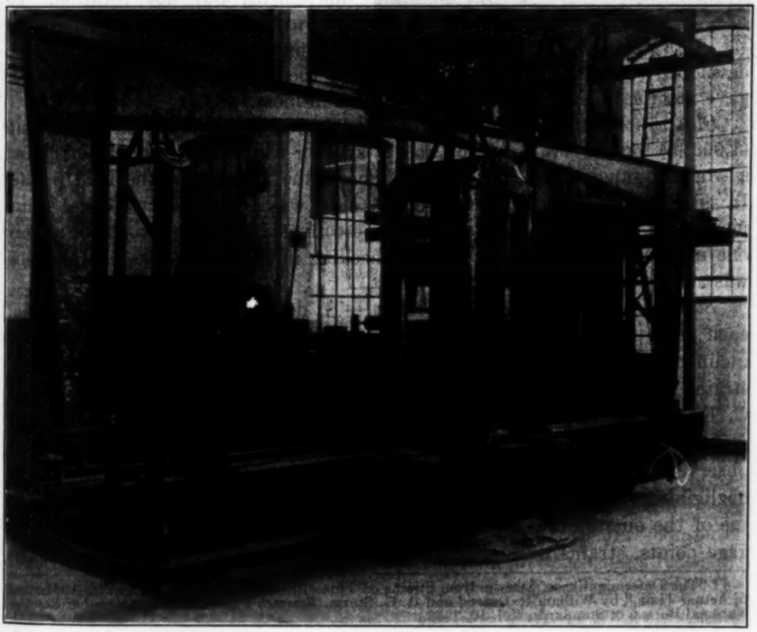

FIG. 3.—SQUARE-KNEE FRAME IN A TESTING MACHINE

center was there any appreciable deflection where frictional resistance to vertical movement might be developed. Comparative tests, with and without the center support, gave practically identical results, so the frictional restraint was considered negligible.

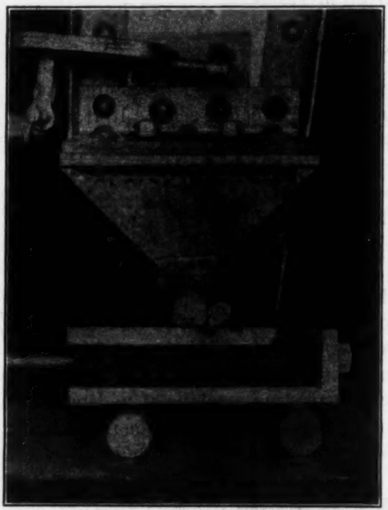

FIG. 4.—MOVABLE HINGED BASE

For the most part the rigid frame specimens were tested as two-hinged frames. Therefore, the apparatus shown in Fig. 4 was developed to provide a point bearing for the frame supports and at the same time transmit the horizontal reaction to the tie bar. The bearing area of the pin was always less than 1 in. wide, which was sufficiently small for the assumption of a point support.

It was also considered worth while to investigate how much restraining moment was produced by the base when the frame rested upon flat bases which restrained horizontal movement, but not rotation. To provide this condition, the two sets of apparatus shown in Fig. 5 were developed (the frame proper is indicated by the shaded areas). Since the two gave identical results, Base No. 2 was used in most tests.

Observations and Test Data; Loading.—In all tests the total load was one kip (1,000 lb) for the zero condition and 13 kips for the working condition, giving a working range of 12 kips. Fig. 1 shows the location of the load points. In some of the early tests, the working load was applied in two equal increments, but for the most part it was found convenient to apply the load in only one increment. For the purpose of checking in the latter case, each loading was always repeated.

Stress Distribution at Knee Sections.—To determine the state of stress at each gage point on the web, three strain readings (horizontal, vertical, and inclined at 45°) were observed. Stresses were obtained from the observed strains by the graphical method developed by W. R. Osgood, M. Am. Soc. C. E., and R. G. Sturm,[6] Assoc. M. Am. Soc. C. E. At each flange gage point, only the strains parallel to the longitudinal dimension of the flange were observed, as the transverse stresses in the flange may generally be considered negligible. Wherever possible, flange strains were observed at both heel and toe of the outstanding legs of the angles and on the edge of the web. At all gage points, strains were observed simultaneously on both sides of the frame in order to eliminate the effect of lateral bending. These strain observations were made with tensometers having 1-in. gage lengths. With these instruments, stresses could be obtained within an expected accuracy of 300 lb per sq in. The instruments were held in position on the web plate by means of $\frac{1}{8}$-in. bolts and holes tapped in the web. As it was desirable to keep the number of holes at a minimum, only three strain readings were observed at each point. Instead of the check usually obtained by the fourth reading, a repetition was made of each loading and observation. The tensometer attachments for web and flange strain measurements are shown in Figs. 3 and 6.

[6] "The Determination of Stresses from Strains on Three Intersecting Gage Lines and Its Application to Actual Tests," by William R. Osgood and R. G. Sturm, *Research Paper No. 559, Journal of Research*, National Bureau of Standards, Vol. 10, 1933.

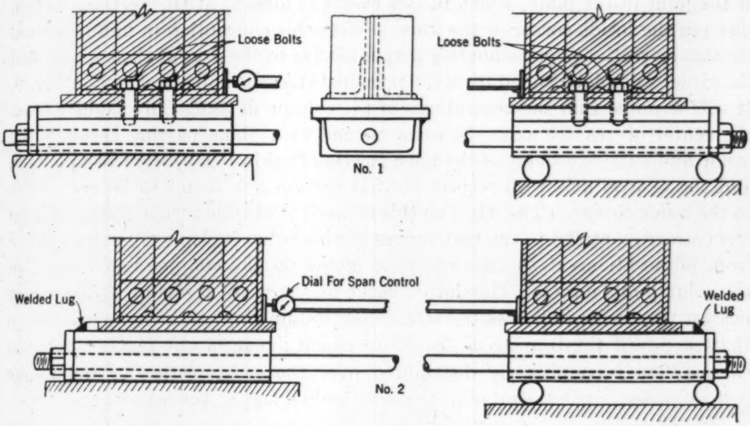

FIG. 5.—FLAT BASE DETAILS

Three complete sets of stress-distribution data were obtained for the square-knee frame, one set for each knee of the frame at normal span length, and one for the east knee with the supports allowed to move outward $\frac{1}{4}$ in. under load. In general, the results for the two knees were so similar that the data from only one are presented herein. The variation of distribution due to movement of the supports is discussed in another section.

For the curved-knee frame (see Fig. 7), two complete sets of stress-distribution data were observed, of which only one is presented herein, for the reason given in the preceding paragraph. The bases were maintained at the normal distance apart for these tests.

From the strains observed at each gage point on the web of each rigid-frame knee, principal stresses and maximum shearing stresses were determined graphically by the method mentioned previously. On the backs of the flanges longitudinal strains only were observed, from which stresses were computed directly. The values of principal stresses and maximum shearing stresses are indicated by lines of equal stress (contour lines) for the square knee in Fig. 8(*a*), and for the curved knee in Fig. 8(*b*). The directions and approximate magnitudes of the principal stresses at each of the gage points are also shown in the diagrams.

In the square-knee frame the knee joint may be considered as a rigid beam-and-column connection in which the column extends to the top of the frame. Whether the girder or column extends through the knee depends on the location of the joint in the plate, which in this case was located at the vertical section through the inside corner of the knee. With this conception in mind, normal stresses on sections approximately perpendicular to the axes of the column and the girder were determined from the principal stresses, and are shown in Fig. 9. It will be noted that the neutral axis of the column deviates only slightly from the center of gravity axis. Stresses normal to a plane passing through the inside and outside corners of the knee (section *O–O* in Fig. 9) were also plotted, and the neutral axis with respect to that section was found to be very close to the inside corner. The stress on this plane at the inside corner was computed from stresses parallel to the two flanges at this point, which were extrapolated from observations at the nearest gage points on the compression flanges of the column and girder. The dotted curve on the vertical section in the girder nearest the corner indicates the stress distribution that might have existed on that section if the bearing of the compression flange of the girder upon the column had been properly distributed over the cross section of the flange instead of being concentrated in the outstanding legs of the angles.

In the testing of the curved-knee frame it was observed that the stresses at the toes of the outstanding legs of the curved flange angles were only 40 to 70% of the stresses at corresponding points at the heels of the angles or on

FIG. 6.—TEST SET-UP SHOWING ARRANGEMENT OF TENSOMETERS ON THE SQUARE-KNEE FRAME

the edge of the web. The stresses at the heels of the angles and on the edge of the web agreed very closely. Fig. 10 shows flange stresses observed on three sets of gage lines: On the edge of the web, at the heels of the angles, and at the toes of the angles. This transverse variation of stress in the outstanding legs of flange angles did not exist to any extent on straight flanges whether subjected to tension or compression. The explanation of this phenomenon was found to be a kind of buckling action in which the outstanding legs of the curved flange angles bent away from their center of curvature, thus elongating relative to the edge of the web and relieving some of the compression in the outstanding legs. For the observed differential in stress between the edge of the web and the toes of the angles to have taken place, the toes of the outstanding legs would have had to deflect about 0.01-in. relative to the edge of the web. The slight transverse bending observed, as measured by a transverse bending stress of about one kip per sq in., was not sufficient, however, to produce this deflection, indicating that some rotation was probably taking place about the rivet line. The stresses on all three sets of gage lines increased approximately in proportion to the load.

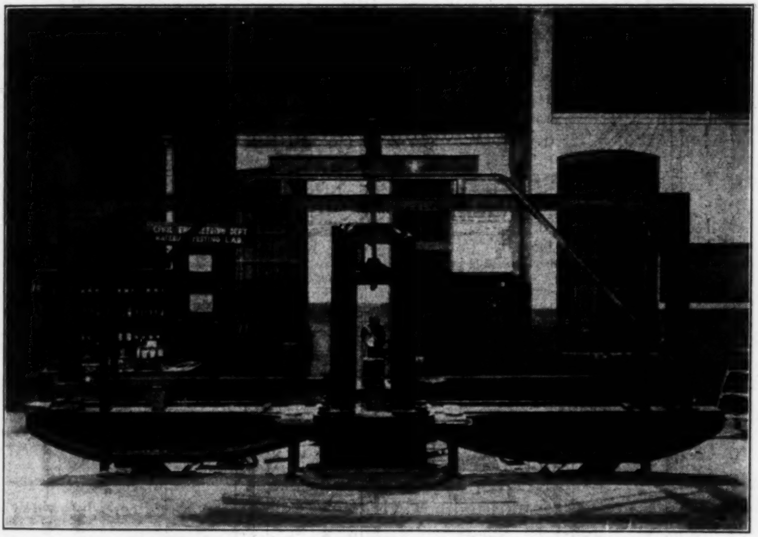

FIG. 7.—CURVED-KNEE FRAME AND DEFLECTION APPARATUS

Normal stresses on planes radial to the curved flange are shown in Fig. 11. It will be noted that the straight-line distribution of stress of the straight-beam theory does not exist on the sections within the knee, and that the neutral axis is between the center-of-gravity axis and the curved flange. stress values at the back of the curved flange indicated in Fig. 11 were obtained by assuming that the stress was constant across the backs of the angles at each section, that the neutral axis would remain where observed, and that the moment of the compression area about the neutral axis would be the same as observed. From the observed stresses and the position of the neutral axis, the average stress was then computed. The difference between the maximum and average stresses was as much as 25% at some gage points.

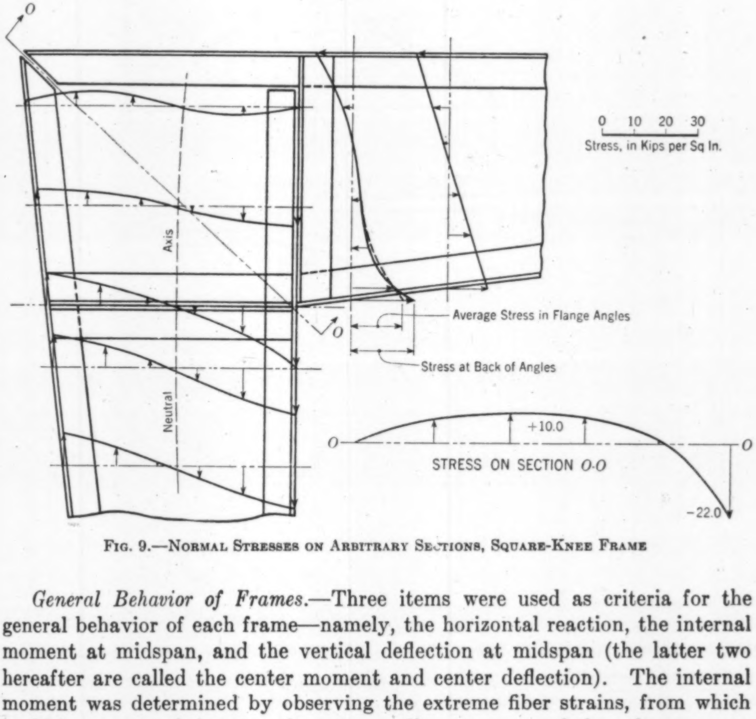

FIG. 9.—NORMAL STRESSES ON ARBITRARY SECTIONS, SQUARE-KNEE FRAME

General Behavior of Frames.—Three items were used as criteria for the general behavior of each frame—namely, the horizontal reaction, the internal moment at midspan, and the vertical deflection at midspan (the latter two hereafter are called the center moment and center deflection). The internal moment was determined by observing the extreme fiber strains, from which could be computed, in turn, the extreme fiber stresses and then the moment, assuming that the conventional theory of flexure held true at this location. The horizontal reaction was determined by observing the strain in the tie bar with a 10-in. strain gage and computing the stress and load therefrom. The vertical deflection of the frame at midspan was measured by a 0.001-in. Ames dial between the top flange of the frame and a framework built up from the bases of the frame as shown in Fig. 7.

Load-reaction curves and load-deflection curves for each frame, shown in Fig. 12, illustrate that the frame as a whole behaved as an elastic structure; that is, the observations varied in direct proportion to the load. Individual stress observations were generally made in only one increment; but at several random points load-stress data were observed, and a straight-line relationship was obtained.

Since only six 1-in. extensometers were available for use (all of these being stationary by nature) many repetitions of loading were necessary to obtain all the desired data. Strain observations on the tie bar were made at regular intervals throughout the course of the testing, and no appreciable change in reaction was noticed. Evidently such phenomena as permanent set due to high localized stresses and slippage of rivets, if such existed, had a negligible effect on the frame as a whole. However, a decrease of about 5% in the high localized stresses at the inside corner of the square knee occurred during the course of the testing.

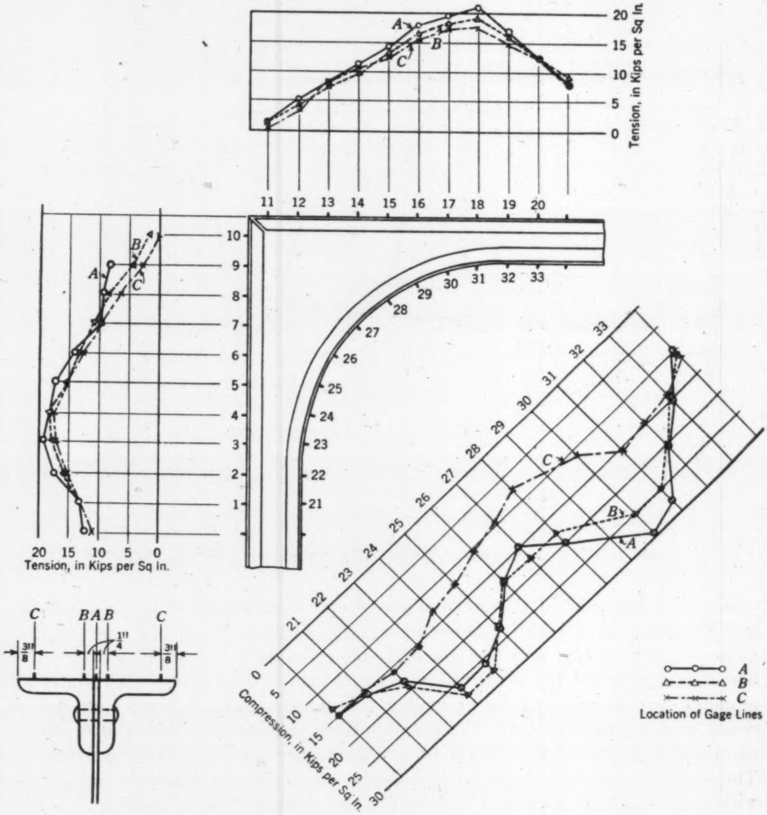

Fig. 10.—Flange Stresses on Various Gage Lines, Curved-Knee Frame

Horizontal Movement of Supports.—In order to simulate one of the most important problems in rigid-frame construction—that of horizontal foundation movement—the bases of the frames were moved inward or outward as the load was being applied. Each frame was studied under five such conditions, the span length being varied from the no-load state by the following amounts: $-\frac{1}{2}$ in., $-\frac{1}{4}$ in., 0 in., $+\frac{1}{4}$ in., and $+\frac{1}{2}$ in. A $\frac{1}{4}$-in. movement in the model corresponded to a 1-in. movement in the prototype.

FIG. 11.—NORMAL STRESSES ON RADIAL SECTIONS, CURVED-KNEE FRAME

The adjustment of the span length was controlled by a 0.001-in. Ames dial bearing against one column base and fastened to a long light angle clamped at its opposite end to the other column base. Rollers supported the angle along its length. The two ends of this device are shown in Fig. 5. Readings at zero load were always taken at normal span length; that is, the span length (distance between supports) under no load. As the load was being applied, the span was adjusted by the nuts on the tie bar, so that, at maximum load, the span length was as desired, either normal, or plus or minus a given quantity.

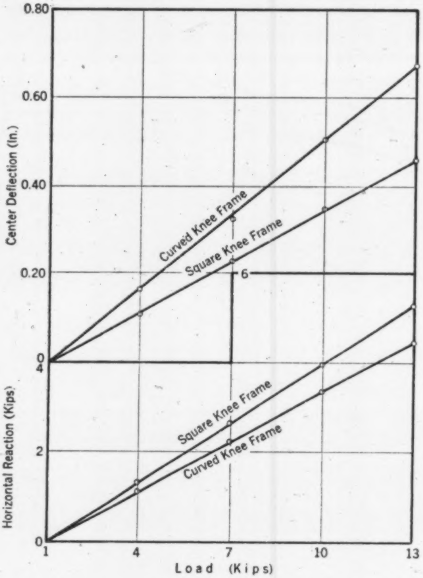

FIG. 12.—OBSERVED LOAD-DEFLECTION AND LOAD-REACTION CURVES FOR NORMAL SPAN

For each test, the horizontal reaction, the center moment, and the center deflection were determined from observations. The values of these quantities for each of the variations of span length are shown plotted with computed values in Fig. 13 for both rigid frames. It is noted that a linear variation was found for each of the items observed.

A complete set of stress-distribution data was observed for one of the knees of the square-knee frame with the supports allowed to move outward $\frac{1}{4}$ in. relative to each other under load. The results obtained were qualitatively similar to those presented in the paper obtained for the normal span condition (Fig. 8(*a*)), the values of the stresses observed being slightly less, as would be expected in view of the fact that the moments and shears acting on the knee are smaller if the supports are allowed to move outward.

Flat Base Tests.—Both frames were tested while supported on the flat plate bases shown in Fig. 5 in order to determine the amount of rotational restraint produced by this type of a base. Internal moments were determined from flange strain measurements at two locations in each frame. Since the horizontal reaction was also observed, it was then possible to compute the location of the point of inflection in the column, if it existed. In both frames, the point of inflection was found to be so close to the base of the column that this type of base was considered to produce, in effect, a hinged support.

Further evidence that the frames resting on the flat plate bases acted as hinged frames is presented in Table 2, which gives ratios of observed to computed horizontal reactions, center moments, and center deflections for both hinged and flat-base tests. All computations were based on the assumption that a hinge existed at the base. It is noted that the two base conditions gave very similar results for both frames.

RELATION OF TEST DATA TO ANALYSIS

Moment of Inertia.—A test was made to determine the correct moment of inertia for use in computations. With the curved-knee frame inverted in the testing machine, the girder that was of uniform section was tested as a simple beam with two equal and symmetrically situated loads. At a working load for the girder, strains were observed on the top and bottom of the girder. Stresses were computed from the observed strains, and the effective moment of inertia was computed from the extreme fiber stresses, applied loads, and dimensions of the girder.

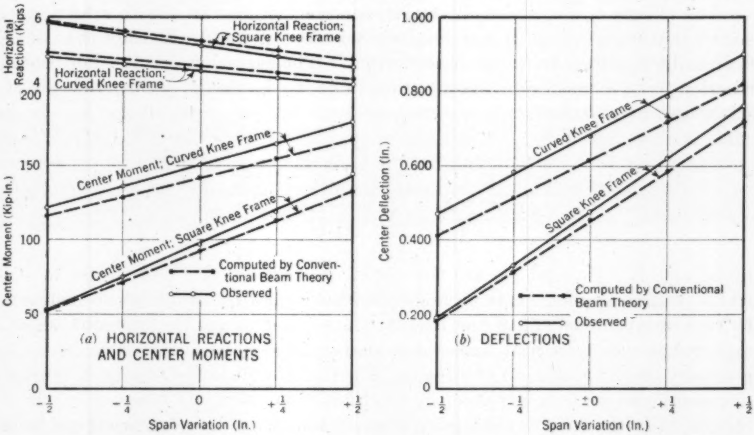

FIG. 13.—COMPARISON OF OBSERVED AND COMPUTED REACTIONS, MOMENTS, AND DEFLECTIONS

The effective moment of inertia was slightly less than the gross moment of inertia, and almost exactly equal to that obtained by assuming the total volume of the rivet holes to be uniformly distributed along the length of the girder. This average moment of inertia was used in all computations. If the gross moment of inertia had been used, the error would have been about 3% for this girder.

TABLE 2.—COMPARISON BETWEEN HINGED-BASE AND FLAT-BASE RESULTS

$$\left(\text{Ratio} = \frac{\text{Observed}}{\text{Computed}} \right)$$

Type of base	(a) SQUARE-KNEE FRAME			(b) CURVED-KNEE FRAME		
	Horizontal reaction	Center moment	Center deflection	Horizontal reaction	Center moment	Center deflection
Hinged	0.985	1.06	1.02	0.965	1.07	1.10
Flat	0.975	1.08	1.04	0.955	1.09	1.11

Horizontal Reaction.—In order to compare the test results with computed values, analyses were made for both frames by the Maxwell-Mohr (unit dummy load) method as applied to a two-hinged arch. Since both frames were of non-uniform cross section, the members of each frame were arbitrarily divided into short sections and the necessary integrations were made as algebraic summations. The arbitrary sections are shown in Fig. 1.

The effects of shear and direct stress were included in the computations, since for comparison with test results a greater degree of accuracy than that ordinarily required in design was desired. The equation for the horizontal reaction (H), considering deformations due to bending, shear, and direct stress, can be written:

$$H = \frac{\sum \frac{M_1\, m_h\, \Delta s}{E\, I} + \sum \frac{V_1\, v_h\, \Delta s}{A_w\, G} + \sum \frac{N_1\, n_h\, \Delta s}{A\, E}}{\sum \frac{(m_h)^2\, \Delta s}{E\, I} + \sum \frac{(v_h)^2\, \Delta s}{A_w\, G} + \sum \frac{(n_h)^2\, \Delta s}{A\, E}} \qquad \text{(1)}$$

in which: M_1, V_1, and N_1 are the actual moment, shear, and thrust in the frame, due to applied loads on a simple frame (that is, assuming no restraint to horizontal movement of the bases); m_h, v_h, and n_h are the moment, shear, and thrust due to a unit horizontal load applied at the supports; Δs is an arbitrary length of section of a frame; E is the modulus of elasticity in tension and compression; G is the shearing modulus of elasticity; I is the moment of inertia; A is the total cross-sectional area; and A_w is the cross-sectional area of the web. Actual evaluation of the different quantities indicated that, for rigid frames of types similar to the two models, the last two terms of the numerator and the last term of the denominator may be neglected for all practical purposes, giving:

$$H = \frac{\sum \frac{M_1\, m_h\, \Delta s}{E\, I}}{\sum \frac{(m_h)^2\, \Delta s}{E\, I} + \sum \frac{(v_h)^2\, \Delta s}{A_w\, G}} \qquad \text{(2)}$$

Neglecting the remaining shear term would introduce an error of about 3% for the square-knee frame and about 1% for the curved-knee frame.

The application of Eq. 2 for H is a routine matter provided the structure behaves in accordance with the assumptions on which the theory is based. Figs. 9 and 11 show, however, that at the knees of both rigid frames straight-line distribution of normal stresses does not exist, and, in all probability, sections that are plane before bending do not necessarily remain plane after bending. As a result, the actual bending deformations $\frac{M\, \Delta s}{E\, I}$ and the approximate shearing deformations $\frac{V\, \Delta s}{A_w\, G}$ in the sections at the knee will differ from those computed by the Maxwell-Mohr theory[7] for straight beams. Therefore, a study of the stress distribution at the knee of each frame was made to determine the treatment of the corner sections that would most nearly approach actual conditions as interpreted from observed data.

---

[7] "Elementary Treatise on Statically Indeterminate Stresses," by J. I. Parcel and G. A. Maney, Members, Am. Soc. C. E., John Wiley & Sons, Inc., New York, 2d Ed., 1936, Chap. 1.

The changes in theoretical horizontal reaction due to variations in span length were determined directly from Eq. 2. The numerator of Eq. 2 represents the horizontal deflection of the supports due to the applied loads when the supports are free to move horizontally; that is, the variation in span length for a 100% change in reaction. Since the change in reaction is proportional to the variation in span length for a given loading, the horizontal reactions for the various span lengths were obtained by direct proportion.

Deflections.—Vertical deflections at the center of each frame were computed by the Maxwell-Mohr method, involving the application of a vertical unit load at the point at which the deflection was desired. For convenience, it is recommended that the moments due to the unit load be computed for the determinate frame (supports free to move horizontally), that is:

$$\delta = \sum \frac{M\, m\, \Delta s}{E\, I} \qquad (3)$$

in which: δ = deflection at any point; M = actual moments in the structure due to applied load; and m = moments due to a unit load applied to the determinate structure at the location of, and in the direction of, the deflection desired.

Corner Section, Square-Knee Frame.—Of primary importance is the degree to which the sections within the knee may influence the determination of the horizontal reaction. Total neglect of knee sections in the computations for horizontal reaction (that is, considering the knee to be infinitely stiff) increased the computed value by about 3%.

An approximation to the actual deformation of the square knee was obtained from the information in Fig. 8(*a*). Since the principal stresses within the knee were approximately circumferential and radial, the knee was divided into circumferential bands, as shown in Fig. 14(*a*). Average radial and circumferential stresses were assigned to the bands in accordance with the observed stress distribution. From the average principal stresses the elongation of each band was computed, which, when plotted together, gave the total angular change between the two internal faces of the square knee, also shown in Fig. 14(*a*). This angular change was practically the same as that computed from the observed shears in the knee (Fig. 14(*b*)), indicating that bending, as ordinarily considered, contributed very little to the deformation of the knee.

The effect of shear in the knee is represented by the analysis presented in Fig. 14(*c*), in which $\sum \frac{V\, \Delta s}{A_w G} = 0.00072$. This practice of treating the column as a free body acted upon by the reactions of the frame and by the flange forces and end shear of the girder (neglecting the moment and thrust carried by the web) is used now by some designers. When the knee is considered to be loaded in this manner, bending about the neutral axis of the column will contribute little to the effective deformation of the knee which was already indicated by test results in Fig. 14(*a*) and Fig. 14(*b*).

Two conventional methods of treating the corner of a square rigid-frame knee for mechanical integration are shown in Fig. 14(*d*), in which $\sum \frac{M\,\Delta s}{E\,I} = 0.0018$; and Fig. 14(*e*), in which $\frac{M\,\Delta s}{E\,I} = 0.0017$. The computed bending deformations at the knee for the two cases were approximately equal and considerably greater than the deformation indicated by the analysis shown in Figs. 14(*a*) and 14(*b*). If, however, the effect of shear is neglected throughout the frame (as would be done in design), the large bending deformation assigned to the knee tends to offset the absence of shear deformation in the frame as a whole. The results thus obtained differed only slightly from those in which shear was considered. A comparison between the observed horizontal reaction and the values obtained by the several treatments of the knee section is as follows:

Computed by Analysis in Figs. 14(*d*) or 14(*e*):	
Shear included	5,320
Shear neglected	5,360

Computations of all theoretical values used for comparison with observed values were based upon the treatment shown in Fig. 14(*c*), including the effect of shear.

In connection with the rigid-frame investigation conducted at the National Bureau of Standards, a theoretical analysis[3] of a rectangular rigid-frame knee was developed. The analysis involved an application of the theory of elasticity to a rectangular plate loaded at the edges with shears, thrusts, and moments in its own plane as shown in Fig. 15. The resulting contours of principal stresses and maximum shears, which were computed by H. D. Hussey, M. Am. Soc. C. E., for a rigid-frame knee of practically identical proportions as the square knee are also given in Fig. 15. By comparison with Fig. 8(*a*) it is noted that the general agreement between theoretical and observed results is very satisfactory.

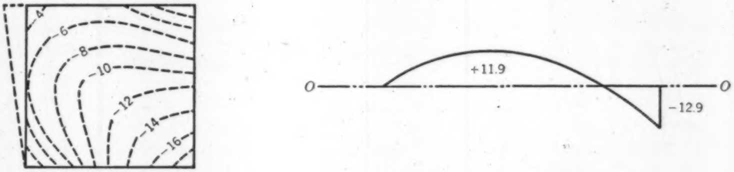
CONTOURS OF MAXIMUM STRESS



CONTOURS OF MINIMUM STRESS

NORMAL STRESS ON 45° PLANE, STRESSES IN KIPS PER SQ IN.

Fig. 15.—Analysis of Rectangular Knee by the Theory of Elasticity

A comparison of observed and computed extreme fiber stresses in the vicinity of the knee is presented in Fig. 16. Computed stresses are based on the conventional formulas for flexure and direct stress. In plotting the computed tension values it was assumed that the stresses reach a maximum at the section that passes through the inside corner of the knee, and decrease uniformly along the flanges of the knee to zero at the outer corner. The stresses represented by triangular dots on the vertical section passing through the inside corner of the knee were computed on the assumption that the flange angles of the girder transmitted all of the moment and thrust in the girder to the column. This assumption is reasonable if it is noted that the web splice is located at this section.

A simple method for computing normal stresses on the 45° plane through the inside corner of the knee was developed from the test data shown in Fig. 9. In accordance with the stress distribution on the diagonal plane, the neutral axis for this section was assumed to be at one fifth the length of the diagonal from the inside corner, the tension stress area was assumed to be a second-degree parabola, and the compression-stress area a triangle. With these assumptions and the equilibrium equations for direct stress and bending on the section, the maximum values of tension and compression stresses were determined. Considering the compression flange (but not the tension flange of the girder nor the horizontal stiffening angles) to be acting with the web, the maximum tension and compression stresses computed by the foregoing method fell within 5% of the observed values.

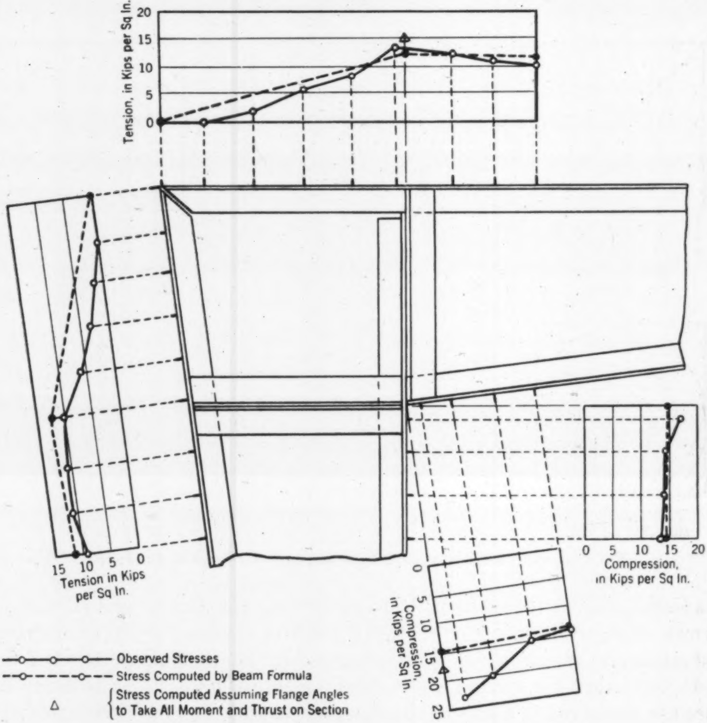


FIG. 16.—COMPARISON OF OBSERVED AND COMPUTED FLANGE STRESS

Fig. 8(*a*) shows that the maximum shearing stresses are very nearly constant over most of the web in the knee and are all approximately horizontal and vertical, being inclined at 45° to the direction of the principal stresses. Computations show that the average of the horizontal shearing stresses over the entire knee is 98.4% of the average of the maximum shearing stresses. Thus, a correct determination of the horizontal shearing stresses would be adequate for design purposes. Fig. 17 presents a comparison between the horizontal shearing stresses determined from observations and those computed on the assumption that the web resists a horizontal shear equal to the tension in the top flange of the girder. The girder flanges have been assumed to take all the moment and thrust on the section at the column face as shown in Fig. 17.

Computed on the Basis of Indicated Loading

FIG. 17.—AVERAGE HORIZONTAL SHEARING STRESSES IN THE SQUARE KNEE, IN POUNDS PER SQUARE INCH

Corner Section, Curved-Knee Frame.—In the curved-knee frame the horizontal reaction was 3.5% below the computed value. Average compression-flange stresses at the knee varied from 15% to 50% in excess of stresses computed by the conventional formulas for flexure and direct stress as shown in Fig. 18. Therefore, the bending deformations in sections within the knee were probably greater than those computed by conventional methods—that is, the knee was not as stiff as assumed. To remedy this condition, a simple and arbitrary method for reducing the moments of inertia and section moduli of sections within the knee was developed from the test results. Using these modified values, computations gave a horizontal reaction and compressive stresses within the knee in close agreement with the observed data.

For knees of this type radial sections are the most convenient to use and were employed in all analyses involving mechanical integration. To obtain what will be called the "effective" section modulus (S') for each section, the moment at a given section was divided by the average observed compressive stress at the extreme inner fibers. The ratio of "effective" section modulus to actual section modulus $\left(\frac{S'}{S}\right)$ was determined for each section and plotted against a central angle C, as shown in Fig. 19. The approximately linear relationship between the ratio $\left(\frac{S'}{S}\right)$ and the angle C can be expressed by the linear equation,

$$\frac{S'}{S} = 1 - \tfrac{1}{2}\left(\frac{C}{45}\right) \quad \ldots\ldots\ldots\ldots (4a)$$

that is,

$$S' = S\left(1 - \frac{C}{90}\right) \quad \ldots\ldots\ldots\ldots (4b)$$

Due to the origin of Eq. 4, the compressive stresses based on the "effective" section moduli agreed closely with the average observed compressive stresses. Furthermore, the same principle used in the modification of the section modulus may be applied to the moment of inertia in order to correct for the discrepancy in observed and computed horizontal reactions. The procedure in an actual design, assuming that the stress in the extreme compressive fibers is constant across the width of the flange, would be to compute the "effective" moment of inertia, I', from the relationship:

$$I' = S'c \ldots\ldots\ldots\ldots (5)$$

in which c is one half the actual depth of section. In the case of the curved-knee frame, however, the deformation of the knee depended not on the average flange stresses, but on the maximum compressive stresses which occurred at the

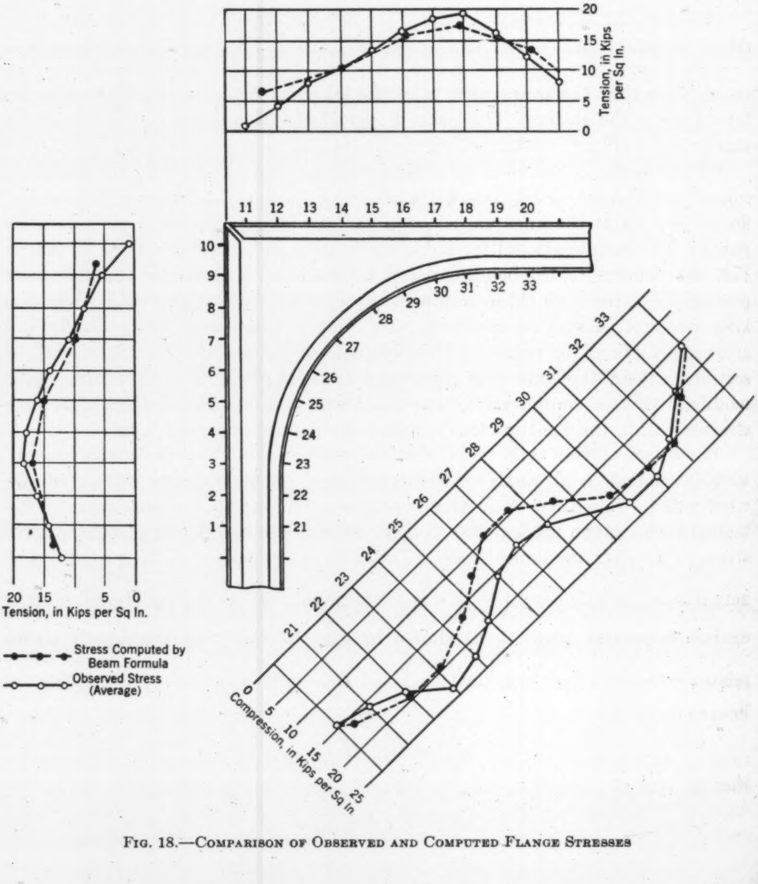

Fig. 18.—Comparison of Observed and Computed Flange Stresses

edge of the web. By using the "effective" moments of inertia based on the maximum compressive stresses in the web, the value of the theoretical horizontal reaction (neglecting shear) was reduced from 4,690 lb to 4,480 lb, as compared with the observed value of 4,530 lb.

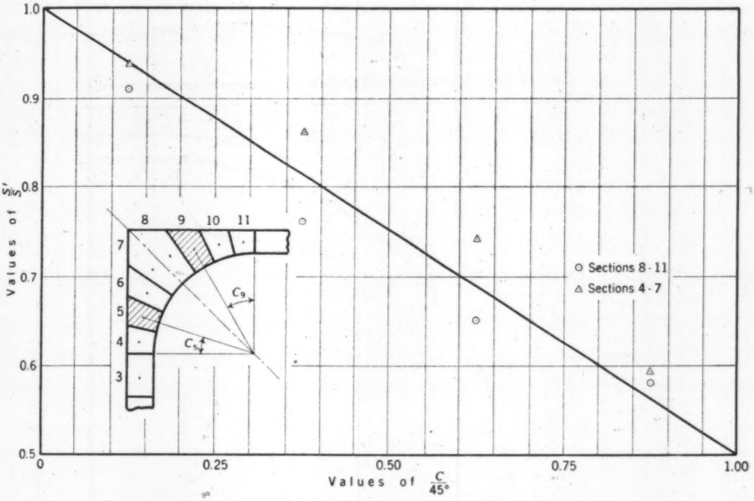

FIG. 19.—GRAPH FOR THE DETERMINATION OF A MODIFIED SECTION MODULUS

Maximum tensile stresses at the knee occurred at the outer extreme fibers of sections near the points of tangency of the curved flange and were in fairly close agreement with values computed by the conventional formulas for flexure and direct stress (Fig. 18). On the radial section through the exterior corner of the knee, however, the maximum tensile stress cannot be computed in this manner. A simple solution for this section was derived from the test results in Fig. 11, identical in principle with the method applied to a corresponding section in the square-knee frame. The assumptions made were that the neutral axis was one quarter the distance from the compression flange to the exterior corner, and that the stress distribution followed a second-degree parabola on the tension side and a triangle on the compression side. Assuming that the tension flange angles did not act with the web, and applying the equations of equilibrium, the maximum observed tension and compression stresses on the section were checked within about 10%. Since this is not likely to be a critical section, the check was considered satisfactory.

In connection with the tests on rigid-frame knees made at the Bureau of Standards, an analysis[4,8] was developed by Mr. Osgood for the knee frame with the curved inner flange. This analysis determines normal and shearing stresses on arbitrary circular-cylindrical sections for members having nonparallel

---

[8] "A Theory of Flexure for Beams with Nonparallel Extreme Fibers," by W. R. Osgood, *Journal of Applied Mechanics*, September, 1939.

extreme fibers. No consideration is taken of the possibility that the edges of the member may be curved. A comparison of normal stresses computed by this method and observed normal stresses is presented in Fig. 20 for the curved-knee frame. In general, the observed stresses at the extreme fibers are somewhat higher than the computed stresses, although the agreement is considerably better than that obtained by comparison with the theory of flexure for straight beams with parallel edges. The neutral axis, as located in Fig. 20, is the axis of zero stress rather than the true bending neutral axis.

FIG. 20.—COMPARISON OF OBSERVED NORMAL STRESSES WITH ANALYSIS AT NATIONAL BUREAU OF STANDARDS

In Fig. 8(*b*) it is noted that the greatest maximum shearing stresses in the knee, except those at the curved flange, lie approximately within a square, at the exterior corner of the knee, with two of its boundaries coinciding with the straight flanges of the knee and with its interior corner on the observed neutral axis (see Fig. 11). This square is shown in detail in Fig. 21. From Fig. 8(*b*) it is also noted that the maximum shearing stresses within the square are nearly all horizontal and vertical. The forces acting on this section of the web are illustrated in Fig. 21, the shears introduced by the flange tensions being very great in comparison to the bending loads due to the web. Therefore, the horizontal and vertical shears in the square were considered to be approximately equal to the shear introduced by the flanges. The total stress in the angles that must be unloaded into the web through the rivets along the two exterior sides of the square can be computed by the conventional formulas for flexure and direct stress. Assuming the square to be isolated from the remainder of the knee and loaded with horizontal and vertical shears equal to the average of the tensions in the two flanges, which were nearly equal, the resulting average shearing unit stress agreed closely with the observed maximum shearing stress. The comparison between observed and computed results is shown in Fig. 21. The high shearing stresses along the curved flange are a direct function of the normal stresses there, and they will not become excessive if the normal stresses do not exceed working limits.

FIG. 21.—SHEARING STRESSES IN THE CURVED KNEE

General Behavior of Frames.—The extent to which the frames, each considered as a whole, behaved in accordance with currently accepted theory is shown in Fig. 13. For both frames the observed horizontal reactions were slightly less than the computed values, varying from 0 to 4% for the square-knee frame, and being constant at about 4% for the curved-knee frame. The observed center moments and deflections were greater than the computed values, varying from 0 to 8% for the square-knee frame, and from 5 to 13% for the curved-knee frame. According to the laws of the statics, observed reactions and center moments should always check each other. In general they agreed very well. Any excessive deformation at the knee sections would be reflected

TABLE 3.—COMPARISON BETWEEN TEST DATA AND COMPUTED VALUES FOR TESTS ON NORMAL SPANS

Description	(a) SQUARE-KNEE FRAME			(b) CURVED-KNEE FRAME		
	Horizontal reaction (lb)	Center moment (kip-in.)	Center deflection (in.)	Horizontal reaction (lb)	Center moment (kip-in.)	Center deflection (in.)

Computed from observed horizontal reaction	....	98	0.485	....	154	0.700

in the value of the horizontal reaction obtained, but not in the relation between the observed reaction and observed moments.

By comparing the observed values of horizontal reaction, center moment, and center deflection with theoretical values and with semi-theoretical values obtained by using the observed horizontal reaction, a good indication of the efficiency of the knee joint as well as of the frame as a whole was obtained. Such a comparison is given for each frame in Table 3. All values refer to the normal span condition.

DISCUSSION OF RESULTS

Stress Distribution, Square-Knee Frame.—In general, the parts of the frame outside of the knee behaved in accordance with conventional theory. On sections only a few inches away from the boundaries of the knee, straight-line distribution of normal stresses was obtained. However, immediately adjacent to the knee, observed stresses in the compression flanges of both column and girder were considerably greater than stresses computed by the conventional beam formula for flexure and direct stress. Probably two principal causes contributed to this condition. First, the web of the frame was discontinuous through the vertical joint at the knee, which resulted in the flanges of the girder carrying more than their share of the moment and thrust on the section at the column face. This premise is upheld by the normal stress distribution shown in Fig. 9 on the girder section next to the knee. It is noted that on this section the web is understressed and the flange angles overstressed. Second, the presence of shims between the compression flange of the girder and the column caused practically all of the compression in the girder to be transmitted to the column through the outstanding legs of the flange angles. At a point on the girder 2.5 in. from the column face, the outstanding legs were carrying about three fourths of the total load in the compression-flange angles. The average stress in the compression flange agreed closely with the stress computed on the assumption that the girder flanges carry all the moment and thrust in the girder at the knee joint. The high stress noted in the compression flange of the column at the inside corner of the knee was probably caused, in part, by the extreme concentration of bearing at that point. It seems probable that any additional concentration of stress in the column or girder at the knee because of the sharp reentrant angle was of small magnitude.

Whatever concentration of stress does exist is directly dependent upon the bearing condition at the corner. An accurate fit along the entire joint will produce lower stresses in the flanges but higher stresses in the web. Local variations of this nature are of general occurrence in steel structures, where these high localized stresses are usually disregarded as unimportant. Therefore, with regard to concentrations of stress at sections adjacent to the knee, the rigid frame may be treated as any other steel structure. However, a loose fit is to be avoided because of the possible effect on the horizontal reaction and therefore on the stresses at midspan.

Within the knee the stress distribution cannot be determined by any simple theoretical analysis. The application of the theory of elasticity is too complicated and tedious for practical use by designers. Moreover, Figs. 9 and 16 indicate that the critical sections for normal stresses at the knee are the horizontal and vertical sections through the inside corner of the knee, which were discussed in the preceding paragraph.

Shearing stress is apparently quite important in a rigid-frame knee of this type. The unit shearing stress in the web within the knee was about twice the stress just outside the knee, which is ordinarily considered to be the critical section with respect to shear. A study of the maximum shears (Fig. 17) showed that designing for horizontal and vertical shearing stress in the knee, on the basis of an external shear equal to the total tension in the top flange of the girder, was both adequate and correct.

Stress Distribution, Curved-Knee Frame.—As in the case of the square-knee frame, the parts of the frame outside the knee gave results in accord with conventional theory. Within the knee, the stress distribution differed markedly from that obtained by the ordinary beam theory. Throughout the entire curved part of the compression flange at the knee, the observed stresses were much greater than the computed values. Two factors probably contributed to the observed difference. First, the neutral axis has a pronounced curvature at the knee. However, an application of the curved-beam theory could account for only a small part of the differences between observed and computed stresses, particularly on the compression flange. The second and possibly the most important factor is the rapid change of section that occurs at the knee. This latter problem introduces complexities that may be solved reasonably only by a highly theoretical analysis, or by an arbitrary procedure based on test results. The arbitrary procedure presented in the section on analysis gave good agreement with the observed results, but it made no differentiation between the separate effects of the two aforementioned factors. Such a differentiation would be necessary if the method of analysis were to be extended to knees having decidedly different degrees of curvature or different proportions of flange area to web area.

The stress distribution was complicated by a stress relief in the outstanding legs of the curved flange angles. The radial component of compression due to the curvature of the flange caused the outstanding legs to deflect away from the center of curvature and thus elongate relative to the edge of the web. However, if there had been a cover plate on the backs of the curved flange angles, it is possible that no appreciable radial displacement of the outstanding legs could have occurred. Not only would the outstanding legs have been reinforced by an additional thickness of metal, but any rotation of the individual angles about the rivet line would have been effectively reduced. In the section on analysis it was assumed that cover plates would be present. Consequently the effect of stress relief in the outstanding legs was eliminated by using an average extreme fiber stress, although this phenomenon is too important to be overlooked in design.

The analysis developed by Mr. Osgood was applied to the curved-knee frame, and it gave fairly good agreement with the observed results, although the observed extreme fiber stresses along the curved flange were somewhat higher than those computed by this method. In the Bureau of Standards' tests on a rigid-frame knee of similar shape and proportions, the observed extreme fiber stresses along the curved flange were slightly lower than the computed stresses. This apparent discrepancy might have been caused, in part, by the presence of the transverse variation of stress across the outstanding legs of the curved flange angles. In the tests described herein, strains were measured on several gage lines (Fig. 10) and an attempt was made to determine a properly weighted average extreme fiber stress. To the best knowledge of the writers, in the Bureau of Standards' tests, strains were measured on two symmetrically situated gage lines, each about midway out on the outstanding leg of a flange angle. The difference in the manner of observation would cause the Lehigh results to be higher relatively than the Bureau of Standards' results, and may afford the explanation for the apparent disagreement cited. Since this method of analysis did not take into consideration the curvature of the frame at the knee, it is not without reason that the observed normal stresses in the curved flange might be slightly greater than the computed values. If the effect of the curvature of the neutral axis were taken into account, it is probable that an even better agreement with the observed compressive stresses could be obtained.

General Behavior.—In both frames the observed horizontal reactions were slightly lower than the computed values, 1.5% for the square-knee frame and 3.5% for the curved-knee frame. These relations refer to the normal span condition. Although this degree of accuracy appears to be satisfactory, the discrepancy is on the dangerous side. A decrease in the horizontal reaction will produce an increase of much greater magnitude in the center moment. A greater degree of accuracy in the computations was obtained for the curved-knee frame by arbitrarily reducing the moments of inertia within the knee in accordance with observed stresses.

In general, observed center moments and deflections agreed very well with corresponding values computed from the observed horizontal reactions. Therefore, the accuracy with which stresses and deflections can be computed is merely a reflection of the accuracy of the computations for the horizontal reaction. In other words, the knee of a two-hinged rigid frame affects the frame as a whole only in so far as it affects the horizontal reaction.

The observed normal span deflections of 0.46 in. and 0.67 in. for the square-knee and curved-knee frames, respectively, seem large when it is considered that the deflections in the prototypes are four times as great. In this connection, reference is made to deflection tests,[9] reported by R. M. Hodges, M. Am. Soc. C. E., on three structural-steel rigid-frame bridges in Westchester County, New York. In these tests, the floor systems and cutoff walls, which were not included in the deflection calculations, evidently acted with the frame girders to a great extent. The observed deflections in some cases were only one eighth of the computed values.

Foundation Slippage.—The importance of preventing horizontal movement of the supports of rigid frames is clearly illustrated by Fig. 13. For an increase in span length of $\frac{1}{4}$ in. (that is, each support deflecting outward $\frac{1}{8}$ in.) the horizontal reaction for the square-knee frame decreased 7% and the center moment increased 20%. Corresponding variations were not quite as great for the curved-knee frame because of its greater flexibility.

---

[9] "Deflection Tests Show Rigidity of Steel Rigid-Frame Bridges," by R. M. Hodges, *Engineering News-Record*, September 3, 1931.

The accuracy of computations for the effect of horizontal movement of the supports upon the frame as a whole depends chiefly on the accuracy with which the horizontal reaction is determined. Changes in horizontal reaction for known variations of span length did not check the computed values exactly (the computed and observed curves in Fig. 13 are not exactly parallel), but the agreement was satisfactory for all practical purposes.

Flat Base Tests.—It is of interest to note that practically no rotational restraint was developed at the supports by allowing the base plates of the rigid-frame models to rest upon flat plates which resisted only horizontal movement. In fact, the horizontal reactions were less than the values computed, assuming the supports to be hinged, whereas the presence of any reaction moment should have the effect of increasing the reaction. This might have been due to a slight misalinement of the frames. If the bases were not truly horizontal, the reaction might easily have been located inside the centroid of the base. Such a condition would have produced a reduced horizontal reaction. However, the test results shown in Table 2 definitely indicate that, unless specific provisions are made to prevent rotation at the base of a rigid frame, the frame will act as a two-hinged structure.

Recommendations for Design

For most practical purposes, horizontal reactions in two-hinged rigid frames of the types tested in this investigation may be computed satisfactorily by any theoretically sound method of analysis. Fig. 13 presents a criterion of the accuracy that can be expected.

If greater accuracy is desired for the curved-knee frame, the following recommendations are made: Arbitrarily reduce the moments of inertia of sections within the knee by means of the graph in Fig. 19. Shear is of secondary importance and need not be considered when radial sections at the knee are used.

Design.—Concerning the design of the knee in each frame, the following recommendations are made:

For a square knee,

1. The horizontal and vertical sections through the inside corner of the knee are critical sections with respect to normal stresses. Apply the usual formula for flexure and direct stress to the horizontal section. On the vertical section, assume that the flange angles carry all the moment and thrust in the girder, and apply the same formula.
2. Design the web to take a total horizontal shear equal to the tension in the top flange of the girder computed in step 1.
3. If the web plate is thin in comparison to that in the test specimen, it may be well to investigate the tension in the web on the 45° plane through the inside corner. For this section, the neutral axis will be located at about one fifth of the length of the diagonal from the inside corner, and the stress distribution may be considered to take the form of a second-degree parabola on the tension side, and of a triangle on the compression side. Maximum stresses

may then be computed from the equations of equilibrium for bending and direct stress on the section.

For a curved knee,

1. Critical sections for direct stress at the knee occur within 15° from the points of tangency of the curved flange. Maximum compression stresses may be determined by use of conventional formulas for flexure and direct stress in straight beams if the section moduli are reduced in accordance with Fig. 19. Maximum tension stresses may be determined in the same manner, but using nominal section moduli. Flange stresses may also be computed satisfactorily by the Osgood theory.[8]

2. The web should be designed for shear on the basis of the arbitrary method illustrated in Fig. 21. Shears outside the square will be smaller than those computed for the square.

3. If the web plate is thin in comparison to that in the test specimen, the 45° plane through the outside corner should be investigated, using the same procedure that was recommended for a corresponding section in the square knee. However, in the curved knee the neutral axis is located at a distance from the compression flange equal to about one fourth the entire diagonal distance.

SUMMARY

The important findings in this investigation may be summarized as follows:

(*a*) The square knee did not act as a continuous homogeneous corner. It may be analyzed and designed as a rigid girder and column connection, in which the reactions of the girder upon the column consist chiefly of a top-flange tension, a bottom-flange compression, and a vertical shear, neglecting the moment and thrust carried by the web at the splice.

(*b*) Stress concentrations at the sharp reentrant angle of the square knee were due principally to imperfect bearing rather than to any inherent property of rigid-frame knees.

(*c*) Normal stresses upon radial sections of the curved knee did not exhibit a linear relationship. The neutral axis lay between the centroidal axis and the compression flange. On the radial section through the exterior corner the neutral axis was about one fourth the distance from the compression flange to the exterior corner.

(*d*) Maximum stresses in the curved knee occurred on sections just inside the points of tangency of the curved flange. Average extreme fiber stresses in the curved flange were from 15 to 50% higher than stresses computed by the conventional formulas for flexure and direct stress in straight beams.

(*e*) A simple method of reducing section moduli and moments of inertia within the curved knee produced close agreement between observed and computed values for compressive stresses in the curved flange and also for the horizontal reaction.

(*f*) The outstanding legs of the curved-flange angles deflected away from the center of curvature under the radial component of compression introduced by the curvature. As a result, the stresses observed near the toes of the outstanding legs at various points along the curved flange were only from 40 to 70% of the stresses at corresponding points on the heels of the angles and on the edge of the web. Maximum stresses on the edge of the web were as much as 25% greater than the average values used for comparing test results with computations.

(*g*) Conventional methods of rigid-frame analysis gave horizontal reactions slightly greater than those observed; 1½% for the square-knee frame and 3½% for the curved-knee frame at normal span.

(*h*) Conventional methods gave center moments and deflections as much as 10% less than observed values for both frames.

(*i*) Center moments and deflections generally agreed closely with values computed from observed reactions and applied loads.

(*j*) Changes in horizontal reaction, center moment, and center deflection due to horizontal movement of supports also checked theoretical values fairly closely.

(*k*) No appreciable rotational restraint was developed by setting the base plates of the rigid frames on flat plates which resisted horizontal movement of the supports, but not rotation. Rigid frames in which no special precaution for preventing base rotation is taken, therefore, will act as two-hinged frames.

(*l*) The results of this investigation agreed very well in general with the results obtained at the National Bureau of Standards and with the English tests reported by J. J. Leeming and S. C. Redshaw[10] in 1939.

ACKNOWLEDGMENTS

The program for this investigation was prepared by the Technical Research Committee of the Institute, consisting of Jonathan Jones, M. Am. Soc. C. E., chairman; O. E. Hovey, Hon. M. Am. Soc. C. E.; the late H. G. Balcom, the late Aubrey Weymouth, and F. H. Frankland, H. D. Hussey, and J. R. Lambert, Members, Am. Soc. C. E. Acknowledgment is due to the members of the committee for their active interest in the work and their advice and guidance; to E. L. Durkee, M. Am. Soc. C. E., G. L. Gray, Jun. Am. Soc. C. E., and W. B. McLean Assoc. M. Am. Soc. C. E., of Fabricated Steel Construction, Bethlehem Steel Company, for the design of the square-knee model and for their valuable assistance in the theoretical analysis of the frames; to Mr. Hussey for the design of the curved-knee model; and to the members of the laboratory staff for their assistance in testing the models and the preparation of the report.

DISCUSSION

C. J. Posey,[11] Assoc. M. Am. Soc. C. E. (by letter).—When continuous corners of structural steel first came into use not many years ago, their design usually was based upon the methods that had proved satisfactory for the design of beams and girders. Structurally, however, a corner is very different from a beam, although it may be built with the same cross-sectional shape. The fact that serious consequences may result from designing a corner by the methods used for designing a beam is gradually becoming known. The authors' tests and the companion investigation at the National Bureau of Standards reveal some of the basic differences in structural action of the two types of members.

The most important structural characteristic of a steel corner of I-shaped cross section having a curved flange is the tendency of the web to buckle.[12] When the inside of the corner is in compression (as was the case with the frames tested by the authors) the curved flange puts a large radial compressive loading on the web, and if the web is not adequately reinforced with stiffeners, it will buckle. The tendency to buckle appears at comparatively low loads.

The existence of such an effect is recognized in the report on the curved inner flange riveted steel rigid frame tested at the Bureau of Standards. Messrs. Stang, Greenspan, and Osgood include the following statement among their conclusions:

> "The design was such that the frame failed by elastic instability. The inner-flange angles at failure were stressed to less than half their yield point. This emphasizes the necessity of providing adequate bracing for the inner flange at the knees of rigid frames of this type."[4]

What is vaguely referred to as "elastic instability" is nothing other than the tendency of the web to buckle due to the radial compressive forces. Bracing the inner flange, except by means of stiffeners, would not decrease the stress in the web.

The authors do not mention this important phenomenon at any point in their paper. Fig. 7 seems to show that sidewise deflection of the inner flange was prevented to some extent by the frame holding the specimen. Such support is seldom, if ever, provided when curved knees are used in construction. Even with this type of bracing, which decreases the effective slenderness ratio of the web and thus increases its resistance to buckling, the tendency toward "elastic instability" should become evident. The data included with the present paper do not seem to permit any comparison that would reveal this, although it may be noted that the span with curved flanges was more flexible, in comparison with computed values, than was the span with a sharp corner, although the fabrication of the latter was admittedly inferior.

[12] "Handling Corners in Rigid Frames," by B. J. Lambert, M. Am. Soc. C. E., and C. J. Posey, *Engineering News-Record*, August 4, 1938, p. 147.

W. J. ENEY,[13] ASSOC. M. AM. SOC. C. E. (by letter).—In 1938 the writer completed a study of a rigid frame celluloid model to determine the effect of the shape of the knee and footing on the reactions, moments, and deflections. The data obtained are presented herein with the belief that they will prove useful in appraising the investigation reported by Messrs. Lyse and Black. Unfortunately the study was well under way before the American Institute of Steel Construction (A.I.S.C.) tests were started; otherwise the same prototype could have been used. The prototype (shown in Fig. 22) was one of the steel frames in a 96.5-ft span highway bridge erected over the Pennsylvania Railroad on City Line, Philadelphia, Pa. The general dimensions of the frame are given in Table 4 and Fig. 23. The model was constructed of sheet celluloid 0.125 in. thick to a geometric scale of 1 in. = 30 in. At corresponding sections, the width of the model, in inches, was made numerically equal to the cube root of the moment of inertia of the structure in foot units. The initial square, filleted, knee model (designated as Model L 2) was progressively altered at the knee and footing to obtain successively Models L 3, L 4, L 5, and L 6. The general nature of each of these changes is given in Fig. 24, together with the detailed dimensions. Influence lines for horizontal reaction, reaction moment, moment at and deflection of load point 10 L, were determined for both the hinged-base and fixed-base condition.

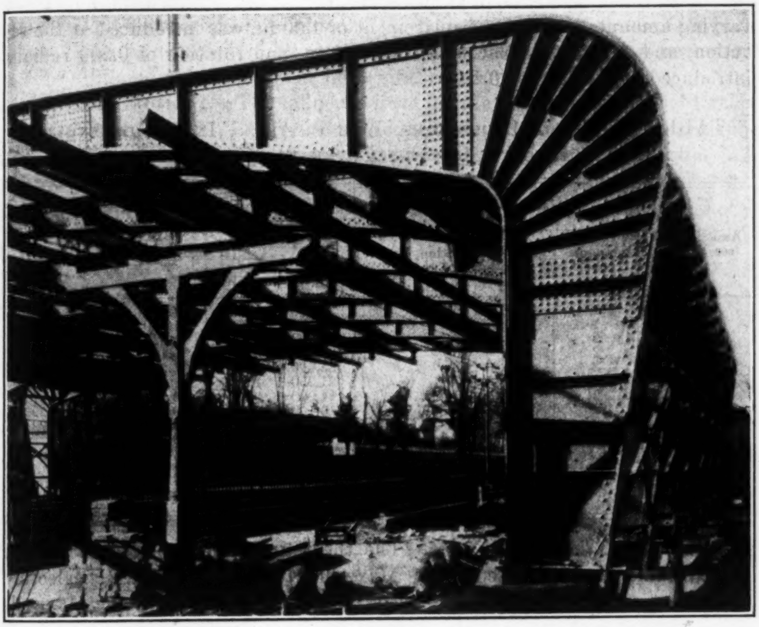

FIG. 22.—PROTOTYPE OF CELLULOID MODELS

---

[13] Asst. Prof., Civ. Eng., Lehigh Univ., Bethlehem, Pa.

The deformeter apparatus used in the study is shown in Fig. 25 attached to Model L 3. The displacements of the load points were measured with a scale oriented in the direction of loads acting on the prototype. This scale, graduated to one hundred divisions per inch, was read easily with a watchmaker's loupe to an accuracy of plus or minus 0.002 in. The scale slides along a reference bar permitting the measurement of the displacement of all load points at one setting of a gage.

Two types—a reaction gage and an internal deformeter—were used. They permitted the introduction of known shear, thrust, or rotation displacements of varying amounts. A shear displacement of 1.00 in. was introduced at the reaction, and a thrust displacement of 0.500 in. and rotation of 0.200 radians introduced at load point 10 L.

[a] Coordinates for the division of center structure (see Fig. 23).

Computed Influence Ordinates.—The theoretical values presented for the hinged frame were computed by the Maxwell–Mohr method (Eq. 2, neglecting the shear term); and those for the fixed frame were computed by the Maxwell-Mohr method and checked by the method of Elastic Weights. The theoretical prototype had a round knee as in Model L 2, and a base corresponding to that of Model L 6. The frame was divided into section lengths varying from 6.30 ft to 7.42 ft for the algebraic summations in Eq. 2.

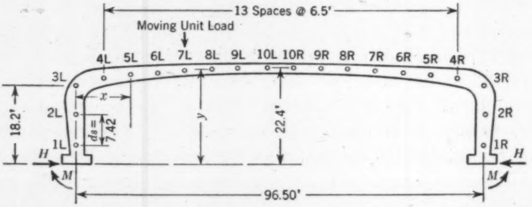

FIG. 23

Horizontal Reaction.—The influence lines for horizontal reaction are shown in Fig. 26. All of the observed values for the various modifications of the hinged end models lie along one curve. The ratio of the observed ordinates to the theoretical ordinates was 1.00 for the square-knee model L 2 and 0.975 for the round-knee model L 6. The corresponding ratios for the steel model were 0.985 and 0.965.

The effect of the modifications of the knee on the fixed frame horizontal reactions are negligible as the values for Models L 2, L 3, and L 4 are almost identical and one curve suffices for the three models. The observed ordinates are 92% of the theoretical ordinates. The reduction in the stiffness of the base of the frame as represented by converting Model L 4 to Model L 5 caused an 8.5% additional reduction in the horizontal reactions.

Reaction Moments.—The influence lines for the moment at the right reaction are shown in Fig. 27. The computed maximum moment at the right support is approximately 11% greater than the observed value for Model L 3. The modifications of the knee, changing Model L 2 to L 3 and then to L 4 and from L 5 to L 6, produced an increase in the moments of approximately 5.5%. Notching the footing, changing Model L 4 to L 5, caused a decrease of approximately 20% in the moments.

FIG. 24.—DETAILS OF CELLULOID MODELS 12 TO 16, INCLUSIVE

This 20% decrease in reaction moments is accompanied by a corresponding 8.5% decrease in the horizontal reaction, as stated. Since these produce opposing moments in the frame, the reduction of the stiffness in the footing has little effect on moments at the knee or center of the frame. The moments

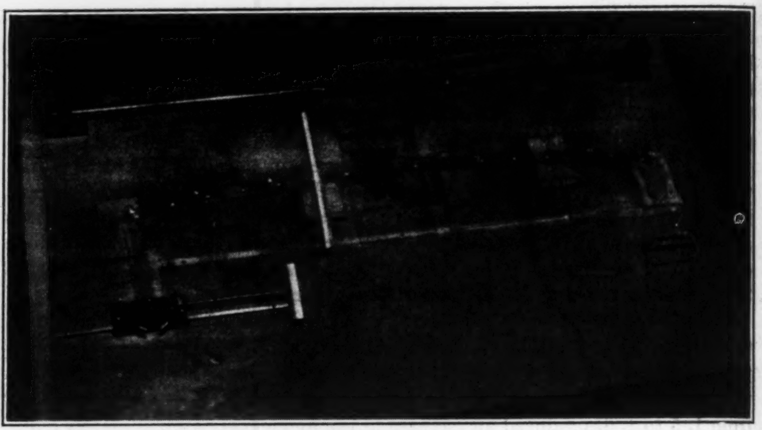

FIG. 25.—DEFORMETER APPARATUS AND MODEL L 3

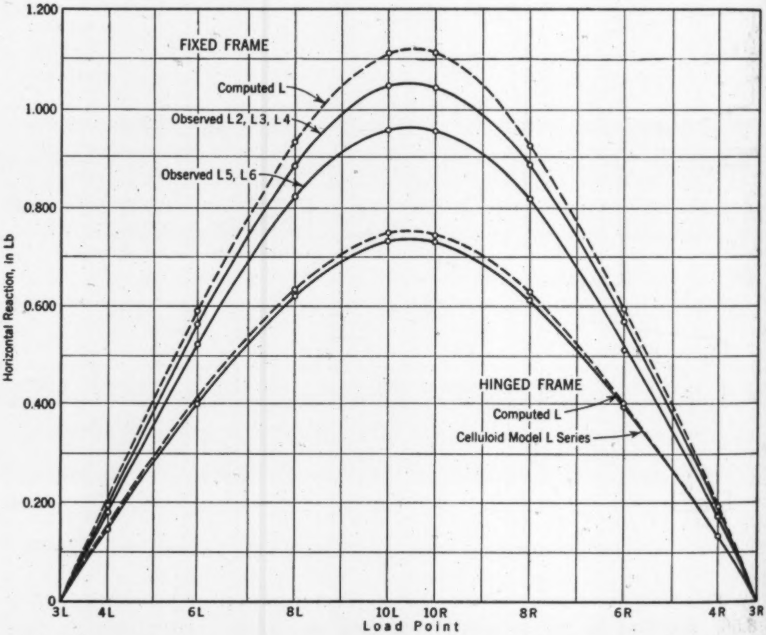

FIG. 26.—INFLUENCE LINES—HORIZONTAL REACTION, FIXED FRAME AND HINGED FRAME: CELLULOID MODELS

at the knee, computed from the observed reactions, disagreed by approximately 5% with the theoretical moments.

Influence Lines for Thrust at Load Point 10 L.—The influence lines for thrust at load point 10 L were observed for Models L 3, L 4, L 5, and L 6 for

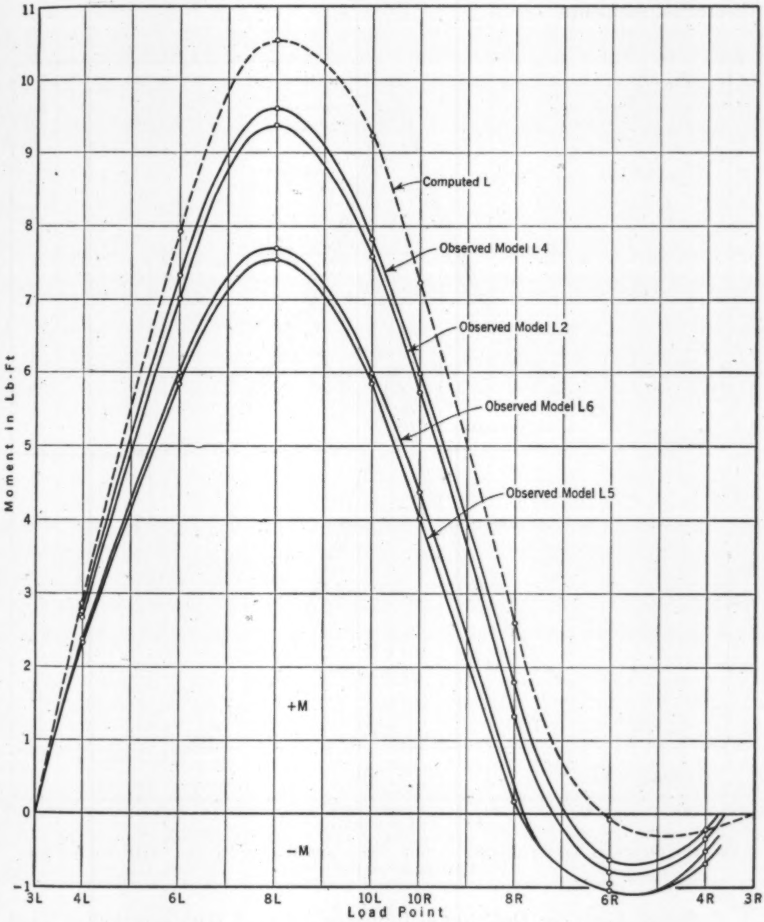

FIG. 27.—INFLUENCE LINE, MOMENT AT RIGHT FOOTING, FIXED FRAME

both hinged and fixed frame conditions. The values were in agreement with the corresponding horizontal reactions and are therefore represented by Fig. 26.

Moment Near Center Frame.—The influence lines for moment at 10 L are given in Fig. 28. The effect of the modifications of the knee and the footing on the moment at 10 L in the case of the hinged end model was negligible—

one curve fits the values for all models. In the case of the fixed frame the modification of Model L 2 progressively to L 6 caused an increase in the moment at 10 L of approximately 5%. The comparison between the theoretical and observed ordinates reveals the same relationship as was found with the steel model—the observed moments were from 6% to 11% larger than the theoretical moments.

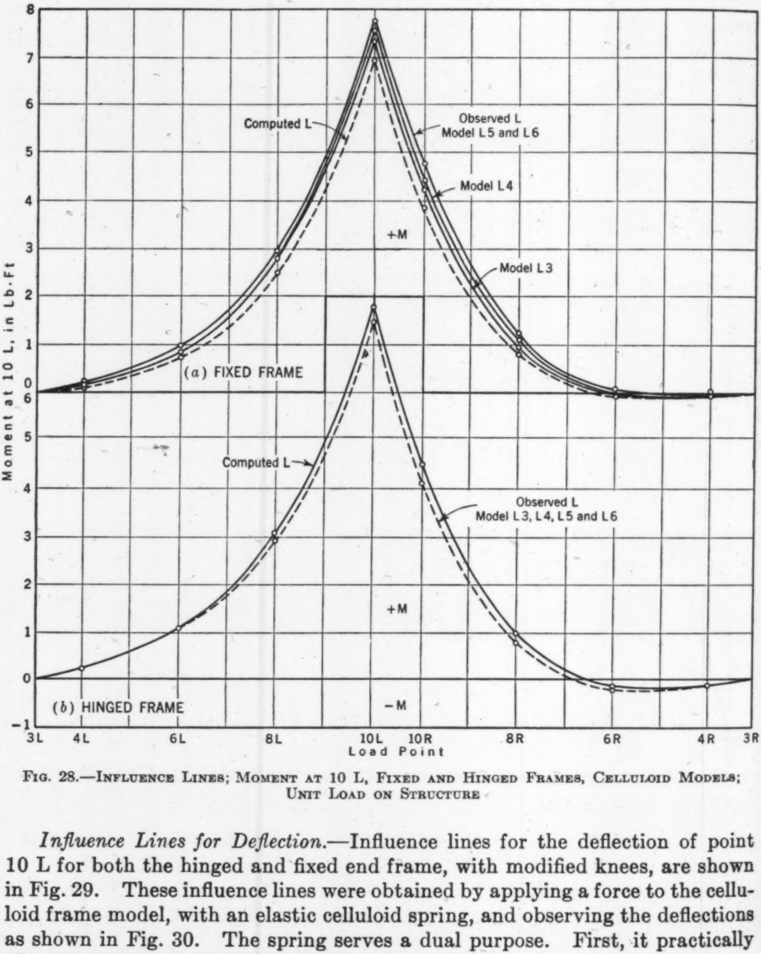

FIG. 28.—INFLUENCE LINES; MOMENT AT 10 L, FIXED AND HINGED FRAMES, CELLULOID MODELS; UNIT LOAD ON STRUCTURE

Influence Lines for Deflection.—Influence lines for the deflection of point 10 L for both the hinged and fixed end frame, with modified knees, are shown in Fig. 29. These influence lines were obtained by applying a force to the celluloid frame model, with an elastic celluloid spring, and observing the deflections as shown in Fig. 30. The spring serves a dual purpose. First, it practically eliminates the annoying creep of the plastic model; and second, it serves as a convenient means of applying an accurate force to the model, eliminating the pulleys necessary where weights are used. An identical force can be applied to different models by means of a graduated scale on the spring.

The relation between the deflection of corresponding points on the model and structure can be expressed by the equation:

$$\delta_s = \delta_m N^3 \left(\frac{I_m}{I_s}\right)\left(\frac{E_m}{E_s}\right) \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

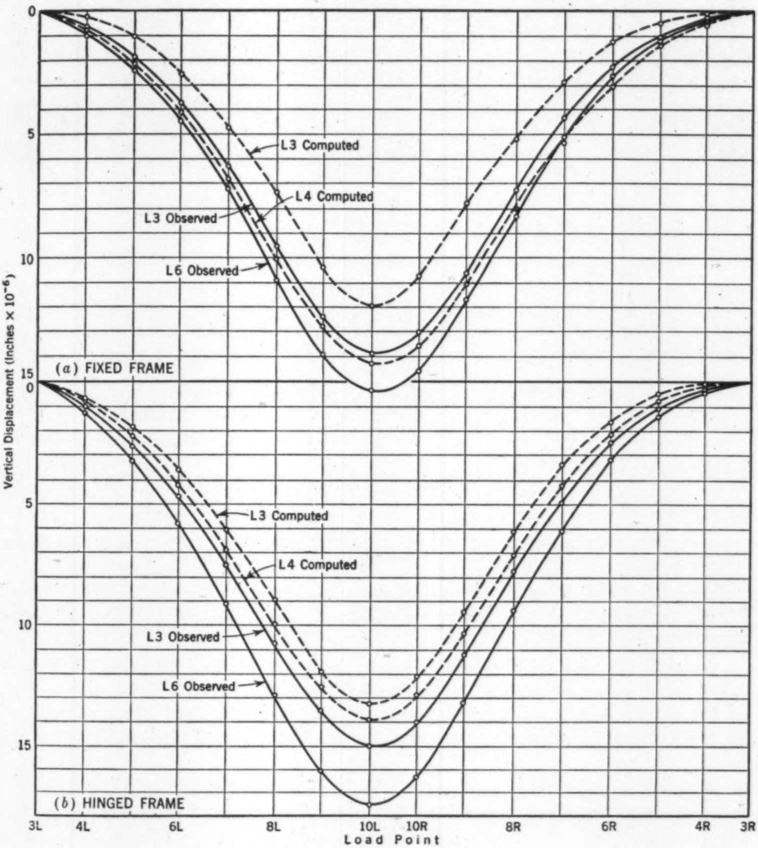

FIG. 29.—INFLUENCE LINES, DEFLECTION OF POINT 10 L, UNIT LOAD ON STRUCTURE

in which: δ_s = deflection of structure; δ_m = deflection of corresponding point on model; $\frac{I_m}{I_s}$ = ratio moment of inertias of model and structure at corresponding sections = a constant for the model, and $\frac{E_m}{E_s}$ = ratio modulus of elasticity of model and structure; and N = units of length in the structure represented by one unit of length in model.

In proportioning the model a section of the structure having a moment of inertia of 1 ft^4 was represented by a section of model 0.125 in. thick and 1.000 in. wide. The modulus of elasticity was determined to be 380,000 lb per sq in. by applying a force to a cantilever beam cut from the same sheet of celluloid as the frame model. Therefore:

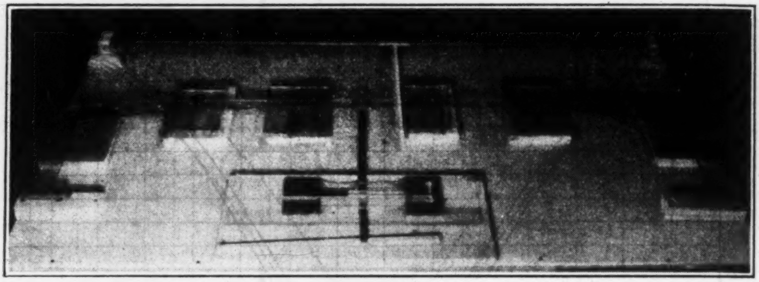

Fig. 30.—Measuring Deflections of Celluloid Model

$$\delta_s = \delta_m N^3 \left(\frac{I_m}{I_s}\right)\left(\frac{E_m}{E_s}\right) = \delta_m 30^3 \left(\frac{0.125 \times 1^3 \times \frac{1}{12}}{1 \times 12^4}\right)\left(\frac{380{,}000}{30 \times 10^6}\right) = \frac{\delta_m}{5{,}820}.$$

The frame model, therefore, deflects 5,830 times the deflection of the structure for equal loads.

The data presented in Fig. 29 show that the shape of the knee has a small effect on the frame deflections. Chamfering the outside of the knee and removing the fillet, converting Model L 3 to L 6, increased the hinged frame deflection at point 10 L approximately 15% and the fixed frame deflections approximately 10%.

The computed influence lines marked "L 3 computed" were determined by using the method of dummy unit loading and theoretical moments computed by the elastic theory, whereas the one marked "L 4 computed" was determined by the tangent offset method in which a conjugate beam was loaded with the $\frac{M}{I}$-diagram and the moments obtained by the mechanical analysis of Frame L 4. These computed deflections did not include the effect of shear or rib shortening. The deflection would be increased 0.6% due to rib shortening and approximately 2.0% due to shear. The observed deflections are from 6% to 17% greater than the computed deflections. Messrs. Lyse and Black found the observed deflections for the hinged, round knee steel model to be 11% greater than the computed deflections.

Comparing the observed deflection of Model L 3 one finds the fixed frame deflects about 90% as much as the hinged frame. This slight increase in rigidity is easily destroyed by a very slight rotation of the base. The largest observed rotation of the footing of the hinged model amounted to 0.00206 radians for a unit load of 10 L. As Messrs. Lyse and Black show, unless the footing is firmly restrained against rotation the flat base frame acts as a hinged frame.

Conclusions.—Although it is true that there is probably a vast difference between the action of a steel frame with a knee stiffened radially in Fig. 22, and the round celluloid knee of the model, the results obtained with the celluloid model nevertheless are indicative of the effect of the shape of the knee on frame action. These results are in agreement with those of Messrs. Lyse and Black and, in addition, indicate the probable effect of the knee and footing on the fixed frame.

LAMOTTE GROVER,[14] M. AM. SOC. C. E. (by letter).—The tests described have made an excellent start in the investigation of stresses in rigid-frame knees. The authors are to be commended for their thorough interpretation of results and especially for giving structural designers practical rational methods of stress analysis that will yield sufficiently accurate results at least for knees of shapes and proportions similar to those tested, when they are subjected to static loading. These methods have the virtue of focusing the attention of the designer upon the structural behavior of such knees and the stress distribtion in them, thus providing at least some orientation in the matter of designing for dynamic loadings.

It is important to recognize that this investigation, together with its companion investigation at the National Bureau of Standards, covers too small a range of knee shapes to warrant conclusions as to the best general type, such as quite a number of structural engineers seem to have assumed after reading the reports; although no such conclusions are represented by the investigators. None of the tests has included a welded curved knee. The welded knee tested by the Bureau of Standards had straight sloping inner flanges.

It was perhaps inopportune that the Lehigh riveted curved knee was proportioned similar to the one tested by the Bureau, which had confirmed the belief that serious elastic instability is inherent in such widely expanded and flexible knees as have been used for some building frames, usually to conform to architectural plans. It might have been better to strive for proportions that would provide the best distribution of stresses possible with a curved inner flange of smaller radius, decreasing the large flexible web area and increasing the compression flange stiffness. In the design tested, flange angles were used alone without cover plates.

In comparing the general behavior of the square-knee frame with that of the curved-knee frame, it must be borne in mind that the members themselves in the square-knee frame were considerably deeper and stiffer.

The riveted square knee, as tested, was designed principally with the viewpoint of facilitating fabrication, which is of paramount importance. High concentrations of stress were found at the sharp inside corner but it was concluded that these were due largely to extreme concentration of bearing at that point, resulting from shims driven in between the face of the vertical leg and the outstanding legs of the compression flange angles of the girder, where it is very difficult to obtain reliable bearing in riveted construction. Little significance was attributed by the authors to the general effect of the sharp reentrant angle. This conclusion seems highly questionable in view of the drastic effects upon stress distribution that have been observed for such sharp angles or "notch effects" in other investigations. Even higher local concentrations of stress might have been found if the corner areas had been explored more fully by differential tensometer readings.

---

[14] Structural Welding Engr., Applied Eng. Dept., Air Reduction Sales Co., New York, N. Y.

It is questionable whether the normal stresses on the sections perpendicular to the axes of the leg and the girder (Fig. 9) carry much significance within the square knee and immediately adjacent to it. Normal stresses on diagonal or radial sections passing through the inner corner would seem more significant in view of the orientation of the maximum principal stresses in this vicinity, a fact recognized by the authors in discussing Fig. 14(*a*).

One of the conclusions was that any effect of plastic flow or permanent set and slippage of rivets upon the behavior of the frame as a whole was negligible. However, Table 3 shows an appreciable decrease in observed horizontal reaction and an approximately corresponding increase in observed center moments and deflections as compared with computed values, for both types of frames. Although Fig. 12 indicates elastic behavior throughout the range of loading, it must be remembered that the loading was repeated many times in gathering all the data for the investigation (because of the limited number of only six tensometers available for use). Initial loadings, prior to taking the readings for Fig. 12, could have produced permanent relative rotations between the axes of the intersecting members at the knees, which would result in initial no-load stresses for the next following tests. Under these circumstances, elastic behavior would be expected unless the initial load were exceeded. The effect of rivet slippage, and permanent set or plastic flow, might be more pronounced in a multiple-span frame with three-branch knees at the intermediate supports.

As inferred at the beginning of this discussion, the tests conducted thus far cannot be considered much more than a good start in an adequate investigation of rigid-frame knee design. To gain an impression of the ground that remains to be studied, as well as an indication of the nature of further investigations that are needed, it should be helpful to review briefly what has been done by other investigators in this field, and to point out wherein their conclusions seem to be reinforced by the results of the Lehigh tests and also where there appears to be disagreement.

In Europe, development as well as research in rigid-frame construction has been based for the most part upon welded details because of their inherently greater effectiveness in providing rigid connections with a minimum amount of material.

In Belgium and Germany extensive studies of stress distribution in rigid-frame joints of various types have been made along with many tests under static and fatigue loadings, of large and small scale steel models of built-up flanged specimens as well as plane models. Meticulous determinations of stresses and their distribution have been made throughout the webs and flanges, and transversely across the latter, by means of tensometer readings on short gage lengths—some of them differential readings, where stresses vary rapidly. These quantitative readings have been supplemented by photoelastic studies and also by the determination of stress patterns as revealed by the cracking under tensile stress of a brittle, tightly adhering coating of varnish that is applied to specimens before loading, for investigation of tensile stress, or applied while the specimen is under load, for investigation of compression stress. Some of these investigations have included three-branch joints simulating the rigid connection of a flexural member to a column or chord carrying considerable direct stress.

Investigators agree that in knees of all types, as indicated by mathematical analyses, the neutral axis lies between the centroidal axis and the inner flange, and the distribution of normal stresses departs from a straight-line distribution within the knee. Both tangential and radial stresses are concentrated at and near the inner flange, increasing considerably as the curvature or haunch angles of this flange become sharper.

There is general agreement that under usual conditions of design loading the critical section for tensile stresses as well as compression lies between the diagonal section through the center of the knee and the section where the knee joins one of the members, usually close to the latter if not directly at it. This suggests the possibility of fatigue failure at these critical sections under repeated stress, even though the frame would fail by buckling of the compression flange well within the knee under a static loading of considerably greater magnitude.

Quite a number of investigators have concluded that abrupt angles or sharply curved inner flanges must be avoided to eliminate high, local stress concentrations which are especially objectionable under dynamic loading. As in the Lehigh investigation, they have found that the radial component of the stress in a curved compression flange, which becomes greater as the curvature becomes sharper, causes transverse bending or cupping of that flange with consequent concentration of flange stresses near the junction with the web, and reduction of the effective flange area. Because of unavoidable lack of perfect symmetry of the cross section, due to slight inaccuracies in fabrication, an eccentricity develops which accentuates the effect of the radial compression force. However, when quite large radius haunches are used, the knee area is so large and the web so flexible, even though stiffened, that it will buckle under comparatively small loads and permit lateral deflection and buckling of the compression flange. It is necessary, therefore, to balance a design between consideration of stress distribution on the one hand and elastic stability on the other.

Conclusions reached from the Lehigh curved-knee test attribute major importance to the rapid change of section occurring at the junctions of the members with the knee. Belgian and German investigators have concentrated much of their attention upon this same feature. Their objective has been to reduce the rate of change in curvature at the beginning of curvature, and to avoid discontinuities at these critical sections, thereby eliminating stress concentrations or rapidly increasing principal stresses, which are distinctly revealed in the stress-line patterns by sharply curved lines. Stress lines, especially those along the inside edges of the knees, have been studied in many models involving rectilinear inner edges or flanges and geometric curves of various shapes and sizes, parabolic, hyperbolic, elliptical and sinusoidal (symmetrical and unsymmetrical or deformed, depending upon the relation between the direct stresses and bending stresses in the members joined).

An assumption commonly made by proponents of knees with rectilinear borders is that bending stresses are largely channeled in the flanges, and that the logical arrangement is that of straight flange elements combined with stiffeners in such a way as to form triangular force systems in equilibrium somewhat similar to those in trusses. Some of those technicians who favor curved inner flanges oppose the use of stiffeners or other special appendages for the transmission of stresses, because they have been held partly responsible for rather sharp transverse deviations in stress paths in the flanges to which they have been joined. It is apparent from test results, however, that curved compression flanges and adjacent web areas must be stiffened to reduce transverse bending of the flanges and to prevent lateral flange deflection and buckling in the web, unless it is practical to make the proportions of the width, thickness, and curvature of the flange and the thickness of the adjacent web such that elastic stability and good transverse stress distribution are assured. L. C. Maugh, Assoc. M. Am. Soc. C. E., has concluded from model tests at the University of Michigan, Ann Arbor, Mich., that stiffeners are required when the quantity $\frac{b^2}{4\,t\,r}$ exceeds 0.3 (b and t being the width and thickness of flange and r its mean radius of curvature). This expression does not evaluate the effect of web thickness. Professor Maugh feels that stiffeners should extend the full depth of the web so that the compression flange will receive lateral support from the tension flange through the stiffened web. Other investigators consider it sufficient to provide only small triangular transverse corner diaphragms that stiffen the compression flanges and adjacent web areas. A combination of the two types of stiffeners seems expedient, with all of them welded to the web and to the compression flange.

Unless a very decided advantage can be shown for the curved knee in the way of eliminating high stress concentrations that would contribute to real structural damage under repeated stress at the critical sections, and unless that advantage would be reflected in a substantial saving in weight of material, the economic preference will undoubtedly be in favor of the square or rectilinear knee for riveted rigid-frame bridges as well as buildings. Any such economic preference for the rectilinear knee is much less pronounced in the case of welded fabrication. One must also consider whether there is a general architectural preference for either the curved knee or the sharp-corner knee, one over the other.

The several rational methods of design that have been formulated by various investigators provide a much better insight into the behavior of rigid-frame knees than that afforded by conventional methods applied to many other commonly used structural details. Stresses in the members at sections only a short distance away from the knee have been found to conform well to computations by conventional theory. Designers should not hesitate, therefore, to use rigid frames.

Nevertheless, further tests of a comprehensive nature are needed in the United States to confirm or refute the conclusions of foreign investigations and perhaps to correct misinterpretations that have been made of meager tests in this country. This is the more important now that the completion of European tests has been interrupted by war activities. More information is needed about the influence of knees upon the behavior of a frame as a whole, especially the effects of plastic deformation or permanent set in cases of overloading, small settlements and horizontal movements of supports; also information to enable a better evaluation of the significance and importance of comparatively high shearing stresses that are known to exist within rigid-frame knees.

It is not merely the matter of a possibility of saving a comparatively small amount of material in the knee itself, as opposed to a generous proportioning of that element. The shape and type of knee and its rigidity exert a marked influence upon the stresses at the critical sections, adjacent to the members of the frame, which members, therefore, are likewise influenced at least locally. It is very desirable to evaluate these influences under repeated stress.

It may be that foreign investigators, as well as some students of stress analysis in the United States, have very greatly exaggerated the importance of sharp deviations in stress paths in the knees of rigid-frame bridges. Practical minded American engineers would surely not be willing to add much cost to their structures merely for the sake of an elegant solution to a stress problem. However, if there is really no practical value in refinements in the proportioning of rigid-frame knees, this should be proved definitely once and for all.

In many other structural details it has been proved quite important to avoid forms of details that cause abrupt disturbances in stress paths at critical points, even in statically loaded structures. It is evident from test results that there is a distinct correlation between fatigue strength and stress distribution. Therefore, it is logical to pursue further studies of rigid frames largely through fatigue tests. The most favorable proportions for each type should be determined for comparison to evaluate relative advantages. This can be done more quickly and at less expense if the fatigue tests are supplemented by static tests of models coated with brittle varnish to reveal the stress patterns and thereby guide the investigators more rapidly to a determination of the best details for resisting fatigue stresses, as well as static load stresses.

The program of further tests should be arranged objectively and without prejudice. In too much of the research work that has been done already, one type or another has been virtually disqualified at the start, as a result of subjective or premature conclusions.

WILLIAM R. OSGOOD,[15] M. AM. SOC. C. E. (by letter).—It is very much worth while to have tests checked in different laboratories. Such checking or duplication is common in many scientific laboratories such as laboratories of physics, chemistry, medicine, etc. It is not so common in engineering laboratories, possibly because of the frequently greater costs involved. When it can be done, however, it is to be welcomed. The authors have confirmed test results obtained at the National Bureau of Standards and have introduced ideas of their own. The paper contains much that can be a source of only satisfaction to those interested in rigid frames. Some points will bear discussion and comment.

---

[15] Materials Engr., National Bureau of Standards, Washington, D. C.

The authors state (see "Synopsis") "In the square knee, a concentration of stress existed at the inner corner but was found to be of minor importance." In view of the fact that a comparable square-knee frame tested at the National Bureau of Standards[3] failed by buckling of the outstanding flanges of the angles at the inner corner, it would be interesting to know on what grounds the authors base their statement.

The results shown in Fig. 20 confirm the validity of the theory developed at the Bureau of Standards[4, 8] even better than the tests which led to that development, at least so far as the stresses in the flanges are concerned. Before making too much of disagreement between theory and test, it is suggested that equilibrium of the part of the frame on one side of a circular section be considered. The theoretical stresses on such a section are in equilibrium with the applied loads on either side of it. Are the observed stresses in equilibrium with these loads? If not, the observed stresses are manifestly in error; and if the necessary adjustment of the observed stresses to bring about equilibrium is of the order of the difference between observed stress and theoretical stress at any point, then it may be impossible to draw any conclusions as to how imperfect the theory is.

The "Observed Position of Neutral Axis" in Fig. 20 may be misleading. If this axis is the axis of zero normal stress on radial sections, it bears no relation to the points of zero normal stress on the circular sections shown in the figure.

The authors make the statement that for a curved knee "critical sections for the direct stress at the knee occur within 15° from the points of tangency of the curved flange." The implication is that these sections will always occur there, regardless of the positions of the applied load. The writer does not think that this will be the case. If the approximate rational method of determining the critical sections is used, as suggested in reference 4, the critical curved-flange sections for the loading shown in Fig. 11 occur at 9°.8 from the upper point of tangency and 7°.4 from the lower point of tangency. These sections are close to the sections of maximum stress shown in Fig. 18. If the ratio of P to H in Fig. 1(*b*) had been considerably larger, for example, it is probable that the upper critical section would have been found at an angle greater than 15° from the point of tangency of the curved flange.

The theory presented by the writer[8] in 1939 is not of the simplest, as the authors intimate, but on the other hand, it is not at all difficult to use. Three sets of curves are given[8] in which the ratio of stress computed by the ordinary beam theory to stress computed by the tapered beam theory is plotted against the ratio of flange area to total circular sectional area. It is only necessary then to compute the stress by the ordinary beam theory, enter the chart at the proper ratio of flange area to total area, and read the ratio of the two stresses at the curve drawn for the proper angle measured from the point of tangency of the curved flange.

It is perhaps significant that the authors do not even mention radial stiffeners and buckling of the web of the frame having the curved inner flange. Evidently there was no evidence of buckling due to radial compressive stresses, even though the average compressive fiber stress in the curved flange was as high as 24,000 lb per sq in. and the highest nearly 30,000 lb per sq in. (Figs. 18 and 10). This finding is of importance because it has not infrequently been the practice to stiffen the web radially, and "in massive doses." The authors' test was not carried to destruction, it is true; but the Bureau of Standards' test on a similar frame was, and there was no evidence that the web buckled. The radial compressive stresses were low, with probable maximum values not exceeding 12,000 or 13,000 lb per sq in. at spots. "Failure occurred suddenly, by lateral deflection of the curved inner portion of the frame," [4] that is, as a sidewise displacement of the inner flange as a whole, not as a curling over of the flange. This kind of failure can only be prevented by lateral bracing—radial stiffeners are useless to prevent it.

M. HIRSCHTHAL,[16] M. AM. SOC. C. E. (by letter).—Tests of large-scale models of indeterminate structures are of the utmost value to the engineering profession as a verification of theory (or its disproof), as well as for the clarification or decision of controversial questions in connection therewith. However, to accomplish such results, meticulous care must be exercised so that neither a predetermined theory nor methods pursued in similar investigations exercise any influence on the researcher in his tests. It is to be feared that the authors permitted themselves to be somewhat influenced in both ways. There is no question of the great advantage to be gained in planning tests that will either confirm or deny results previously obtained by the selection of similar forms for tests, but no attempt should be made to read into the results identity with the prototypes (tests) or to resort to "modified sections" to confirm theoretical analysis in which assumptions must necessarily be made as a basis for logical results. The tests were well planned, yet it is questionable whether the degree of accuracy was sufficiently great when the variations between assumed theory and stresses obtained from strain readings are of approximately the same amount at times as the expected accuracy of 300 lb per sq in. in the instruments used. The authors state that the number of readings or observations was governed by the desirability of limiting the number of holes made in the angles. Could not the remedy have been found in welding and thus this difficulty been eliminated? Gage lines along the gravity lines of each of the angles of the curved inside section might have furnished valuable information. In selecting the configuration for the curved-knee frame (Fig. 1(*b*)), the authors made the crown thickness 6 in., carrying the soffit of the beam parallel to the extrados, whereas the leg is $7\frac{1}{2}$ in. thick at the base. The result is that the sections at the diagonal through the knee are not equal—the vertical section through the beam is $13\frac{7}{8}$ in. deep and the horizontal section through the leg is $15\frac{3}{8}$ in. deep (Fig. 31). In the case of the square-knee frames, these sections are of the same depth, which is preferable.

---

[16] Concrete Engr., D. L. & W. R. R., Hoboken, N. J.

An examination of Fig. 18 discloses the fact (and it is pointed out by the authors) that, from the tangent point 22 (opposite 2) around the curve to the tangent point 32 (opposite 19), the observed stresses (computed from the strains) are considerably higher than those computed by the "beam formula." Beyond these points, both in the horizontal beam and in the vertical legs, the stresses are lower than those computed theoretically. The writer differs from the authors on two points as to the reasons and the results of these conditions.

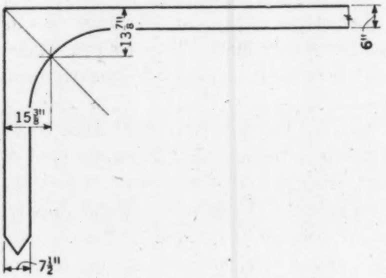

FIG. 31

First: Since points 32 and 22 and the points opposite them are subjected respectively to the maximum compressive and maximum tensile stresses, it is evident that (*a*) the sections through these points (practically the points of tangency) are at the points of maximum negative moment of the respective horizontal and vertical spans; (*b*) that they are the "fixed ends," and (*c*) that the section between, or the knee section, furnishes the restraint for such fixedness. Under such conditions (Fig. 11) the stress distribution along a diagonal across the knee would not follow the "straight-beam" theory, but rather, more nearly, that resulting from a thrust against this diagonal section. The resistance to this thrust is offered by the remainder of the frame (the other half of the knee and the leg) down to the hinged support (Fig. 32). The bending moment at the end of the beam span, resulting in tension in the upper plane and compression in the lower, together with the vertical shear, may be considered replaced by a thrust acting eccentrically on the section, the eccentricity being equivalent to that resulting in the aforementioned bending moment. From the observed location of the zero strain (therefore, zero stress), the resultant thrust is evidently applied very close to the inside edge of the diagonal. The point of zero stress under this assumption would be located at three times the distance from the inside edge to the point of application of the resultant, similar to the condition of a

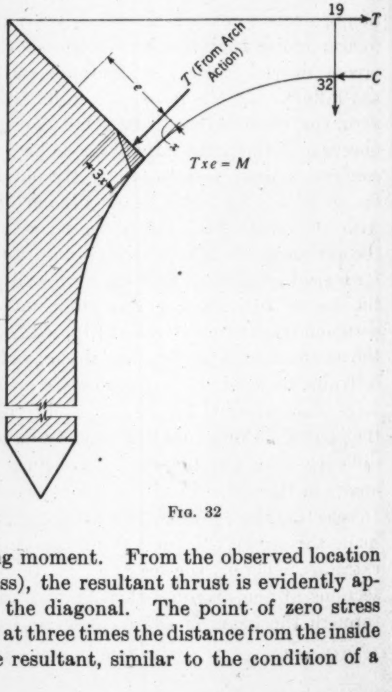

FIG. 32

footing on rock or other unyielding material, in which the resultant of the pressure falls outside of the middle third of the base. As long as there is no yielding under the point of maximum compression (in other words, if the surface resists distortion), there is no possibility of a tensile stress at the outer edge.

Second: From the fact that the extreme fiber stresses between the tangent points of the horizontal and vertical members, as computed from the observed strains, were considerably greater than those calculated from the theoretical assumptions, the authors conclude that the knee was "not stiff enough." The writer differs with this conclusion, and feels that on the contrary the knee, because of its very stiffness, was capable of taking greater stresses than assumed. Thus it relieved the sections of the horizontal beam, and the vertical legs beyond the knee, of part of the stresses or moments, resulting in the lower actual observed stresses noted in those sections. The situation is similar to that occurring at the junction of two members, such as a column and a beam, subjected to a bending moment, in which case the stiffer member takes the larger share of the moment. Likewise, within a member itself the section having the greater stiffness will take the greater part of the moment. Perhaps this is the explanation of the fact that a reinforced-concrete beam never yields a deflection anywhere near that calculated for the particular condition of loading. A well-proportioned beam has about one third of its tensile reinforcement bent up for shear and diagonal tension, and this reinforcement is carried into the opposite plane for proper anchorage, thus providing a cross section at the supports far stiffer than that assumed for the theoretical consideration of a reinforced-concrete beam design from which the deflection is ordinarily computed.

The condition at the knee is not unlike that posed when a deep girder is connected with a relatively light column and the column selected is found to be overstressed. An increase in the column section will result only in an increase in the share of the bending moment it will be required to resist. Thus, it is evident that, to relieve the column of its overstress, it will be necessary to increase the girder section at its junction with the column so as to take a greater share of the moment because of its increased stiffness. This, however, does not end the problem, which cannot be treated herein.

Square Knee.—In Fig. 16, which shows the distribution of stress for the square-knee section, it is to be noted that the compressive stress in the corner (the junction of the soffit of the horizontal beam with the vertical leg), from gage observation, is much higher than that which had been computed—the theoretical stress. F. E. Richart, M. Am. Soc. C. E., in his tests of reinforced-concrete knees at the University of Illinois, found a similar concentration of stress at the inside corner of the specimen. At that time, the writer had suggested that this might have resulted from the fact that the horizontal section through the leg and the vertical section through the beam, at their junction, have a common extreme fiber in compression and such a concentration of stress was to be expected. Where these sections are at right angles to each other, the resultant compressive stress would be the square root of the sum of the individual squares of the individual extreme fiber compressive stresses; and, where the depth of section and reinforcement are the same in both sections, this resultant stress would be 1.41 times the compressive stress of either. This would also apply to the structural steel section. This assumption appears to be practically verified in Fig. 16 where the observed stress in the horizontal member is about 22 kips, whereas the theoretical stress is only 15 kips per sq in., although the section for the vertical member does not quite corroborate this value. For the foregoing reason, the writer would suggest including this consideration in the recommendation for design that the authors include in recommendation 1.

In the opinion of the writer the results of the tests are not quite conclusive and do not justify the other definite conclusions embraced in the recommendations.

JAROSLAV J. POLIVKA,[17] M. AM. SOC. C. E. (by letter).—The investigation is a valuable contribution to the analysis of framed structures with variable moments of inertia. In the analysis of such types of structures, certain assumptions are made, and it is important to know how nearly these assumptions conform with the actual behavior of the structure, as proved by reliable tests.

The authors' comparison between the results of the tests and conventional methods of analysis shows that a fair conformity may be obtained. The observed horizontal reactions differ slightly from the computed values, considering the influence of shear on deformation; but the computed center moments and deflections are as much as 10% less than observed values—a fact affecting, seriously, the design of the structure and its safety.

The writer has analyzed, completely, both types of hinged frames subjected to investigation, using the "ellipse-of-elasticity" method, and has found a very good conformity with the results of the tests. The method is essentially graphical. Better accuracy may be obtained by expressing the constants of the ellipse of elasticity by algebraic values. Generally, the method requires some knowledge of geometry (especially projective geometry), but the analysis is greatly simplified in cases where the change of moment of inertia can be expressed by algebraic terms permitting the use of tabular values. Three of the most common of such cases are demonstrated in Fig. 33.

Eqs. 1 and 2 are correct as long as the sections Δs are very small so that the elastic centroid of the section may be properly assumed as coinciding with the geometrical center of gravity. For sections in Fig. 33 (relatively long with respect to the change of the depth of the structural part) the elastic centroid approaches considerably nearer to the smaller cross section. It affects the elastic weight $\frac{\Delta s}{E\,I}$ and other elastic constants of the section considered, such as semi-axes of ellipse of elasticity, angular rotations, and respective centers of elastic rotations.

In Fig. 33, let: s = distance between elastic centroid S and face B; G = the elastic weight of the element $A\ B$, concentrated at elastic centroid S; and d = the distance between center of rotation (produced by a force F acting along the face B) and face B. Then the following equations express the elastic

---

deformations of the face B with respect to the face A due to pure bending:[18]
Angular rotation—

$$\Delta\delta = F\,G\,s \quad \ldots\ldots\ldots\ldots (7)$$

Displacement along the line of action of the force F—

$$\Delta = d\,\Delta\delta = F\,G\,s\,d \quad \ldots\ldots\ldots\ldots (8)$$

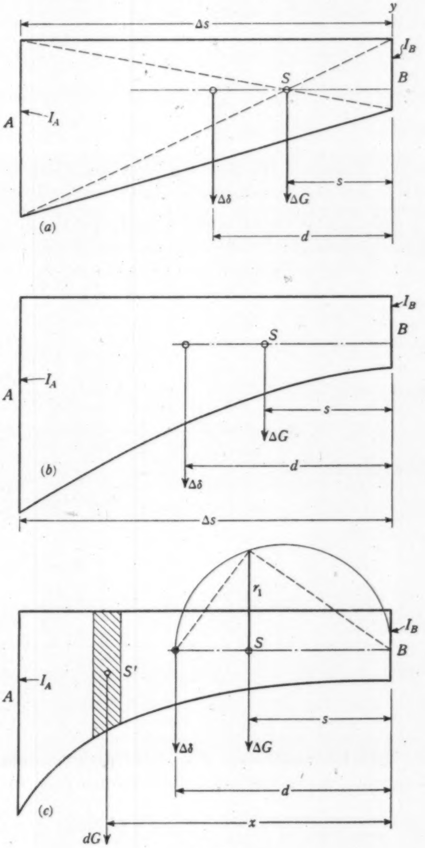

FIG. 33

Moment of inertia of elastic weight with respect to the face B—

$$I_G = G\,s\,d \quad \ldots\ldots (9)$$

Square of longitudinal semi-axis of ellipse of elasticity—

$$r_1^2 = (d - s)\,s \quad \ldots. (10)$$

Considering the effect of shear on deformation, Eq. 9 becomes (see Fig. 33)—

$$I_G' = \int_0^{\Delta s} \left[x^2 + (r_2')^2\,k\,\frac{E}{S} \right] dG \,. \quad (11)$$

in which: S is the modulus of elasticity in shear; r_2' is the radius of gyration of an element ds; and k is a numerical constant depending on the cross-sectional shape of the member (section). For prismatic members the value of k is $\frac{6}{5}$; and for **I**-shaped members it is approximately $\frac{A}{A'}$, in which A is the full cross-sectional area and A' is the cross section of the web.

The elastic constants of sections having the shapes shown in Fig. 33 are computed as follows:[19]
Straight line—

$$G = G_B\,\frac{2 + C}{2\,(1 + C)^2} \quad \ldots\ldots\ldots\ldots (12a)$$

in which I_B is the moment of inertia of cross section at B; and,

$$G_B = \frac{\Delta s}{E\,I_B} \ldots\ldots\ldots\ldots (12b)$$

$$C = \sqrt[3]{\frac{I_A}{I_B}} - 1 \ldots\ldots\ldots\ldots (12c)$$

$$s = \Delta s \frac{1}{2 + C} \ldots\ldots\ldots\ldots (12d)$$

$$d = \frac{\Delta s}{C^3} [2 \log_e (1 + C)(1 + C)^2 - C (2 + 3\,C)] \ldots\ldots (12e)$$

and

$$G\,s\,d = G_B \frac{\Delta s^2}{C^3} \left[\log_e (1 + C) - C \frac{2 + 3\,C}{2\,(1 + C)^2} \right] \ldots\ldots (12f)$$

Eq. 12*d* is determined exactly by the intersection of diagonals.

Parabolic—

$$G = \frac{G_B}{8} \left[\frac{5 + 3\,C}{(1 + C)^2} + \frac{3}{\sqrt{C}} \text{arc tan} \sqrt{C} \right] \ldots\ldots (13a)$$

$$G\,s = G_B\,\Delta s \frac{2 + C}{4\,(1 + C)^2} \ldots\ldots\ldots\ldots (13b)$$

and

$$G\,s\,d = \frac{G_B\,\Delta s^2}{8} \left[\frac{C - 1}{C\,(1 + C)^2} + \frac{1}{C\,\sqrt{C}} \text{arc tan} \sqrt{C} \right] \ldots\ldots (13c)$$

Sharply curved—

$$G = G_B \frac{1 + b}{2} \ldots\ldots\ldots\ldots (14a)$$

in which

$$b = \frac{I_B}{I_A} \ldots\ldots\ldots\ldots (14b)$$

$$s = \Delta s \frac{1 + 2\,b}{3\,(1 + b)} \ldots\ldots\ldots\ldots (14c)$$

and

$$d = \Delta s \frac{1 + 3\,b}{2\,(1 + 2\,b)} \ldots\ldots\ldots\ldots (14d)$$

Elastic constants for these three shapes are compiled in tables.[20] For example, using the tabulated values p, q, and u:[20]

$$G = (p + q)\,G_B \ldots\ldots\ldots\ldots (15)$$

$$s = \frac{p}{p + q} \Delta s \ldots\ldots\ldots\ldots (16)$$

and

$$d = (1 - u)\,\Delta s \ldots\ldots\ldots\ldots (17)$$

---

[20] Discussion by Walter Ruppel, Assoc. M. Am. Soc. C. E., of "Moments in Restrained and Continuous Beams by the Method of Conjugate Points," by L. H. Nishkian and D. B. Steinman, Members, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 90 (1927), pp. 167–187.

These formulas are valid for each shape shown in Fig. 33. Only the values of d are affected by shear. Considering the shear, the moments of inertia of the elastic weight with respect to face B are $I_G' = I_G + I_G''$, in which the values of I_G'' (due to shear) are given by the following equations (in which $(r_2')^2 = \frac{I_B}{A_B}$):

Straight line—

$$I_G'' = k\,\frac{E}{S} \times (r_2')^2 \times \log_e \frac{1 + C}{C}\,G_B \ldots\ldots\ldots\ldots\ldots (18a)$$

Parabolic—

$$I_G'' = k\,\frac{E}{S} \times (r_2')^2 \times \frac{1}{\sqrt{C}} \text{arc tan } \sqrt{C}\,G_B \ldots\ldots\ldots\ldots (18b)$$

Sharply curved—

$$I_G'' = k\,\frac{E}{S} \times (r_2')^2 \times \frac{3}{4} \times \frac{1}{1 - b}\,(1 - \sqrt[3]{b^4})\,G_B \ldots\ldots\ldots (18c)$$

The framed structure is divided into sections allowing the application of the foregoing formulas (Fig. 34). The redundant horizontal reaction is computed by that one of the following methods of analysis, based on the principles of the ellipse of elasticity, which appears most suitable for a given case:

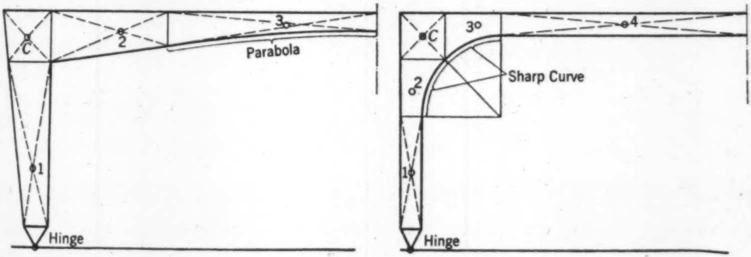

FIG. 34

(1) Compute the angular rotation $(\delta)_M$ for a simply supported beam $A\,B$ due to the given loading, and its center D_M (Fig. 35(a)). The horizontal reaction is then

$$H = \frac{(\delta)_M}{G\,s_H} \times \frac{d_M}{d_H} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

in which G is the total elastic weight of the framed structure concentrated at the elastic centroid S; s_H is the lever arm of the elastic weight G with respect to the line of action of the force H (passing through hinges C and D); d_H is the perpendicular distance between the center of rotation D_H of the force H and the line $C\,D$, D_H being the antipole of $C\,D$ with respect to the ellipse of elasticity of the whole structure; and d_M is the perpendicular distance between the center of rotation D_M of a simply supported beam $A\,B$ due to the given loading.

(2) Consider $A\ B$ as fixed at A and B (Fig. 35(b)), and compute the angular rotations of the columns at A and B due to unit moment. These angular rotations define and determine the elastic weights G_A and G_B of supports A and B. Combine the elastic weights of the supports with the elastic weight G_0 of the beam $A\ B$ and determine the end moments M_A and M_B of the restrained beam.

FIG. 35

(3) Determine the deflection Δ_F at the point of application of the force F and the displacement Δ_H along $C\ D$ due to a force $H = 1$. From the basic principle of reciprocity of deformations, the magnitude of the horizontal reaction is found to be:

$$H = -\frac{F\,\Delta_F}{\Delta_H} \qquad (20)$$

(4) When the loading consists of a group of concentrated forces, or of uniformly distributed weights, it is preferable to draw the deflection curve due to $H = 1$, acting along $C\ D$, with the pole distance $\Sigma\Delta G\ y$, which is the influence line of the redundant force H (Fig. 35(c)):

$$H = -\frac{F\,y'}{d_H} \qquad (21)$$

in which d_H has the same significance as in Fig. 35(*a*). As far as the stress distribution within the knee of the investigated frames is concerned, the results reported by the authors were compared with photoelastic tests, at the University of California,[21] relating to stress concentrations at sharp reentrant angles and curved fillets.

Conclusion.—The tests reported in this paper are checked very closely by the analysis outlined herein.

A. C. Barrow,[22] Assoc. M. Am. Soc. C. E. (by letter).—The data presented in this paper can be tested by applying the formula:

$$f = \frac{P}{A} \pm \frac{P\,e\,c}{I} \qquad (22)$$

in which: f represents a unit stress at either edge of the section, depending on whether the plus or minus sign is used; P represents the force acting on a section, symmetrical about at least one axis through the center of gravity of the section; A represents the area of section under consideration; e equals the eccentricity of the line of action of the force F; c is the distance from the center of gravity of the section to the edge of the section where the value of f is to be determined; and I is the moment of inertia of the section about an axis through the center of gravity and at right angles to the axis through its center of gravity and the point of application of the force P. The flange stresses throughout the rigid frame can be computed by Eq. 22, both for square knees and curved knees.

The Curved Knee.—The knee in these frames (see Fig. 18) may be considered to be loaded or stressed by a moment produced by an eccentric loading, consisting of the horizontal reaction acting through the hinge and the vertical reaction acting through the same point and decreasing the resulting moment of the horizontal reaction.

The writer made a drawing of this frame to a scale of 6 in. equals 1 ft, and the lever arms of these forces were scaled from it. First, a vertical section was passed through point 27, Fig. 18. The moment of the horizontal reaction about the center of this section was obtained. This was decreased by the moment of the vertical reaction of 6,000 lb about the same point. The result was multiplied by the distance of the outermost fiber from the center of the section, and this result was divided by the moment of inertia of the section about its center and at an angle of 90° with the vertical axis of the plate. The horizontal reaction of 4,350 lb was divided by the area of the vertical section. This latter value was subtracted from the result already obtained to find extreme fiber stress in the outer flanges and added to find the stress in the inner flanges. The gross moment of inertia was used. The author states (see heading "Relation of Test Data to Analysis: Moment of Inertia") that "The effective moment of inertia was slightly less than the gross moment of inertia * * *," and that "If the gross moment of inertia had been used, the error would have been about 3%, for this girder." Therefore, 3% was added to the foregoing results. The inner edge of the knee was at an angle of 45° at point 27 and the value found for the inner flanges was multiplied by the secant of 45°.

[a] Computed values rounded out to nearest 100 lb per sq in.

Table 5 shows the results of the values thus determined compared with the observed values as shown in Fig. 18.

A different procedure is required for finding the flange stress in the vertical leg of this frame. It is obvious that the flange stress at point 26 is the same as that at point 28, except that it carries its proportion of uniformly distributed force, producing the vertical reaction of 6 kips, over a horizontal section through point 26. Fig. 18 shows the unit stress at point 26 to be slightly more than at point 28. From this consideration there should be a difference of about 1 kip. The difference in the stress at these points increases down the vertical leg, and this is as it should be because the total stress is the same (6 kips) and the area of the section decreases to and including point 23.

For point 27, the agreement is close (Table 5), but for other points on the inner edge of the knee the difference between the computed values and the observed values increases. Eq. 22 is valid only for short increments of length, and it is the elasticity of the frame at these points that causes a greater stress and increased differences. They are given to show how far Eq. 22 may be used to check the observed values.

The Square Knee.—Applying Eq. 22 to the square knee and using a horizontal reaction of 5,280 lb, the stress at the inner corner is 16,571 lb per sq in. and the observed stress is about 17,000 lb per sq in. Just above this point, there is a computed stress of 14,473 lb per sq in. and an observed stress of about 14,000 lb per sq in. (Fig. 16).

In the paper it is stated (see heading "Test Specimens") that

> "At the intersection of the compression flanges at both knees, where tight bearing should be obtained, small gaps existed. It was considered advisable to fill these gaps with shims that were tackwelded in place, but which produced tight bearing only along the outstanding legs of the girder flange angles."

This connection produces another case of eccentric loading, and Eq. 22 determines a stress of 23,055 lb per sq in. at this point. Fig. 16 shows an observed stress of 23,000 lb per sq in. in the horizontal flanges some distance from this inner corner. The stress decreases rapidly from the inner corner and, if this line is produced to a point in the graph directly opposite the inner corner, a stress of 25,000 lb per sq in. would be indicated.

The observed and computed stresses both show clearly the danger of imperfect bearings at the inner corner of the rigid frame with a square knee.

W. E. BLACK,[23] JUN. AM. SOC. C. E. (by letter).—Those who submitted discussions have contributed many interesting comments and constructive criticisms. It was gratifying to note that the results of the tests made at the National Bureau of Standards were brought into the discussion frequently. The two investigations represent the only experimental work on steel rigid frames reported in the United States to date (1941), and any discussion of the analysis or design of steel rigid frames should rightly refer to both. Much of the discussion centered about two controversial points—the concentration of stress at the sharp inner corner of the square knee, and the stability of the curved knee. Therefore, each will be discussed individually.

Concentration of Stress in Square Knee.—Several of the discussers have taken exception to the writers' conclusion that the concentration of stress at the inner corner of the square knee was of relatively minor importance. In a continuous and elastic knee of this type, it is generally recognized that the compression stress at the inner corner of the knee is extremely high under the usual manner of loading. Photoelastic tests have demonstrated this fact incontrovertibly. However, it is the writers' contention that, due to the method of fabrication, the type of knee tested does not act as a continuous member. The reactions of the horizontal girder upon the inner face of the column may be assumed to consist of the tension in the top flange, the compression in the bottom flange (both acting approximately at the flange centers of gravity), and a vertical shear. This assumes that the web transmits very little, if any, of the moment or thrust across the connection, a contention that is supported by Fig. 9.

If the action of the knee is represented accurately by the foregoing assumptions, the intensity of stress at the inner corner will be directly dependent upon the type of bearing obtained. In the Lehigh tests, an extreme concentration of bearing was encountered, and a high stress resulted. However, the average stress in the compression flange was not excessive. In the Bureau of Standards tests, tight bearing was not obtained, and the maximum stress in the compression flanges at the inner corner of the knee was comparatively low. Mr. Osgood points out that failure in the Bureau of Standards' square knee occurred by local buckling of the compression flanges adjacent to the inner corner. Is it strange that such would be the case when the failure load was two and one half times the "design load," and when any accepted method of analysis will locate the point of maximum stress in the knee at the inner corner? Furthermore, in the usual rigid-frame knee, the compression flange will include cover plates, and local buckling will be less likely to occur, and probably not before the yield point of almost the entire compression flange is reached. However, the possibility of this type of failure should be recognized, and steps should be taken in design to prevent its occurrence.

---

[23] Instr., Dept. of Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.

Mr. Grover warns of the possibility of fatigue failure at the knee. The writer believes that repeated stress will not be an important factor in the design of steel rigid frames of this type since a reversal of stress is not likely to occur. The endurance limit of structural steels, tested from zero to a maximum stress in either tension or compression, is well above the yield point. A fatigue failure at the point of greatest stress concentration, the inner corner, is practically impossible since it is almost always subjected to a compression stress. A tensile failure at the opposite side of the member is equally improbable since the greatest stress there will seldom be as high as the allowable working stress.

One of the worst mishaps that may befall a square type rigid-frame knee is the occurrence of a loose fit at the inner corner. This condition would be equivalent to a decrease in stiffness of the knee. Although complete failure could not result from this cause, there would result excessive stresses and deflection at midspan. On the other hand, an extreme concentration of stress at the inner corner, if not accompanied by local buckling of the compression flanges, would be relieved by the ductility of the metal. In general, even though the stress at the inner corner should reach the yield point, nothing serious would happen until practically the entire compression flange was so stressed, a condition which could not be obtained until the design load was greatly exceeded under the method of design recommended by the writers.

In Mr. Hirschthal's discussion of the maximum compression stress at the reentrant corner of a rectangular rigid-frame knee, he is perhaps underestimating the magnitude of the theoretical maximum compression stress. The determination of this stress is scarcely as simple as Mr. Hirschthal suggests. T. J. Dolan[24] found by photoelastic tests that the maximum compression stress at the reentrant corner of a similarly-shaped bakelite model was about 2.5 times the stress computed by the flexural theory. This stress, however, is extremely local, and in the case of a riveted steel rigid frame, it may be much lower, depending upon the condition of bearing at the corner, the degree of continuity in the knee, and the angle of the reentrant corner.

Stability of the Curved Knee.—Attention was focused on the instability of certain types of rigid-frame knees by the results of tests on rigid-frame knees at the Bureau of Standards.[3, 4, 5] A knee with a large circular fillet (very similar to the Lehigh curved knee frame) failed by lateral buckling of the entire curved flange at a load but little greater than the design load. Similar knees having sharp reentrant corners at the inside of the knee supported more than twice their design loads and then failed by local buckling of the compression flange near the reentrant corner. Each of the latter specimens had at least one pair of web stiffeners at the knee. Whether or not web stiffeners would have prevented buckling of the curved knee is problematical. Professor Posey is inclined to think they would, whereas Mr. Osgood expressed the belief that lateral bracing would be necessary to properly stiffen such a knee frame.

---

[24] "An Investigation of Rigid Frames, Part I, Tests of Reinforced Concrete Knee Frames and Bakelite Models," by F. E. Richard, T. J. Dolan, and T. A. Olson, *Bulletin No. 307*, Univ. of Illinois Eng. Experiment Station, November, 1938.

Mr. Grover suggests that web stiffeners may be used to reduce lateral deflection of the compression flange as a whole, and, in addition, stiffen the outstanding legs of the compression flange against transverse bending of the type found in the Lehigh tests. The writers are not at all certain that web stiffeners would prevent, completely, lateral buckling of the curved flange of a knee of this type. However, the compression flange should be stiffened to prevent transverse bending of the outstanding legs, and a web stiffener welded to or bearing tightly against the compression flange, as suggested by Mr. Grover, might help to solve both problems. Further tests should be made to determine the effectiveness of web stiffeners in preventing lateral buckling of knees of this type.

It is to be regretted that more information regarding buckling was not obtained in the writers' tests, but since the primary purpose of the investigation was the determination of stress distribution, other related phenomena had to be neglected because of time limitations. However, as Mr. Osgood states, with the curved flange supported laterally at one point, no web or flange buckling was noticed in the Lehigh curved-knee frame, even though the flange stresses developed were as high as 29,000 lb per sq in. Further information regarding the ultimate strength of rigid frames may be forthcoming, as the American Institute of Steel Construction has made arrangements for testing to destruction the two rigid frames which were tested under design loads by the writers.

General Discussion.—Professor Eney has described a method of investigation of structural frame models that is particularly well adapted to studying the effects of varying the relative proportions of different parts of the frame. Thus he has investigated the effects of varying the stiffness of both the knee and the footing of a fixed frame, a procedure which could not be followed for larger steel models without prohibitive expense. It is gratifying to note that where his results can be compared with those obtained by the writers, a qualitative agreement was obtained.

The writers are indebted to Mr. Grover for his excellent résumé of the work done in this field. With his recommendations regarding further tests the writers are in whole-hearted agreement.

Mr. Osgood's comment regarding the position of the neutral axis in Fig. 20 is quite correct. The observed neutral axis for stresses on the circular sections would probably fall quite close to the points of zero stress shown in the figure.

Mr. Hirschthal points out the fact that the observed stresses near the tangent points of the curved knee were greater than computed stresses, and that away from the knee, observed stresses were slightly the lower (Fig. 18). It might be well to add that the observed stresses at midspan were slightly greater than corresponding computed stresses. The reason for these differences between computed and observed stresses away from the knee is that the computed stresses were determined from the theoretical external reactions, and there was about 3.5% difference between the theoretical and observed horizontal reactions for the curved knee frame. Using the observed external reactions for the computation of flange stresses away from the knee, the agreement with observed stresses was almost exact.

Mr. Hirschthal's discussion of the curved knee includes one misleading item. If, in Fig. 32, the resultant thrust T is meant to be the resultant of the three forces shown at the section through points 19 and 32, it is somewhat misplaced. Fig. 1(*b*) may be used to clarify the matter. The force T must be equal, collinear, and opposite to the resultant of the pin reactions at the base of the vertical leg ($P = 6{,}000$, $H = 4{,}500$ approximately), and therefore must intersect the diagonal section of Fig. 32 at a point almost coincident with the center of curvature of the curved flange, and not within the section at all. To resist such a loading, considerable tension, as well as compression, must be developed within the section. A consideration of the forces acting upon a differential rectangle of the web plate at the extreme outside corner of the knee will show that there can be no tensile stress on the diagonal section at that point, although between that point and the neutral axis, considerable tension must exist (Fig. 11).

Mr. Polivka has presented a method of analysis which appears to be particularly well adapted for application to frames of varying moment of inertia, and in which some of the approximations usually made are eliminated. The agreement obtained between Mr. Polivka's computations and the writers' test results was gratifying.

Mr. Barrow has presented a simple and familiar method of computation, which, with a few modifications, gives surprisingly close agreement with the observed test results. The use of such simple methods of analysis is to be encouraged wherever applicable. That Mr. Barrow's computed stresses for the curved flange of the curved knee were somewhat less than the observed stresses demonstrates further that straight-beam formulas are not quite adequate for this type of member.

Even now, more tests on steel rigid frames are being made in the United States, and definite answers may soon be provided for some of the still debatable questions. It would be well to know, among other items, the most economical and efficient shapes for rigid-frame knees, how to stiffen the more flexible types of knees most effectively, and the effect of cyclic or repeated loads on rigid frames. Nevertheless, the writers are of the opinion that sufficient information concerning the stress distribution in rigid frames and the accuracy of current methods of analysis is now available so that engineers may design rigid frames with confidence and perhaps more economically than has been done in the past.

It is a source of regret to the writer that the preparation of these closing comments could not have been shared by Professor Lyse, now resident in Trondheim, Norway. Distance and disturbed communication conditions, however, have made this virtually impossible.

LABORATORY INVESTIGATIONS OF SOILS AT FLUSHING MEADOW PARK

By DONALD M. BURMISTER,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Gordon E. Thomas and M. N. Sinacori, E. J. Kilcawley, Dimitri P. Krynine, B. K. Hough, Jr., T. B. Rights, and Donald M. Burmister.

SYNOPSIS

Laboratory investigations made to determine the general suitability of the Flushing Meadow in New York, N. Y., for development as a permanent park and for supporting the temporary and permanent structures of the World's Fair, are described in this paper. The problems encountered in the reclamation and development of the site arise from the peculiar nature of the soils of the meadow, which are quite typical of such tidal marsh deposits. The tests included routine studies to determine the general physical character, and consolidation and shear tests to determine the behavior characteristics of the materials encountered. They were made primarily to furnish information on what could be done and how it should be done. The tests and their interpretation are discussed in relation to these problems, and certain suggestions are made as to the correlation of test results which permit the use of data obtained from the simpler tests as a basis for predicting the more general behavior of soils.

INTRODUCTION

The laboratory investigations for the development of the Flushing Meadow Park site for the New York World's Fair were interesting in many respects, not only because of the practical use made of the results of soil tests, but also because of the interesting nature of the problems encountered. The first series of tests was made during the latter part of 1935 for a preliminary report, by the consulting foundation engineers, on the suitability of the Flushing Meadow for development as a permanent park and for supporting the permanent and temporary structures of the World's Fair,[2] and for a later report by the same engineers during 1936 for certain permanent structures.

Note.—Published in January, 1941, *Proceedings*.

[1] Asst. Prof., Civ. Eng., Columbia Univ., New York, N. Y.

[2] "The Application of Soil Mechanics in Building the New York World's Fair," by George L. Freeman, M. Am. Soc. C. E., Hamilton Gray, Jun. Am. Soc. C. E., and George W. Glick, *Civil Engineering*, October, 1940, p. 649; see also "Soil Survey of the Flushing Meadow Park Site, Long Island, New York," by George L. Freeman, *Paper No. C-2*, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Harvard Univ., Cambridge, Mass., 1936, Vol. I, p. 25.

The Flushing Meadow was a low-lying tidal marsh, only about 2 ft above mean tide, consisting of deposits of very soft silty clays extending to a depth of 60 ft or more in some places, and underlaid by sands and gravels. The materials of the deposit were sampled by forty-eight undisturbed samples from twelve borings, 3 in. in diameter, which were tested (see Table 1) primarily to furnish information on the nature of the problems to be encountered, and to serve as a guide for making recommendations as to:

TABLE 1.—SCHEDULE OF SOIL TESTS, FLUSHING MEADOW PARK

Series	Borings	Samples	Routine tests	Consolidation tests	Shear tests
Preliminary report.....	12	48	48	20	19
Permanent structures..	25	70	70	19	48

(1) Methods of filling and grading the site, stable slopes, etc., to prevent lateral subsurface soil movements;

(2) The quantity of fill material required and finished grade elevations to compensate for the expected settlement due to the weight of the fill; and

(3) The allowable foundation pressures in different parts of the area and the settlement to be expected when the structures were erected.

In addition, seventy undisturbed samples from twenty-five borings, 3 in. in diameter, taken at the proposed sites of permanent structures, were tested to furnish detailed information as to the foundation conditions and for use in selecting and designing the most satisfactory and economical types of foundations for the different types of structures. A more detailed study and analysis of the results of the soil tests than was possible at the time, together with the results of subsequent researches on the Flushing Meadow soils, are herewith offered to complete the information on the development of the Flushing Meadow Park site.

PHYSICAL CHARACTERISTICS

Routine tests were made on all samples for the purpose of classifying the soils. These tests included: Natural moisture content, grain-size analysis, liquid, plastic and shrinkage limits, specific gravity, loss on ignition, and a routine squeeze test.

These routine tests gave information on the general character of the soils encountered and their uniformity or variability. Furthermore, they showed whether the Flushing Meadow soils had regular characteristics[3] usually associated with materials of their grain-size distribution, or whether they had unusual or peculiar characteristics that would be expected to influence their behavior greatly. For similar grain-size distributions, soils having regular characteristics have been found to possess similar properties. The peculiar nature of the Flushing Meadow soils is shown by the extremely high values of the liquid limit and plasticity index in relation to those for regular soils. These characteristics are due inherently to the mineralogical and chemical nature of the true clay fraction of the soil.

---

[3] "The Physical Characteristics of Soils with Special Reference to Earth Structures," by Donald M. Burmister, *Bulletin No. 6*, Dept. of Civ. Eng., Columbia Univ., New York, N. Y.

Microscopic studies and X-ray diffraction patterns show that the clay minerals consist chiefly of kaolinite and hydromica. The hydromica clay minerals, which are an intermediate alteration product of a scale-like crystalline structure formed by the weathering of feldspathic rocks to kaolinite, and the high organic content are responsible for the unusual character of the Flushing Meadow soil.

The natural moisture content is characteristically high for these materials, as shown in Fig. 1, being about 100% by dry weight, or more. A striking feature shown by these tests is the fact that the moisture content is practically uniform below the meadow mat down to the underlying sand and gravel layers, and about equal to the liquid limit, a condition which seems to be characteristic of such deposits. These facts explain why this material is so extremely soft in character, and indicate that any serious disturbance would tend to reduce it to consistencies approaching the liquid-limit condition. Although the meadow mat had still higher moisture contents of 200% or more, it had considerable strength because of the strong root system, a fact that made possible, and greatly facilitated, the grading operations. A marked peculiarity of samples from certain areas of the Flushing Meadow was the swelling properties they exhibited, due to the release of dissolved gases (probably marsh gas).

A most important property of the silty clay deposit is its natural structure, which gives the undisturbed material a much higher strength than when remolded or disturbed. It is important, therefore, to obtain preliminary information on the structure and consistency of all samples. The small cylinder test (or cube test) has been used for such purposes, on medium to stiff clays, by Karl Terzaghi,[4] M. Am. Soc. C. E., and by others. A simplified small squeeze test device[5,6] was developed, for the very soft materials encountered in the Flushing Meadow, to obtain preliminary information on the structural capacity of these materials. A small sampling tube is used to cut a cylindrical specimen 2 sq cm in area by 1 cm high. The average final diameter, in centimeters, of the squeeze specimen, after applying a 2-kg load, is taken as the squeeze test value.

The structure of the clay is indicated in the soil profile of Fig. 1 by plotting the undisturbed squeeze test diameter, which is determined primarily by structure, and the remolded value, which is considerably greater and is influenced largely by moisture content.

It is interesting to note that the consistency of the material, as indicated by the undisturbed squeeze test value, does not increase appreciably with depth for boring No. 17, whereas for boring No. 2 the consistency of the upper layers

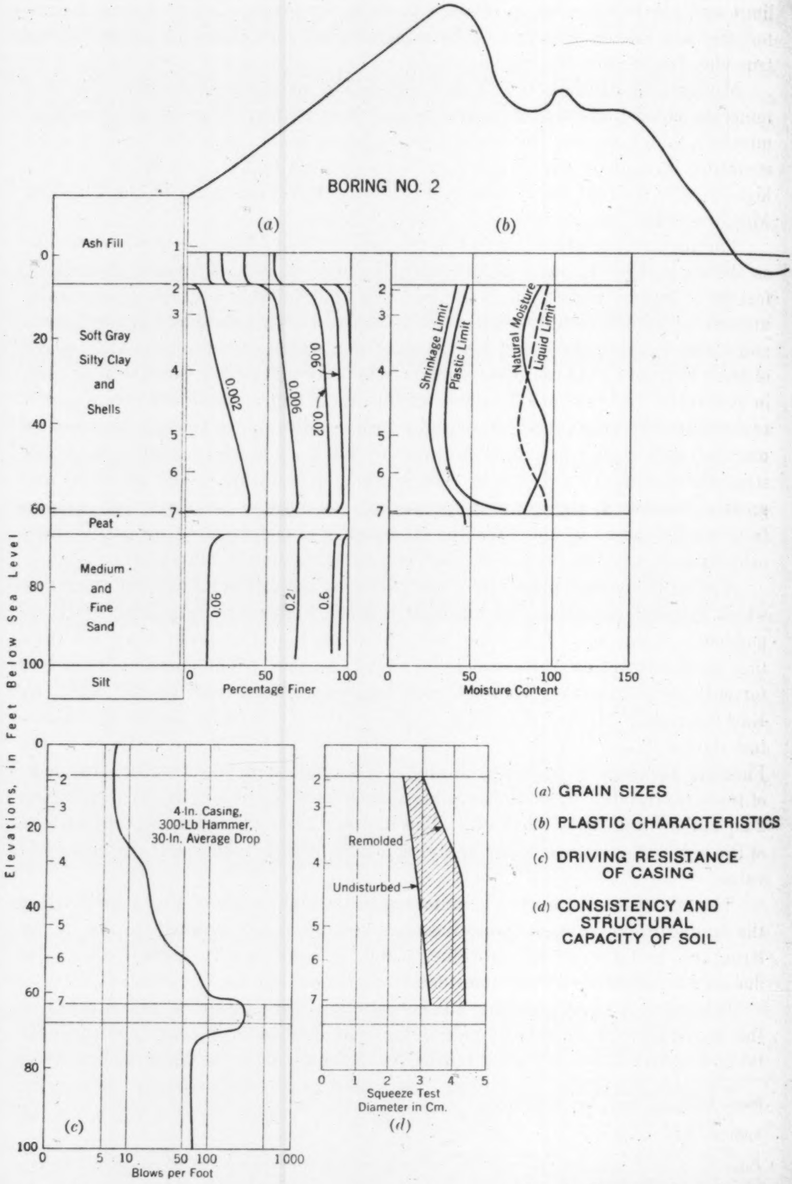

FIG. 1.—PHYSICAL CHARACTERISTICS

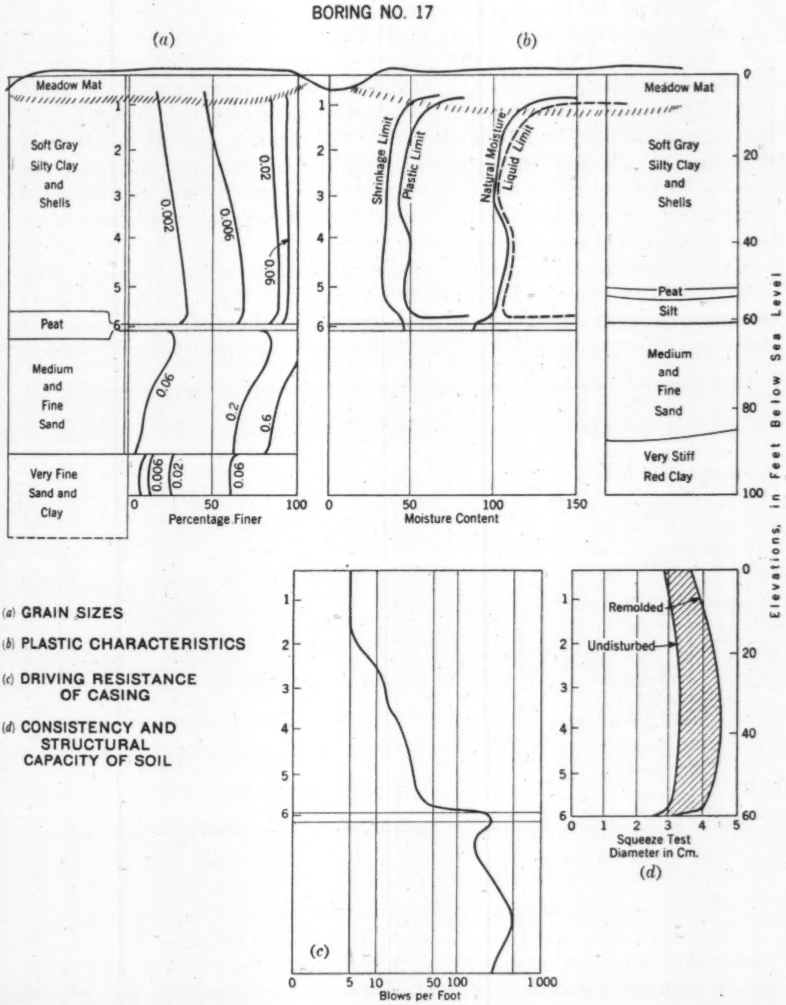

OF THE FLUSHING MEADOW SOILS

directly beneath the ash dump is much stiffer as a result of the consolidation of the material under the weight of the ash fill.

The structural capacity of the soil is indicated by the numerical difference or spread between the squeeze test diameters for the undisturbed and remolded states, about one centimeter indicating a fairly undisturbed and representative sample for these soft Flushing Meadow soils. Correlations with shearing tests on these materials showed that a spread of one centimeter represented a ratio of 6 : 1 between the shearing strength in the undisturbed and remolded states. A comparison of the squeeze test diameters in the remolded state in Fig. 1 with the values obtained for the liquid limit and plastic limit conditions of remolded materials, respectively 3.70 and 1.60 cm, indicates how serious would be the effect of any disturbance to the natural structure of these silty clays with the consequent loss of shearing strength. The shearing strength at the liquid limit is approximately 0.02 kg per sq cm. The routine squeeze test may be used in the laboratory for selecting the more representative and least disturbed samples for the consolidation and shear tests, and also has possibilities in the field for control of sampling operations.

The extremely soft consistency of the materials encountered in each boring is also clearly indicated by typical driving records in Fig. 1. The presence of the underlying sand and gravel layers, together with the relative compactness of these deposits, is shown by the marked increase in driving resistance of the casing.

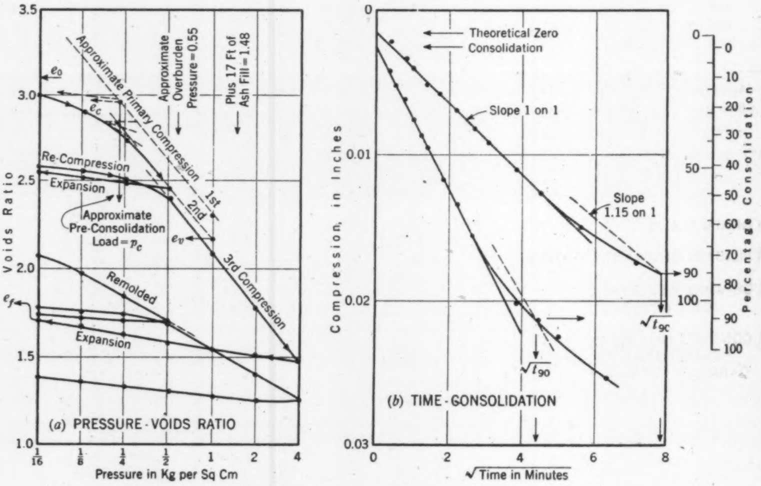

FIG. 2.—TYPICAL CONSOLIDATION CHARACTERISTICS OF THE FLUSHING MEADOW SOILS

CONSOLIDATION CHARACTERISTICS

The consolidation characteristics of the Flushing Meadow deposits were obtained from consolidation tests, which indicated that settlements of considerable magnitude were to be expected from the consolidation of the soft material under the weight of the fill, and of the Fair structures.

Typical pressure-voids ratio and time-consolidation curves are shown in Fig. 2. The subscript v denotes compression or volume-change phenomena in general. It is applicable to all materials, whether simple compression takes place, as in permeable, cohesionless soil; or whether consolidation takes place, as in saturated plastic clays. The subscript c denotes phenomena specifically related to consolidation. The consolidation characteristics required for settlement analyses are as follows:

(1) The voids ratio e_v at a pressure of p' equal to 1 kg per sq cm;

(2) The compression index c_v (slope of the pressure-voids ratio curve on a semi-log plot);

(3) The pre-consolidation load p_c, as defined by Arthur Casagrande,[7] Assoc. M. Am. Soc. C. E.;

(4) The coefficient of consolidation c_c, as determined either by the Casagrande[8] or the Taylor method.[9]

According to the Taylor diagram (Fig. 2) these coefficients are:

Item	Undisturbed	Remolded
$2\,h_o$, in cm	0.405	0.497
$\sqrt{t_{90}}$, in min	4.4	7.8
t_{90}, in min	19.4	60.9
c_c, in sq cm per min	0.0018	0.00078
Load increment, in kg per sq cm	$\frac{1}{4}$ to $\frac{1}{2}$	$\frac{1}{4}$ to $\frac{1}{2}$

A comparison of consolidation coefficients is afforded by reference to Table 2.

TABLE 2.—CHARACTERISTICS OF MATERIAL IN BORING NO. 9, SAMPLE 5 (DEPTH = 52 FT), AT BRIDGE C ACROSS HORACE HARDING BOULEVARD

CONSOLIDATION CHARACTERISTICS				PHYSICAL CHARACTERISTICS	
Item	Symbol	Undisturbed	Remolded	Definition	Value
Voids ratio at pre-consolidation load	e_c	2.96	....	Liquid limit	93.0
Voids ratio at $p' = 1$ kg per sq cm	e_v	2.17	1.55	Plastic limit	42.2
Compression index	c_v	0.361	0.216	Plasticity index	50.8
Coefficient of compressibility ($\frac{1}{4}$ to $\frac{1}{2}$ kg)	c_a	1.25	0.56	Specific gravity	2.73
Coefficient of consolidation in sq cm per min	c_c	0.0018	0.00078	Squeeze Test:	
				Undisturbed	2.9[a]
				Remolded	4.2[a]

[a] Squeeze test units are centimeters.

DEFINING EQUATIONS

Two defining equations used in this paper are:

$$e = e_v - c_v \log_e \frac{p}{p'} \qquad (1)$$

---

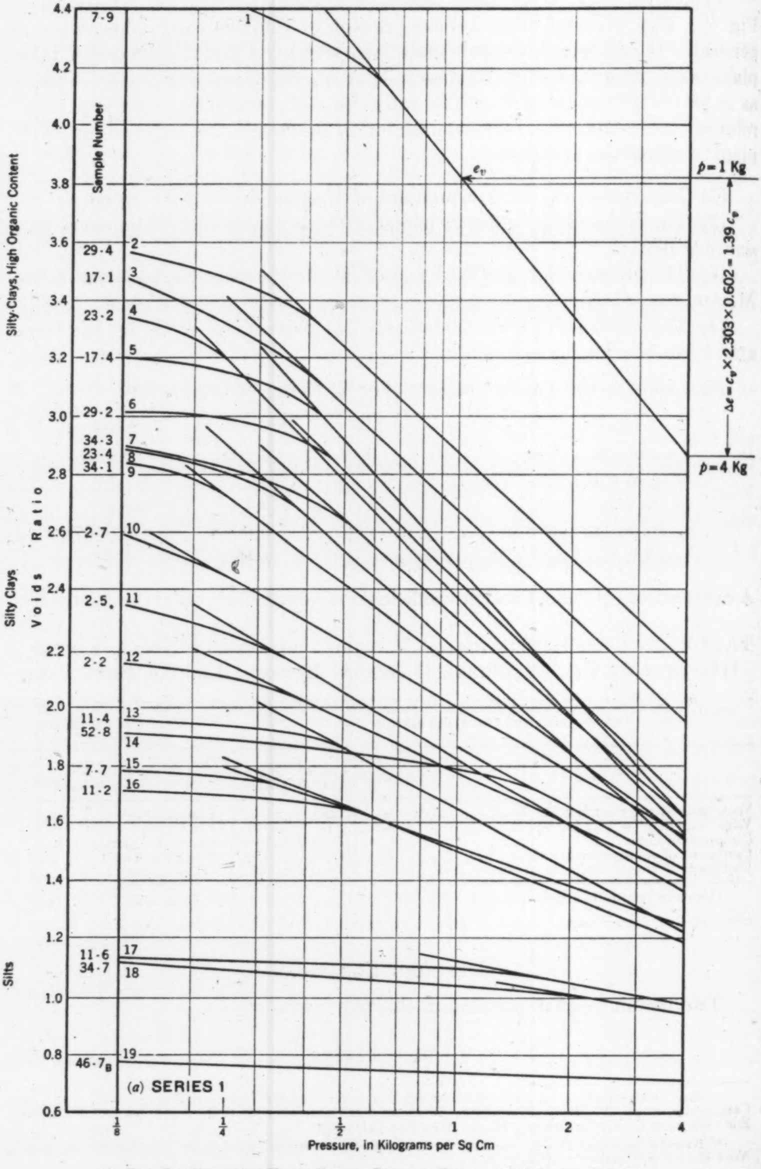

FIG. 3.—PRESSURE-VOIDS RATIO CURVES, FLUSHING MEADOW SOILS

and, total settlement by the summation method,

$$S = \sum \Delta h \frac{e_1 - e_2}{1 + e_1} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which $(e_1 - e_2)$ corresponds to the initial and final pressures, p_1 and p_2, respectively, at the center of the soil layer, the thickness being Δh.

The organic silty clays of the Flushing Meadow deposits are characterized by steep pressure-voids ratio curves, high initial voids ratios, low pre-consolidation loads, and very flat expansion curves, as shown in Fig. 2, which are consistent with the unusual physical characteristics shown in Fig. 1. An unloading and reloading cycle was made in the region just beyond the estimated pre-consolidation load in order to observe and study the characteristics of the consolidation curve in a loading cycle similar to that resulting from the sampling operation.

The marked effect of remolding or disturbance is shown by the fact that a compression of about 25% occurs under the pre-consolidation load as a result of complete remolding before equilibrium under this same pressure is again reached. The spread between the two curves is a measure of the natural structural capacity of the material. It is interesting to note in Fig. 2 that the breakdown of the natural structure and the dispersion of the soil grains by remolding, but without change in moisture content, also tend to decrease or slow up the rate of consolidation appreciably. The coefficient of consolidation is determined by the Taylor method,[9] plotting compression against the square root of time. The parabolic nature of the initial stages of the time-consolidation curve of Fig. 2(*b*) is shown by the linear relationship to about 60% consolidation, which facilitates making preliminary forecasts of settlement.

The pressure-voids ratio curves of series 1 are plotted in Fig. 3 to show the range and characteristics of the materials of the deposits. A striking feature of these curves is the consistent tendency for steep curves of compressible materials to be associated with high values of the voids ratio at the 1 kg pressure, and for flat curves of relatively incompressible materials to be associated with low values. The practical significance of these interrelationships was first presented and discussed orally by Arthur Casagrande and Philip C. Rutledge, Assoc. Members, Am. Soc. C. E. (Fall Meeting of the Society in October, 1937), who suggested that a simple characteristic soil test such as the liquid limit could be used practically for obtaining preliminary estimates of the consolidation characteristics of undisturbed materials.

In a natural state of consolidation, a material passes from a suspension by the simple process of settling or sedimentation to a point where a real structure begins to form, which is capable of carrying stress as the overburden accumulates. A certain amount of pressure (although very small) is then required either to deform or to further compress the material. This moisture content is characteristic and may be considered as the starting point of true consolidation, and the transition from the suspended liquid state to the plastic state. The liquid limit, a characteristic moisture content of a remolded material, represents a moisture condition somewhat below this transition point. However, the same inherent physical characteristics of the material,

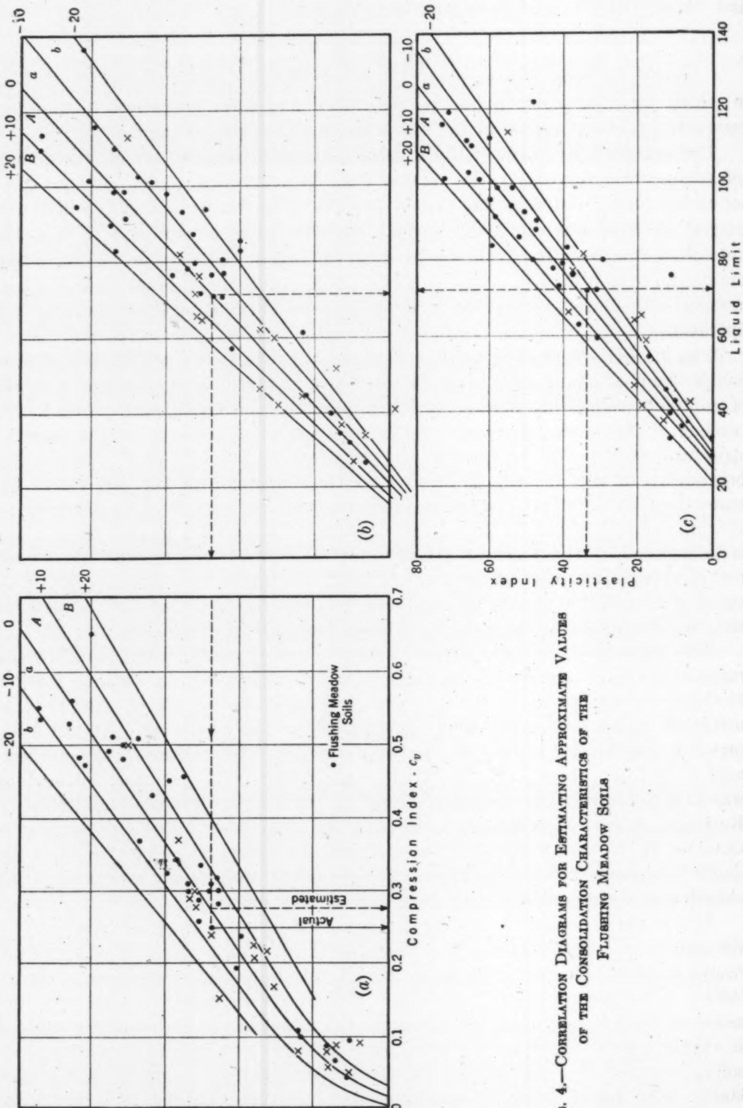

FIG. 4.—CORRELATION DIAGRAMS FOR ESTIMATING APPROXIMATE VALUES OF THE CONSOLIDATION CHARACTERISTICS OF THE FLUSHING MEADOW SOILS

which determine the liquid-limit condition, determine not only this characteristic moisture content at the starting point of consolidation before a real soil structure forms, but also the form of this structure, which is a determining factor in the compressibility of the undisturbed material in a natural state of consolidation.

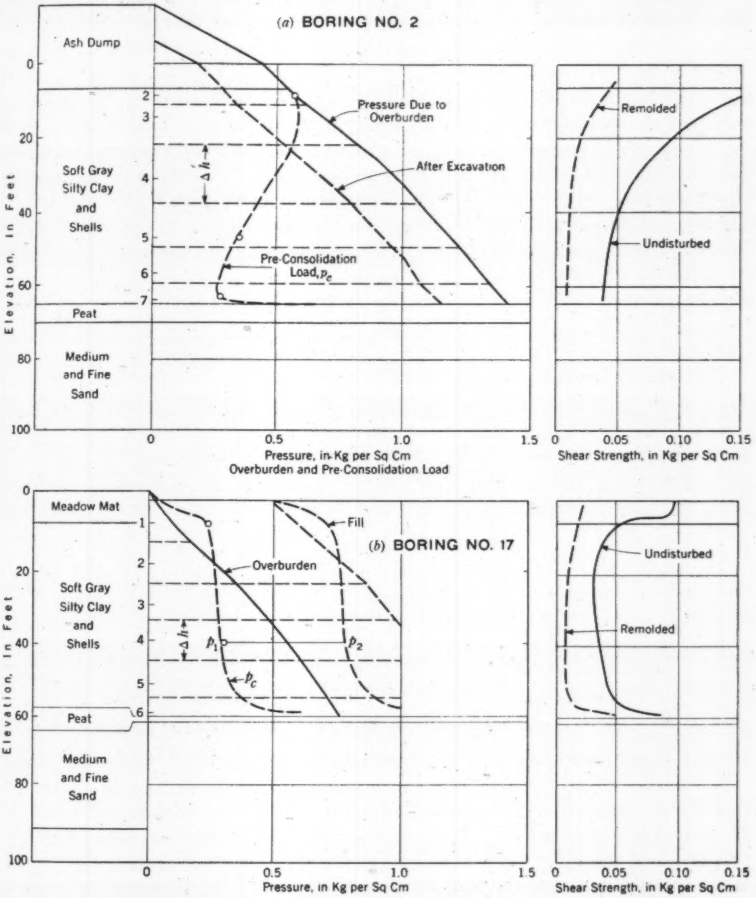

FIG. 5.—STRESS CONDITIONS AND SHEARING STRENGTH, FLUSHING MEADOW SOILS

A subsequent study of these interrelationships for the Flushing Meadow soils and for soils from other localities by C. R. Horne, Jr.,[10] Jun. Am. Soc.

---

[10] "Correlation of Compressibility and Atterberg Limits," by C. R. Horne, Jr., *Thesis No. 494*, Dept. of Civ. Eng., Columbia Univ., New York, N. Y., June, 1938.

C. E., is sufficiently interesting and of practical value to be included here in the diagrams of Fig. 4. About 60% of the values of the consolidation characteristics fall within a band of ± 10%.

Although the relations are not as consistent as desirable, studies seem to indicate that a material of low plasticity, falling in a zone (*a*) of Fig. 4(*c*), might be expected likewise to fall in corresponding parts of zone (*a*) of Figs. 4(*b*) and 4(*a*), tending as a consequence to have slightly lower values of both e_v and c_v. On the other hand, a material of more plastic nature than usual might be expected to lie in zone (*A*) of all diagrams of Fig. 4. These relations show the fundamental nature of the liquid and plastic limits as a characteristic moisture content in relation to consolidation phenomena, and indicate the need for fundamental research on the liquid and plastic limit tests to establish these relations more definitely for all types of materials. The effect of partial disturbance, inaccurate determinations of the liquid and plastic limits, and uncertainties associated with the consolidation test itself accounts for many of the discrepancies. An important fact to remember in all soil testing is variability of material which is always to be expected either in specimens taken from closely spaced samples in a boring or in different borings at the same elevation.

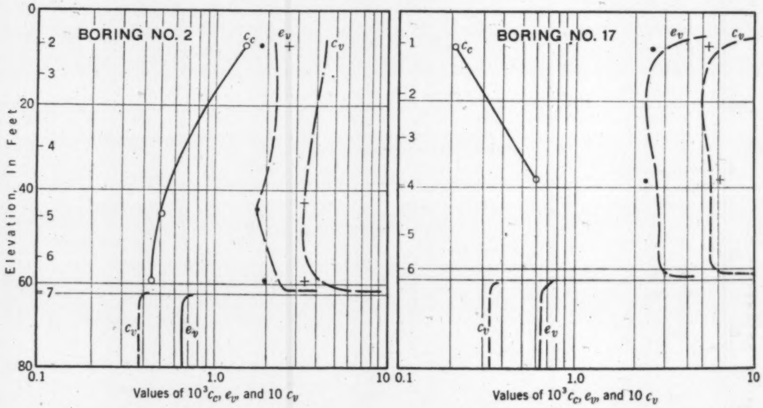

FIG. 6.—CONSOLIDATION CHARACTERISTICS, FLUSHING MEADOW SOILS

The possibility of making quite satisfactory preliminary estimates of the consolidation characteristics from the simpler routine soil tests, and of thereby extending and supplementing the information available for settlement analysis, is illustrated in Figs. 5 and 6. The profiles in Fig. 5 indicate the uniformity of the properties of the Flushing Meadow soils, the extremely compressible character of the meadow mat and the peat layer, and the relatively incompressible nature of the underlying silt and sand layers, the latter values being interpolated from other borings for comparison.

SHEARING CHARACTERISTICS

The major consideration in the development of the Flushing Meadow was to prevent and control subsurface movements in the soft material during grading operations and in the construction of foundations, so as to preserve the natural structure of the material. The shearing characteristics of the Flushing Meadow deposits were obtained from results of direct shear tests of the "quick" and "delayed" shear types.[11, 12, 13, 14] The first group of tests was made in a ring type of shear apparatus with shearing load applied at a constant rate (water loading), and the later tests were made in a Harvard type of shear

box with a strain-control loading at a rate of about 0.05 in. per min. The shearing stress for the undisturbed material in a rapid test in Fig. 7 increases characteristically to a maximum value and thereafter drops off to about 85% of the maximum. In the slow shear test (see Table 3), the stress increases less rapidly with strain. It reaches about the same maximum value but shows only a slight dropping off. A ratio of maximum stresses in the undisturbed and remolded conditions of about 5 : 1 indicates a relatively undisturbed sample for these materials, and is a measure of their structural capacity.

TABLE 3.—BASIC DATA FOR SHEAR TESTS IN FIG. 7

Sample No.	SHEARING RATE			Depth, in ft	MOISTURE CONTENT			Normal pressure, in kg per cm	SQUEEZE TEST	
	Description	Speed, in in. per min	Total time, in hr		Sample as received (w)	Liquid limit	Plastic limit		Undisturbed	Remolded
9_c-4	Quick	0.05	....	42	116.5	100.8	56.7	0	3.0	4.6
9_c-5	Slow	....	18 to 24	52	106.1	93.0	50.8	$\frac{1}{16}$	2.9	4.2

The quick shear test values, together with the values estimated from the routine squeeze test, are given in a typical profile of Fig. 5. The shearing strength varies from about 0.03 to 0.08 kg per sq cm, and does not increase appreciably with depth for boring No. 17, from just below the meadow mat down to the sand and gravel layers. On the other hand, the shear strength of the upper layers in boring No. 2 is considerably greater, due to the consolidation of the upper layers under the weight of the ash dump; but at lower depths the shear strength is about the same as that found in other parts of the deposit. However, this weak material, strengthened near the surface by the meadow mat, was capable of supporting the initial blanketing (with a fill to a height of about 4 ft) and the grading equipment, without showing appreciable disturbance or mud-wave formation due to lateral subsurface movements.

To establish the relation between shearing strength and normal pressure for determining stable slopes, lateral earth pressure, etc., delayed[11] shear tests were made, specimens being pre-consolidated to a series of normal pressures and sheared under these pressures. Typical curves are shown in Fig. 8. The original series of delayed shear tests was made at a fairly rapid rate of 0.05 in. per min. The primary loading branch of the curve for sample 9_c–4 (depth 42 ft) passes through the origin, yielding a value of 20° 35′ for the apparent angle of friction. Because insufficient time was allowed in the rapid test for the volume-change adjustments to take place during shearing, excess hydrostatic or neutral stresses[12, 13, 14] were induced in the pore water, which could not be dissipated by the escape of water. This means that only part of the total applied normal stresses (possibly only 60% to 70%) were effective in mobilizing shearing strength.

Subsequently, slow shear tests were made on sample 9_c–5 from the same boring (depth 52 ft) at a very slow rate (about a 24-hr test), so that the hydrostatic stresses were at all times equal to zero. Therefore, the total applied stresses

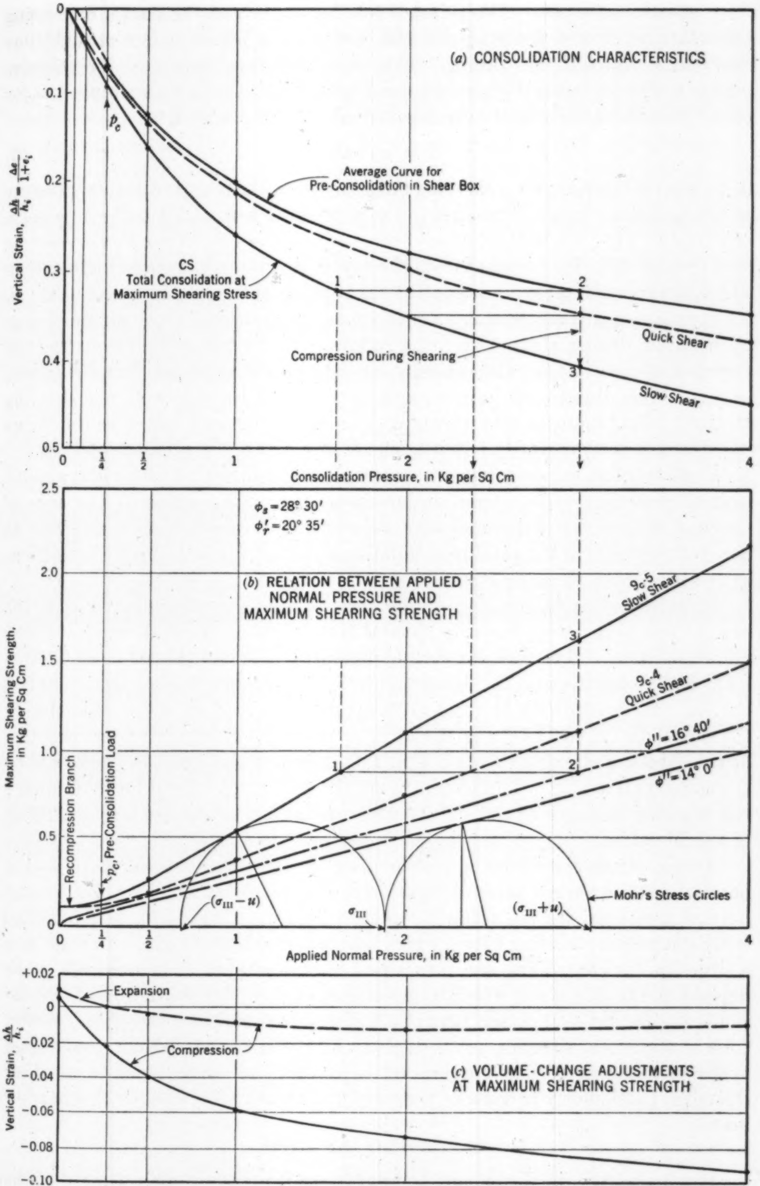

FIG. 8.—SHEARING CHARACTERISTICS OF THE FLUSHING MEADOW SILTY CLAYS AS DETERMINED BY DIRECT SHEAR TESTS OF THE STRAIN CONTROL TYPE

were effective stresses. The primary loading branch of the curve, expressing the relation between shearing strength and normal pressure, is a straight line that passes through the origin. This direct relation is typical for cohesive plastic soils in a natural state of consolidation, and Coulomb's simple law for cohesionless materials applies to the primary loading branch:

$$S = p_N \tan \phi \qquad (3)$$

in which S is the maximum shearing strength, p_N is the effective normal pressure which equals the applied pressure in the slow shear test, and ϕ is the true angle of friction. The angle of friction obtained from the slow shear test on sample 9_c–5 was 28° 3′. It is evident from the curve of volume-change adjustments in Fig. 8 that considerable consolidation takes place during a slow shear test. In a large mass of this material it is conceivable that practically no volume-change could occur during a rapid shearing failure. Under these conditions the apparent angle of friction, theoretically, may be half that of the slow shear test, or less. Also, due to the impermeable character of the material, the shearing strength would increase very slowly with consolidation and therefore the shearing strength is temporarily independent of any externally applied loadings.

Consolidation curve *A* represents complete consolidation under the applied normal pressures. The consolidation-shear curve *CS*, which is the sum of curve *A* and of the volume-change adjustment at maximum shear stress in curve *B*, represents the total consolidation required for equilibrium conditions at the maximum shearing stress.

In interpreting the results of the test, it must be remembered that the sample has been taken from its natural state with consequent relief of stress and expansion. Therefore, for normal pressures, less than the pre-consolidation load, one is operating on the reloading cycle of the consolidation and shear test curves. However, with the typical flat unloading and reloading branches of the consolidation curves of Fig. 2, the quick shear test gives a fair approximation of the shearing strength of the soil in the natural state, and the values are on the conservative side. Therefore, the quick shear test is useful for determining the shearing strength of the soil for such operations as the grading and filling of the Meadow.

Actual stress conditions approximating those in the natural state do not obtain until the normal pressure equals the pre-consolidation load. For greater normal pressures, the reloading curve then becomes tangent to, and coincides with, the primary loading curve, which passes through the origin. In analyzing a situation for controlling and preventing lateral subsurface movements in the deposit due to filling and grading operations, or due to construction of foundations, the profile of shearing strength in Fig. 5 is useful in locating the critical zone of maximum shearing stress as given by the stress conditions for different types of loadings of Leo Jürgenson[11] in relation to critical values of shear strength, particularly in view of the very low values just beneath the meadow mat.

SETTLEMENT ANALYSIS

It is necessary, in settlement computations, to make some estimate of the pre-consolidation load; that is, the probable state of stress in the soil in the natural condition as shown in Fig. 2. Where three or more consolidation tests could be made per boring, a good idea could be obtained of this state of stress; but where fewer samples were tested, it is necessary to obtain an estimate of this stress condition for settlement computations. Because of the very flat expansion curve in consolidation and the fairly consistent relation between shear strength and pre-consolidation load, a correlation curve was obtained for these materials for estimating the approximate value of the pre-consolidation load from the results of the quick shear and routine squeeze tests. The curve was also very useful for estimating the place to make a loading cycle in the region of the pre-consolidation load.

The values of the pre-consolidation load determined from consolidation tests, and obtained from estimates, are plotted in the soil profiles of Fig. 5. It is interesting to note that below a depth of 10 to 20 ft the pre-consolidation load is approximately constant and considerably less than the weight of the overburden. There are two possibilities: Either the material is incompletely consolidated and stress is temporarily carried by hydrostatic pressure in the pore water; or there is permanent artesian water pressure in the sand and gravel layers extending up on either side to the flanks of the adjacent hills, a pressure gradient being established by upward flow through the silty clay deposit. These represent two limiting conditions for settlement analyses.

In the computation of settlement under a given external loading, it is convenient to divide the depth of the deposit into a number of increment sections of thickness Δh, as shown in Fig. 5, and take the appropriate values of pressure, p_1 and p_2, at the center of each section from the pre-consolidation and external loading curves. The summation method can be made to take adequate account of the changes in the character of a deposit. Where consolidation tests have been made, the corresponding values of $(e_1 - e_2)$ are obtained directly from the pressure-voids ratio curves. Eq. 2 is then used directly in the settlement computations. Where the consolidation characteristics are estimated from Fig. 4, it is simpler to reconstruct the primary pressure-voids ratio curves, from the voids ratio at 1 kg of pressure and the voids ratio at 4 kg of pressure, which is equal to $e_v - c_v \log_e \frac{4}{1}$ or $e_v - 1.385\, c_v$ (see Eq. 1).

CONCLUSIONS

The investigations have shown quite clearly that, if a limited amount of time is available for testing, it is very important to make a few carefully conducted consolidation and shear tests to obtain very complete information on the behavior characteristics of a few representative samples as control tests in the given area. The Flushing Meadow soils, although possessing unusual characteristics, exhibit physical properties consistent with their character. The simpler routine soil tests, carefully made on all soil samples, will not only give information on the nature and on the variability or uniformity in the character of the materials, but also will provide (after the correlation curves have been established for different soil properties by the control tests) a practical means for obtaining preliminary estimates on the consolidation characteristics and shearing strength of all samples, and for extending and supplementing the information for settlement and stability analyses.

ACKNOWLEDGMENTS

The writer wishes to express his thanks and appreciation to Moran, Proctor, Freeman and Mueser, Consulting Foundation Engineers, for the opportunity of making the soil investigations in connection with the development of the Flushing Meadow Park site of the New York World's Fair, 1939. The testing was done in the Soils Laboratory of the Department of Civil Engineering at Columbia University, New York City.

DISCUSSION

Gordon E. Thomas,[15] Assoc. M. Am. Soc. C. E., and **M. N. Sinacori,**[16] Jun. Am. Soc. C. E. (by letter).—In presenting a practical application of soil mechanics to foundation engineering the author is to be congratulated. The correlations between Atterberg limits and both shear and consolidation characteristics are indicative of more efficient methods to be used in soil investigations, especially from the preliminary and time-saving standpoints. In order to make these correlations of value, it is quite apparent that proper methods should be used in field sampling as well as in the simplest of laboratory tests.

With reference to the Atterberg limits, the writers wish to show, in passing, what correlations were found to exist in connection with a similar foundation investigation in another part of the United States. They particularly wish to show a further use of these Atterberg limits in borrow-pit studies for suitable impervious rolled-fill material for earth dams in which the material is composed of clay and silt mixtures.

The aforementioned studies were conducted on the foundation and borrow-pit areas of an earth dam situated in the Lower Tennessee River Valley about twenty-three miles from the river mouth. The earth structure is principally on the river flood plains, which are covered with a brown silty clay to a depth of from 10 to 30 ft. At a few locations layers of gray, carbonaceous, silty clay occur beneath the brown clay. In general, however, a 15-ft thickness of sand and clay underlies the top clay blanket, and this in turn overlies the fluvial valley fill consisting of sand and gravel. Samples of the foundation materials were taken with a drill rig using an "undisturbed" clay sampler, and also, where possible, by hand in cubic-foot boxes. Samples from the borrow areas were obtained by using hand augers of the bucket type.

The writers have found that for clays in the Lower Tennessee River Valley the relationship between liquid limit and plasticity index is very close with only small variations from the mean curve. This fact made it possible to use only one of the Atterberg tests in the relations with the other characteristics. For example, there appears to be a relationship between plastic limit and the consolidation characteristics (namely, compression index and voids ratio), taken at 10,000 lb per sq ft. Because of the uniformity of the material and the narrow spread of characteristics, the number of samples tested was not as great as the number presented by Professor Burmister. The samples taken at the start of the investigation were 2 in. in diameter. The diameter was later changed to 3 in. The samples of larger diameter tend to give a more definite correlation. This is probably due to less disturbance in the material. It was also found that the accuracy of the correlation was influenced to a considerable degree by the presence of lenses and pockets of fine sand in some of the samples. The pressure-voids ratio curves obtained from these tests had initial voids ratios of from 0.7 to 0.9, thus placing the material in the range designated by Professor Burmister as silt in Fig. 3. In the case of shear characteristics, the writers found that the natural moisture content of the material had to be introduced as a third variable before a relationship of definite practical value could be realized.

[15] Capt., Corps of Engrs., U. S. A.; Forest Glen, Md.

[16] Associate Materials Engr., TVA, Gilbertsville, Ky.

These simple routine tests can be used to great advantage in obtaining information on the type of borrow material available for a rolled-fill section.

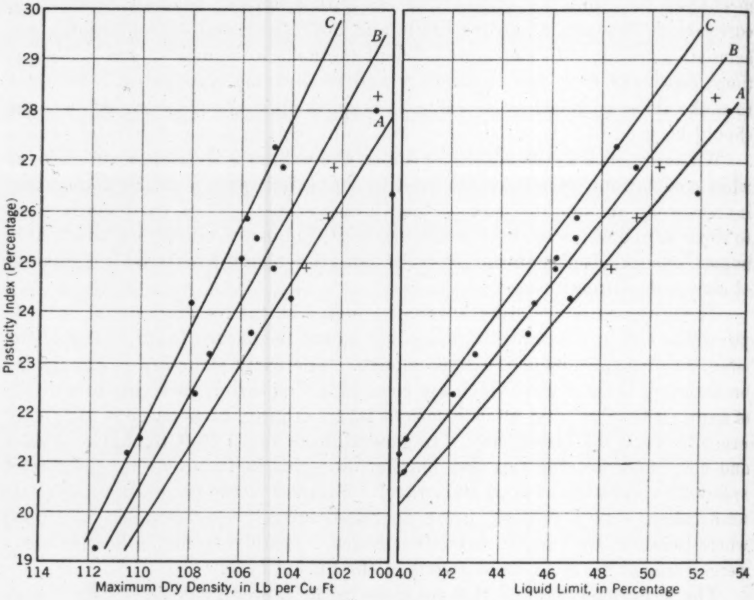

FIG. 9.—RELATION BETWEEN ATTERBERG LIMITS AND MAXIMUM DENSITY

The borrow areas for this particular earth dam are flat, long, and relatively shallow. The intrusion of sand layers, and high moisture contents at shallow depths, together with the necessity of leaving a prescribed thickness of blanket to minimize under-seepage of the dam, resulted in a small depth of borrow. All these factors made it necessary to investigate large areas, one of which was one-half square mile. Due to the stratification and variability of the soil, as well as the great area, a considerable number of compaction tests would have been required to cover this area completely. To save time and work, enough compaction tests were run to cover the various types of materials, as indicated by the pint jar samples from the auger borings. Then curves were drawn correlating liquid and plastic limits with compacted densities. From these original auger samples enough liquid and plastic limit tests were run to establish, more thoroughly, the compaction characteristics of the entire borrow area. Other general tests were run on typical borrow material to determine permeability, shear, and consolidation.

The liquid limit and plasticity index can be correlated very closely with the maximum density of the compaction curve by using the zone method. Fig. 9

shows the plots for a borrow pit on Twenty-Seven Mile Island, Kentucky. However, the plastic limit results, when plotted directly against the compacted maximum densities, show small variations from the mean curve, and are sufficiently accurate for correlating results. Consequently, these plastic limit tests alone were used as a rapid means of estimating maximum densities (Fig. 10). From the foregoing relationships all borrow-pit materials were classified very closely.

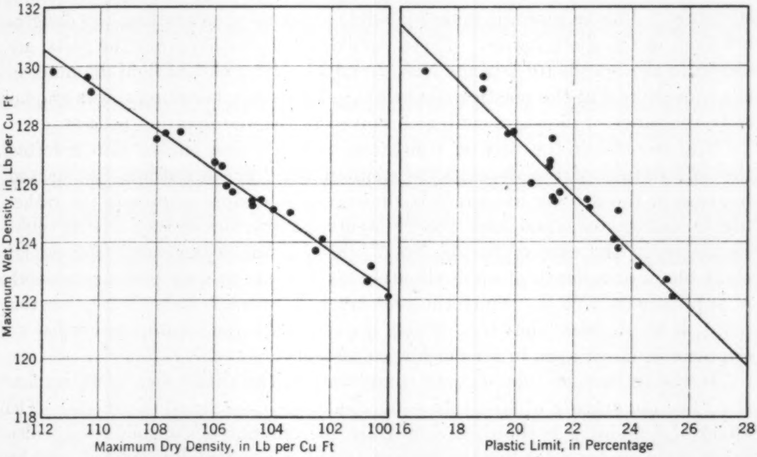

Fig. 10.—Relation Between Plastic Limits and Maximum Density

In dealing with borrow materials, the soil is thoroughly mixed when prepared for compaction, and any local variation in the sample is eliminated. In general it may be stated that Atterberg limits can be more closely correlated with borrow materials than with foundation soils taken in the natural state.

E. J. Kilcawley,[17] Esq. (by letter).—An unusual opportunity is afforded, by this paper, for a comparison of results and conclusions reached under rush conditions and those determined by retesting and study in a more leisurely manner. It represents a comparison and suggested correlations of physical and mechanical test results.

In this later detailed analysis, a method of presenting results of routine tests has been developed and applied. These methods seem to aid materially in visualizing actual field conditions which, in turn, make quick and reasonable conclusions possible. The necessary extent and method of sampling, and further detailed testing to determine and evaluate mechanical characteristics of the deposits, can likewise be done on the basis of the fundamental facts established by simple and quickly performed soil tests.

An excellent example is the work reported in the use of the squeeze test.

---

[17] Prof. of Soil Mechanics and San. Eng., Rensselaer Polytechnic Inst., Troy, N. Y.

The modification of the three-dimensional test proposed by Mr. Jürgenson[18] in 1934 offers an efficient and handy tool for selecting samples, and for showing changes in the structure of the deposit. The method of plotting the final average diameter of the specimen measured in centimeters as abscissa for both undisturbed and remolded samples against the depth at which the sample was taken as an ordinate offers a quick and fairly reliable method of evaluating structure. Furthermore, it makes possible a means of estimating the dangers involved in the disturbance. These results, as concluded from the tests, are shown in the graphs for borings Nos. 2 and 17. The plot of final diameter in the squeeze test at the plastic and shrinkage limits, furthermore, shows graphically the range of moisture content involved in the stabilization process.

The records of the driving resistance of the casing shown also reflected the soft nature of the deposits, as pointed out by the author. A marked increase in the driving resistance is shown as the casings approach the rather highly compacted sand and gravel layers underlying the soft, silty clay. However, in the case of boring No. 2, this resistance increased from about eight blows at a depth of approximately 20 ft to about fifty blows at a depth of approximately 53 ft. Since the peat layer is approximately 10 ft below this point, it would seem that this reflects the fact that quick compression has an appreciable effect even in soils of low consistency.

In the further consideration of consolidation, the author has again emphasized the importance of structure as it affects the consolidation process. The effect of remolding is shown in Fig. 2 by the amount of consolidation which takes place under a loading equivalent to the pre-consolidation load, and by the spread between the consolidation curves for the undisturbed and remolded samples. This spread again offers a measure of the natural structure of the material. The results of repeated compression tests (also plotted in Fig. 2) show graphically the resulting change in structure and internal stress conditions. This part of the paper might well be expanded. Such a method of analysis might be applied to a study of stress history of deposits and of effective stress conditions.

The comparison of pressure-voids ratio curves in Fig. 3 shows both the range and the characteristics of the materials, and confirms the prediction of consolidation characteristics as indicated by the simple soil tests. The data included from the thesis of Mr. Horne[10] show the relation between consolidation characteristics and the liquid limit determination. They further point out the possibility of establishing a reliable guide in making good estimates of mechanical behavior and a means of establishing a maximum range of variation in these values of soil type characteristics. More extended study on this phase of behavior would be valuable.

In the analysis of quick, slow and delayed shear tests, the author has definitely shown the importance of hydrostatic equilibrium and effective stresses in the determination of shearing resistance. The significance of hydrostatic equilibrium as first pointed out by Professor Terzaghi is clearly shown. Volume change and structural adjustment are likewise emphasized and related to the important time factor in shear testing. An important consideration of an evaluation of stress conditions in undisturbed deposits, and in the test before any attempt is made to analyze results, is appropriately pointed out by the author.

---

[18] "The Shearing Resistance of Soils," by Leo Jürgenson, *Journal*, Boston Soc. of Civ. Engrs., July, 1934, p. 242.

In presenting the results of the tests and the correlations with the fundamental theories of Messrs. Terzaghi,[12] Hvorslev,[14] Jürgenson[11] and others, Professor Burmister has made a definite contribution. Certain parts of the paper could have been expanded. More information on the effect of recompression might do much toward explaining varying results obtained on soils which are presumably the same. The underlying lesson taught in this work is the possibility of establishing a maximum range of variation for soil type groups and for the evaluation of physical and mechanical characteristics. Such a possibility deserves the best consideration of all soil physicists.

DIMITRI P. KRYNINE,[19] M. AM. SOC. C. E. (by letter).—An interesting and comprehensive laboratory approach to the solution of a very important engineering problem is given in this paper.

Importance of the Problem.—Material termed "silt," "organic silt," "clayey silt," "silty clay," and "mud," is very common along the Atlantic coast, at least close to the New York metropolitan area. This is organic silt mixed with more or less clay, and sometimes mixed with shells. The thickness of a layer of this material is from a few feet to 100 ft or more. The writer's observations showed this material to be mostly underlain with sand of variable coarseness. At Flushing Meadow this material served as a foundation for the World's Fair; tunnels under the Hudson River pierce horizontally thick silt layers; H-piles supporting the bridges over the Potomac River in Maryland and over the Thames River in eastern Connecticut pierce it vertically to reach the ledge rock or reliable sand. Cutoffs from old roads along the coast often pass through similar materials; and it is very probable that some muddy areas on the shore may sometime become airports, as in Baltimore, Md.

Hence it is very important to correlate different studies of this material in order to draw some general conclusions. From this point of view, Professor Burmister's paper, containing abundant data on the properties of the given soil, is a welcome beginning.

Field and Laboratory Solutions.—No civil engineering problem can be solved definitely in the laboratory. Structures stand in the field and conditions of their stability (particularly properties of the soil) should be studied both in the field and in the laboratory. Laboratory data alone are only indicative—not conclusive. From this point of view, it is highly desirable to take advantage of a situation such as that under discussion. There can be no better large-scale consolidation tests and no better large-scale shearing tests than those made by the City of New York in dumping ashes on Flushing Meadow. It is true that the sequence of operations in dumping is not well known and hence the influence of the time-factor cannot be defined very clearly. Some limiting assumptions, however, can be made in similar cases. For instance, the presence of a mud wave means that the shearing strength of the material at a given place is overcome, and vice versa; the material should be considered safe so far as shear action is concerned, if there is no mud wave at a given place. Professor Burmister has made interesting observations on the penetration of the casing (Fig. 1), and it was possible for the construction engineer to correlate his data with the actual pile-driving records since many structures of the World's Fair were on piles driven through the given material to reach resistance.

---

[19] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

Driving of the Casing.—A 4-in. casing was driven at Flushing Meadow starting with some 5 or 7 blows per ft (Fig. 1). This number gradually increased to about 100 blows per ft in approaching the firm base. Apparently this fact should be ascribed to the increase in the point resistance of the casing due to the support from below. The number of blows in the sand layer was more or less constant although not the same in the case of borings Nos. 2 and 17. A similar picture was observed by the writer at the various times that he had an opportunity to be present.

A variation of the casing-driving diagram (Fig. 1) would correspond to the situation in which the material at the top is so soft that the casing sinks down by its own weight. The writer has observed this phenomenon on the Thames River, at New London, Conn., when a 4-in. casing, similar to that used in the Flushing Meadow investigation, penetrated in this manner from several feet to 39 ft down through the clayey silt. Actual H-piles sank at an average of 25 ft through such material, the range of fluctuations being perhaps 5 ft. The weight of the casing used was 15 lb per ft, and that of the piles 89 lb per ft. In addition to the possibility of computing the coefficient of friction, such studies perhaps may offer as a by-product an opportunity to obtain a general idea of what percentage of the cross section of an H-pile driven into any soil takes active part in the friction against that soil and what percentage remains neutral.

Shearing Resistance.—According to Fig. 5 the shearing strength of undisturbed samples was greater close to the top and to the bottom of the layer, the average shearing strength at a certain depth being of the magnitude of 0.04 kg per sq cm which equals about $0.04 \times 2{,}000 = 80$ lb per sq ft. A very high shearing strength at the top of boring No. 2 is undoubtedly due to the compressing action of the ash pile. The meadow mat and the deep peat layer apparently acted as reinforcing agents.

Besides the direct laboratory shear test in the silty clay in the Thames River, the writer participated in the following simple field tests in Connecticut: (*a*) Brass cylinders containing undisturbed samples extracted from a depth were carefully cut with a hack saw along two parallel planes normal to the length of the cylinder, without disturbing the sample. A force necessary to pull out the ring thus formed was then measured. This test furnished a shearing strength of the order of 100 lb per sq ft; (*b*) when dredging for a cofferdam, huge undisturbed samples were taken directly from the bucket and tested immediately in a field, direct-shear, apparatus (size of the box 8 in. by 12 in.) designed and constructed by Philip Keene, Assoc. M. Am. Soc. C. E., soil mechanics engineer for the Connecticut State Highway Department. This test also furnished a shearing strength of about 100 lb per sq ft, or more. The sample tested was taken 12 ft below the bottom of the river, the depth of water being 44 ft.

Slopes.—Slopes of fills in this material should be designed rather flat using results of the quick shearing tests, as Professor Burmister advises. The shearing strength of the remolded material is perhaps $\frac{1}{4}$ or $\frac{1}{5}$ of that of undisturbed samples (Fig. 5). So far as cuts are concerned, this material is able to maintain astonishingly steep slopes. Reference is made to an article[20] that describes the construction of the present highway bridge at New London, Conn. The dredging operations are thus described in that article: "The dredging was therefore performed as an independent preliminary operation, with a clamshell dredge, and carried down 18 to 23 ft. below the river bottom, the material standing on a slope one to one."

Natural Moisture Content.—The writer agrees with Professor Burmister's statement that the natural moisture content is characteristically high for these materials, being about 100% by dry weight, or more. Smaller percentages may be found also.

The writer wishes to call attention to the fact that the moisture content as determined from an undisturbed sample of such clayey silt, extracted by using a sampler, and the moisture content of the same material in a bucket during the dredging may be different, the latter moisture content being somewhat smaller. The writer suspects that undisturbed samples may be oversaturated.

Odor.—According to the writer's observations, this material has the odor of methane (marsh gas) in the upper layers only, perhaps to a depth of 40 or 50 ft. Again, if an odorous sample is left alone for a few weeks, it does not smell any longer.

Pre-Consolidation Load.—Assuming that the procedure used for determining the pre-consolidation load is correct (and the writer believes that it is), Professor Burmister states that either the Flushing Meadow deposit was not fully consolidated at the time of investigations or that there was artesian water in the underlying sand layer. Assuming the former alternative, it should be concluded that, in the case of boring No. 2, the settlement of unloaded cuts should still have proceeded during the existence of the World's Fair notwithstanding the relief in load due to the excavation of the ash dump.

In this connection, it would be very interesting to study some values of settlement at the Flushing Meadow as computed and as actually observed.

Conclusion.—Professor Burmister is to be commended for his sound views on the value of the soil laboratory work. He calls the attention of the reader to the variability of material either in samples or in different borings at the same elevation, which means that absolutely conclusive results cannot be obtained in the laboratory. In making his settlement analysis he proceeds with extreme care and checks the values of the pre-consolidation load by a special shear-test correlation curve. Finally, he tends to simplify the laboratory procedure as much as possible by trying to correlate consolidation characteristics of a soil with such simple tests as the determination of the liquid limit and of the plasticity index.

B. K. HOUGH, JR.,[21] ASSOC. M. AM. SOC. C. E. (by letter).—In his "Synopsis," the author conveys the impression that the tests described in his paper were conducted for certain very practical purposes, such as determination of the general suitability of the Flushing Meadow for the intended development. It is stated (see "Synopsis") that "They [the tests] were made primarily to furnish information on what could be done and how it should be done." The paper itself is disappointing in that the description of the application of test data to practical problems is very meager.

---

[20] *Engineering and Building Record*, October 11, 1890, p. 296

[21] Area Engr., U. S. Engr. Dept., Elmira, N. Y.

Not only is it a matter of general interest to learn how test data are applied in practice, but, in the writer's opinion, the validity of the data cannot be judged apart from its application. In numerous instances the writer has encountered the popular belief that a given soil has certain characteristic constants which are readily determinable by laboratory tests and which can be applied under any conditions. Opposed to this belief is the theory that testing must simulate (at least in some respect) the anticipated construction procedure, and hence both testing procedure and the type of test data to be secured must be fitted to the proposed work. If space permits in the author's closure, further discussion on application of data might be undertaken.

Other factors bearing directly on the reliability of test results are the equipment and technique used in obtaining samples. Through first-hand knowledge of the Flushing soil formations, obtained during subsurface exploration at various times in Flushing Bay and at the La Guardia Airport, the writer believes that there is some doubt as to the reliability of samples obtained as described by the author, in 3-in. borings. The author's statement that the ratio of maximum stresses in the undisturbed and remolded shear tests was as great as six to one is probably a favorable indication however (see "Physical Characteristics"). Another point in connection with sampling is that observations on the number of blows per foot to drive the casing are not as valuable as the number of blows required to drive the sample spoon at each sampling point. The former reflects a highly complex condition of side friction on the casing which is almost certain to increase with depth since the length of casing steadily increases; whereas the latter indicates with some reliability the resistance encountered at each elevation.

The main thought in the paper appears to be that relatively complicated and expensive characteristics tests need not be run on all samples if some correlation can be established between such data and the results of relatively simple routine tests. This thesis is one that merits further development since the objective of soils engineering is to reduce, not to increase, the over-all cost of earthworks construction. For his contribution to this subject, the author is to be commended.

T. B. RIGHTS,[22] ASSOC. M. AM. SOC. C. E. (by letter).—Professor Burmister is to be congratulated on "lifting the veil" on soil mechanics and the mechanics of making tests. However, the average structural engineer (one who has been out of college ten years or more) is still almost as much "in the dark" as he has always been in regard to soil analysis. The writer realizes that this subject is in the transition period. In fact, as far as the writer knows it is only in the last few years that a few books in the English language have been published on this subject. A few years ago engineers were forced to depend upon mimeographed notes or isolated articles in the technical journals. Investigations made by the committee headed by Robert A. Cummings, M. Am. Soc. C. E., laid the groundwork for the researches that have revealed what is known at present.

---

[22] Roselle, N. J.

When soil mechanics started getting publicity about 1935 or 1936, structural men heaved a sigh and said, "Fine, give us the formulas." When no formulas arrived and the structural men discovered that they would have to make expensive and extensive subsurface explorations, they went back to their old method, which is still good if done by an experienced engineer. The old method, according to the writer, consisted in going out and looking at the site, maybe making one loading test of a 1-ft square area, holding a consultation, and stating "Our company has always used a value of 2 tons per sq ft." After spending most of their time on the design of the superstructure, when the foundation settled extensively or tilted, they consoled themselves with the fact that foundations are tricky things and hoped for better luck next time.

More and more subjects are being pushed into the realm of specialization; but structural engineers should have a basic knowledge of the subject of soil mechanics. The design of large structures should be referred to consulting engineers, but the small structures will still have to be built without their services. This is where the average structural engineer should have a basic knowledge of the subject. Where will he obtain this knowledge? Few colleges are giving this subject in extension courses. There is no place for the man residing outside of very large cities to study this subject, except through extensive reading. Many libraries, even in the larger cities, do not have reference material in soil mechanics. It is not surprising that many engineers and designers do not have enough knowledge to design foundations properly. An example of this was recently reported in the metropolitan papers. A building within 5 miles of Flushing Meadow Park is settling badly. Near the beginning of the news article, the engineers are reputed to have stated that the end of the settling process would occur in two weeks. Near the end of the same article was another statement that no one can tell when the settlement will stop.

These news statements should be contrasted with what was done at Flushing Meadow.[23] After the settlement analysis for the Flushing Meadow grounds had been computed, settlement contours were plotted. Additional fill was placed so that, at the end of the 2-yr settling period, the ground would be properly graded. The same investigation could have been made for the aforementioned building as was made for the New York World's Fair. Although this building is on piles, a complete soil investigation would have determined proper pile lengths to support it without extensive settlements.

A paper like that by Professor Burmister does much to bring before the engineering profession a scientific method of making a correct and complete settlement analysis. The undisturbed samples taken in these soil investigations were 3 in. in diameter. The writer understands that in Boston, Mass., 5-in. samples are used; 6-in. diameter samples would produce more accurate results in soil investigations. The possibility of the disturbance in 3-in. samples is very great. If Professor Burmister and others interested in soil mechanics can persuade clients and those paying for undisturbed samples to use 6-in. sizes, they will do much to establish foundation practice on a scientific basis.

---

[23] "The Application of Soil Mechanics in Building the New York World's Fair," by George L. Freeman, George W. Glick, and Hamilton Gray, *Civil Engineering*, October, 1940, p. 649.

The writer believes that the correlation diagrams in Fig. 4 will prove a "milestone" in soil investigations. If another diagram showing voids ratio versus shear strength is added, it will act as a partial check on the other tests. If a sample falls in the same shear-strength range as the other samples, but the compression index falls outside the same range, it might be presumed that the running of the compression test might be in error. If the sample falls outside the shear-strength range, investigation could be made to see whether a real undisturbed sample was used or whether the sample was disturbed or remolded in either the sampling operation or at some later period.

Donald M. Burmister,[24] Assoc. M. Am. Soc. C. E. (by letter).—It is very gratifying to find that Messrs. Thomas and Sinacori share many of the writer's views and have made practical use of correlation methods on a large project. In Figs. 9 and 10 they have shown how more effective methods were developed in borrow-pit studies, especially from the preliminary, and time and expense saving, standpoint, for obtaining information on the suitability of impervious rolled-fill materials for earth dams. The writer has made similar use of correlation methods in earth-dam investigations.[3] Although generalizations for all soil types are not possible, satisfactory regional correlations can be made for localized areas, where similar soil types are encountered; that is, soils formed essentially by the same geological processes and having essentially the same mineralogical character and grain-size distribution.

An important task of the engineer is to develop more effective methods of soil investigation for specific problems, especially from the time and expense saving standpoint. This involves the application of "Control Test Methods" by making a few carefully conducted and complete soil tests (consolidation, shearing, routine classification tests, etc.) on typical representative soils to define the correlation band or bands for the soil types encountered on the given project. The methods may be extended to the cohesionless soil types by using the "density limits," that is, the loose limit *L*, and the dense limit *D*, which serve the same purpose and reflect the physical character of cohesionless soils in a manner similar to the consistency limits for cohesive-plastic soils. Once a satisfactory correlation has been established, the simple routine tests can be made quickly and at a relatively small expense on a large number of samples in order to obtain estimates of the consolidation, shearing, permeability, and other properties of soils, in as great a detail over an area as is considered necessary for an adequate investigation and solution of the problem. It is much more important to obtain information on the possible range of the estimates of these properties, which have a direct bearing on the analysis of the problem, as given by the width of the correlation band, than it is to know the exact values for a few isolated samples in a given area. Such an analysis would not only permit the engineer to visualize and analyze the situation more completely, but would also serve a very useful purpose for design and construction. Experience will be the best guide in teaching engineers how to make correct practical applications of this information.

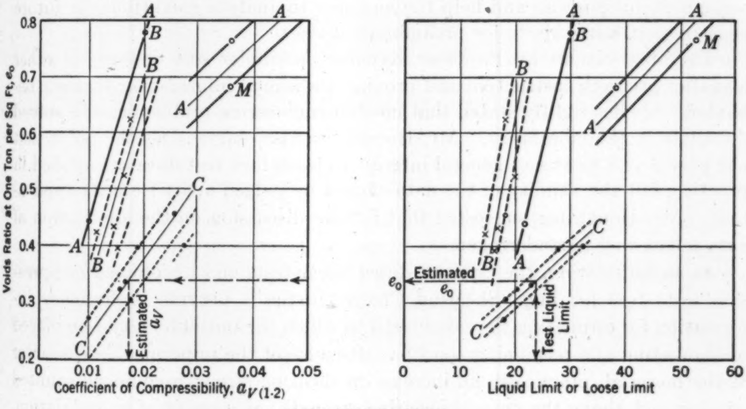
(*a*) GRAIN SIZE DISTRIBUTION (*b*) CONSISTENCY AND DENSITY LIMITS



(*c*) CORRELATION DIAGRAMS

(*d*) CLASSIFICATION OF SETTLEMENT AND BEARING PROPERTIES

FIG. 11.—CONSOLIDATION PROPERTIES

To illustrate further the possibilities of such methods, data for three cases have been analyzed in Fig. 11 for the consolidation properties of the soils. This permits a more satisfactory classification either of artificially placed material or of natural deposits as to their relative settlement and bearing properties for highway subgrades, airport runways, and the like.

Professor Kilcawley states that an important part of foundation investigations is to present the field data as well as the results of laboratory tests so that subsurface conditions can be visualized clearly and interpreted correctly. This requires an accurate knowledge of the kinds of soils encountered—their extent, uniformity, and variability, their physical properties, and their general behavior characteristics. Consistency in the natural state is one of the most important of these simple characteristic properties. In very soft deposits, such as are encountered in the Flushing Meadow, the simple squeeze test is useful for obtaining fairly reliable information on the consistency and shearing strength of all soil samples. For medium stiff and hard clays, unconfined compression tests on small prisms can be made quickly on all samples for determining the shearing strength and to aid in selecting the least disturbed samples for more detailed analyses of their strength and stress-strain characteristics. Professor Kilcawley has emphasized the importance of establishing reliable guides for making estimates of the physical properties of soils and of establishing a maximum range of variation for soil type groups, as indicated by the width of the correlation band. One of the important problems in soil engineering is the accumulation of information on the behavior characteristics of the important soil type groups encountered in different sections of the United States, for example, such as those presented in Figs. 4, 9, 10, and 11, which will serve a useful purpose and help the engineer to analyze conditions for future construction, particularly for preliminary studies.

The observations by Professor Krynine on similar soft deposits in other localities are very instructive and provide additional information on their behavior. He has rightly stated that no civil engineering problem can be solved definitely in the laboratory. Mr. Hough, likewise, emphasizes the point that not only is it a matter of general interest to learn how test data are applied in practice, but the validity of the data cannot be judged apart from its application. Mr. Hough has suggested that further discussion on the application of data might well be undertaken.

As an illustration, the "quick" direct shear tests and unconfined compression tests (see heading "Shearing Characteristics") provide preliminary information for estimating the safe height to which the initial fill could be placed in blanketing and reclaiming the site. Because of the impermeable character of the material, practically no increase in shearing strength could be counted on over and above the natural shearing strength, as a result of consolidation. Such estimates should in every case be checked against field experience, or by a test fill as described by Mr. Freeman.[2] In the application of the theories of elasticity and plasticity to foundation problems, Mr. Jürgenson[11] has given the critical shearing stress conditions beneath the toe of an embankment approximately as follows: Plastic state—

$$S = \frac{p}{\pi} \quad \ldots\ldots \quad (4a)$$

and, failure—

$$S = \frac{p}{\pi + 2} \quad \ldots\ldots \quad (4b)$$

The shearing strength varies with depth as shown in Fig. 5. The situation would be more serious if it were not for the fact that the meadow mat had a very important spreading effect on stresses and strengthened the surface of the underlying soft material so that is was capable of supporting the initial blanketing to a height of about 4 ft and the grading equipment. The critical zone is deeper and is confined to a considerable extent by this mat layer; thus:

Depth	Plastic condition in meadow mat layer	Failure in underlying soft deposit
$p = w\,h =$	$2{,}000\,\pi\,S$	$2{,}000\,(\pi + 2)\,S$
h	$\frac{2{,}000}{100}\,\pi \times 0.08$	$\frac{2{,}000}{100}\,(\pi + 2)\,0.04$
h (in feet)	5.1	4.1

Experience in reclaiming and filling the Flushing Meadow showed that only in a few instances were any appreciable subsurface movements started, if the height of fill was kept within recommended safe limits.

To illustrate the application of the consolidation test results in a settlement analysis, the situation at boring No. 17, Figs. 1, 5, and 6, is considered. The following steps are taken in estimating the settlement to be expected as a result of a blanket fill, for example, of 10 ft:

1. The profiles of the overburden pressure, pre-consolidation pressure, and the pressure due to the fill, are estimated in Fig. 5 for boring No. 17, using the data on the approximate moisture content in Fig. 1 and the consolidation test data for two samples from boring No. 17 in Fig. 3 (also Fig. 2). The profile is subdivided, as shown, into a convenient number of increments of depth (located halfway between each sample, except at changes in the character of the soil).

2. The settlement property of the soils, which is defined by the compression index c_v, is estimated from the results of two consolidation tests in Fig. 3 and from the correlation diagrams of Fig. 4 for the soils of the Flushing Meadow for the remainder of the samples. The liquid limits of the samples of boring No. 17, which are the correlation arguments, are taken from Fig. 1. For settlement analyses it is more important to obtain an estimate of the possible range of the settlement properties of the soils in a deposit at the point where settlement estimates are desired than it is to know an exact value for an individual sample at a certain depth only. Accordingly, for the range of liquid limit for these samples, the approximate maximum range of the estimates of the compression index c_v for the inner correlation band of Fig. 4 is found to be about $\pm 15\%$ from the mean curve of the correlation, which, it is believed, should be considered a fairly satisfactory accuracy considering all of the uncertainties involved in such analyses.

3. The natural stress conditions in the soil (which were discussed in the paragraphs preceding "Conclusions") are assumed for Case 1 to be represented by the dotted curve of Fig. 5, of pre-consolidation pressure (and complete consolidation). The approximate corresponding voids-ratio in the natural

state (e_n) at the elevation of each sample is either taken directly from the pressure-voids ratio curves of Fig. 3 or is computed from Eq. 1. The stresses due to the 10-ft fill are computed on the basis of a unit weight (compacted) of 100 lb per cu ft.

4. In making the settlement estimates by the Increment Depth Method, Eq. 2 is solved by substituting the values of the voids ratios e_1 and e_2, corresponding to pressures p_1 and p_2 from Fig. 5 as follows:

$$\text{Settlement} = h \times \left(\frac{c_v}{1 + e_n}\right)\left(\log_e \frac{p_2}{p_1}\right) \ldots\ldots\ldots\ldots\ldots (5)$$

The approximate estimates of settlement are made as shown in Table 4, which contains the values obtained for each of the foregoing items.

TABLE 4.—APPROXIMATE SETTLEMENT ESTIMATES FOR BORING NO. 17, CASE 1, DUE TO A BLANKET FILL OF 10 FT

Sample No.	Depth, in ft	H, in ft	w_L	c_v	e_v	e_n	$\frac{c_v}{1 + e_n}$	p_1	p_2	$\log_e \frac{p_2}{p_1}$	S, in ft

										$S = 8.44$[b]	

[a] Consolidation test values. [b] Possible range of estimates ±15%, or 7.3 to 9.7 ft.

To obtain some idea of the effect of differences between the possible stress conditions in the deposit and those assumed, the overburden pressure (full line) is assumed to represent the actual stress conditions for Case 2. The corresponding settlement estimate is equal to 7.7 ft. The corresponding settlement estimates for a 5-ft fill are equal to 5.3 and 4.9 ft, respectively. The settlement in the meadow mat layer at the top and the peat layer at the bottom probably occurred largely during the filling operation because of their more permeable character, as evidenced by the continuous flow of water from the toe of the advancing fill as it was constructed. Hence this settlement would be compensated for by additional fill in the operation of filling and grading to the required surface elevation, as suggested by Mr. Rights. Deducting these amounts, the estimates of subsequent settlement to be expected for a 10-ft fill (total height), for Cases 1 and 2, are 6.1 and 5.5 ft, respectively, and for a 5-ft fill, 3.9 and 2.7 ft, respectively.

The rate of settlement is estimated roughly on the assumption of an average value of the coefficient of consolidation, C_c, of 0.0012 cm² per min for the deposit, and of the natural voids ratio, e_n, of 3.32, and a deposit 47 ft thick, exclusive of the meadow mat and peat layers. The estimated times t in years, corresponding to different percentages of the ultimate settlement and time factors T_v, are estimated by the equation:[25]

$$t = \left(\frac{h}{1 + e_n}\right)^2 \frac{T_v}{1{,}400\, C_c} = 70.8\, T_v \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

and are given in Table 5.

In regard to the driving records of the casing and sampler, the writer agrees with Mr. Hough's statement that the number of blows per foot to drive the sampler indicates more reliably the resistance encountered at each elevation. In the Flushing Meadow deposits, only about one or two blows were required to drive the sampler because of its soft consistency. Since, for all important structures, pile foundations were required, the driving resistance of the casing was considered to be a better indication of total resistance, in this case.

TABLE 5.—ESTIMATES OF THE RATE OF SETTLEMENT

Time[a]	PERCENTAGE OF SETTLEMENT				
	10	20	30	40	50
T_v	0.02	0.08	0.17	0.31	0.50
t	1.4	5.6	12.0	22.0	35.4

[a] T_v = time factor; and t = time, in years.

In foundation studies for buildings and earth dams, the writer has devised and used the tentative values listed in Table 6, which has proved to be very useful for investigating and analyzing subsurface conditions with respect to their foundation properties.

TABLE 6.—TENTATIVE VALUES OF APPROXIMATE DEGREES OF COMPACTION

No.	Granular cohesionless soils	No. of blows[a]	Density[b] %	Cohesive plastic soils
1	Very loose silt..................................	<5	.....	Very soft clay
2	Loose sand or silt..................................	5–15	<40	Medium soft clay
3	Loose sand and gravel; medium compact sand or silt...	15–35	40–70	Medium stiff clay
4	Medium compact sand and gravel; compact sand or silt.	35–70	70–90	Stiff or medium hard clay
5	Compact sand and gravel; very compact sand or silt...	>70	90+	Very hard clay

[a] Blows per foot; 3-in. sampler; driving energy, 7,200 in-lb; weight of hammer, 300 lb; average drop, 24 in.
[b] Relative density, expressed as a percentage.

The liquid limit of cohesive plastic soils and the loose limit of cohesionless soils, as laboratory references, are assumed to be 40% relative density based on experience with the measured loosest states found in natural deposits. The plastic limit and the dense limit, respectively, as laboratory references, are assumed to be 100% relative density. On this basis very few natural deposits have a relative density greater than 100%.

The relative densities D_d are determined by the relations: Cohesive plastic soils,

$$D_d = 40 + 60\, \frac{w_L - w_N}{w_L - w_p} \ldots\ldots\ldots\ldots\ldots\ldots (7a)$$

---

[25] Progress Report of Special Committee on Earths and Foundations, *Proceedings*, Am. Soc. C. E., May, 1933, p. 777.

and cohesionless soil,

$$D_d = 40 + 60 \frac{w_l - w_N}{w_l - w_d} \dots\dots\dots\dots\dots\dots\dots (7b)$$

in which:[26] w_L = liquid limit; w_p = plastic limit; w_N = approximate natural moisture content; w_l = loose limit, as a moisture content; and w_d = dense limit, as a moisture content.

A distinction is made in the driving resistance of sand-gravel moistures and sand or silt because the presence of gravel increases the resistance quite as much as an increase in the degree of compactness. There is no simple direct relation for different sizes of samplers and casings, and therefore the numerical values must be determined from field experience. However, for different weights of hammers and drops, fairly consistent values are obtained, if the blows per foot are made inversely proportional to the driving energy (weight of hammer times drop).

The tentative values in Table 6 have not only made it possible to visualize subsurface conditions better as to their foundation properties, bearing capacity, length of piles, etc., but also have served a useful purpose in providing numerical values by which to compare different situations, particularly in cases where settlements are known, where loading tests have been made, etc.; or, in cases where the allowable bearing capacity is to be estimated—for example, from the Boston Building Code, which differentiates between the values for loose and compact conditions of the soils.

In conclusion, the writer wishes to express his gratitute to the discussers for their stimulating comments.

HYDRAULICS OF SPRINKLING SYSTEMS FOR IRRIGATION

By J. E. Christiansen,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Arthur F. Pillsbury, Tom A. Bither, Ralph W. Powell, Harry F. Blaney, and J. E. Christiansen.

Synopsis

Portable systems for sprinkling agricultural crops were first used in the Sacramento Valley of California in 1931, although in 1930 there were a few scattered installations in the southern part of the state. Sprinkling with stationary systems had been confined largely to citrus orchards and truck crops because of the relatively high investment required. Low-cost portable systems, however, made sprinkling a feasible method of irrigating large acreages of field crops such as beans, peas, onions, and sugar beets.

In 1932 the Division of Irrigation of the University of California began a study of sprinkling, principally to determine (1) the hydraulic characteristics of rotating sprinklers, (2) the loss of water by evaporation, (3) the hydraulic characteristics of sprinkler lines, (4) the cost of applying water by sprinkling, and (5) the general success of sprinkling as a method of irrigation. The scope of this paper is defined by the first three of these items.

Portable Sprinkler Systems for Field Crops

In brief, a portable sprinkler system is a line of light-weight pipe with quick-acting couplings (on which rotating sprinklers are mounted) together with a pumping plant. Sprinkler pipe comes in standard lengths of 20 ft; other lengths are furnished on special order. Sprinklers are usually spaced 40 ft apart; but sometimes the spacing is 20 ft (or 30 ft when 30-ft pipe is used). The pipe is moved across the field, usually by two men who carry one length at a time. Several different makes of systems are now available, each with its own kind of coupling.[2] Formerly, only 4-in. pipe was available; but now one can obtain some of the systems in $1\frac{1}{2}$-in., 2-in., 3-in., 4-in., 5-in., and 6-in. sizes and in any

desired pipe length. Special quick-acting couplings are also made for use on smaller pipe for orchard systems.

As a rule, the systems operate with a portable pumping plant that pumps from a field ditch along one side of the field, or through the center. The plant shown in Fig. 1 is operating on two quarter-mile lines of 4-in. and 5-in. pipe,

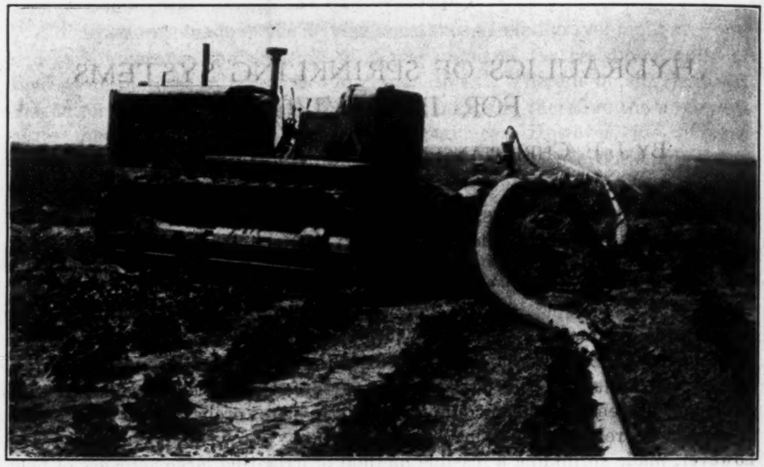

FIG. 1.—TYPICAL PORTABLE PUMPING PLANT

FIG. 2.—MOVABLE SPRINKLER MACHINE PUMPING 500 GAL PER MIN FROM FIELD DITCH

with 61 sprinklers. Its capacity is approximately 1,100 gal per min. The most economical arrangement is to have the supply ditch through the center of the field with a sprinkler line extending in both directions. This minimizes the friction loss in the pipe line and necessitates shutting down only one line at a time when moving pipe, thereby appreciably increasing the operating efficiency of the system.

If the water supply is obtained from wells or if open ditches through the field are not feasible, a stationary pump and a pressure supply line are used. The latter may be either a portable pipe similar to the sprinkler line, or a stationary pipe with valve outlets. On stationary lines the valves are usually spaced about three times the distance the pipe is moved, so that three settings are made from each valve.

Another type of low-pressure system, consisting of light-weight perforated pipe, has recently come into use for field crops and pasture. Water is distributed over a strip 25 to 50 ft wide. These systems operate satisfactorily on pressures as low as 5 or 6 lb per sq in., but the effective width covered increases with the pressure up to about 25 lb per sq in. These systems apply the water at a relatively high rate, which limits their use to pervious soils and necessitates moving the pipe frequently.

Rotating nozzle lines are also used to some extent for irrigating truck crops and nurseries. They are probably more common in Eastern United States than in California.

One innovation is a movable sprinkler machine (Fig. 2) that pumps water from a field ditch and distributes it through two large part-circle sprinklers while traveling very slowly but continuously along the ditch. Several such machines[3] were constructed in 1938. They have capacities up to 600 gal per min and effectively cover a strip about 250 ft wide when operating at a pressure of about 60 lb per sq in.

ORCHARD SPRINKLING SYSTEMS

The several types of orchard sprinkling systems may be divided into two general groups: The overhead systems with sprinklers mounted above the trees; and the under-tree systems with sprinklers mounted on short risers so that they distribute the water under the branches of the trees.

There are three types of overhead sprinkler systems: (1) Those with stationary sprinklers mounted above the trees; (2) those with portable sprinklers and risers that are moved from place to place on a stationary pipe system; and (3) those using portable pipe and sprinklers. There are also different types of under-tree systems, some using stationary sprinklers, others using portable sprinklers attached to hose or mounted on portable pipe. Stationary supply lines with valve outlets are generally used for portable systems.

The under-tree systems are gaining in popularity; some stationary overhead systems are even being converted into them. Under-tree sprinklers are usually spaced the same distance apart as the trees, so that each sprinkler covers an area

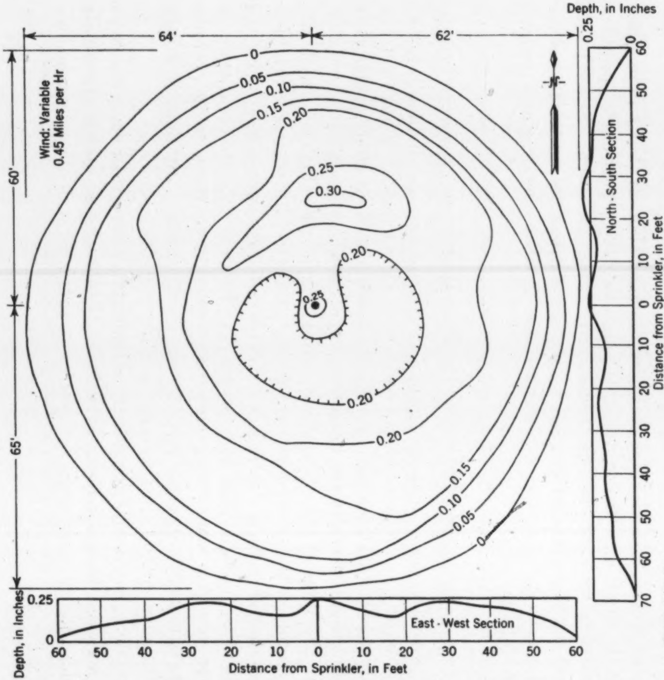

FIG. 3.—TEST 16. DISTRIBUTION OF WATER FROM SPRINKLER WITH $\frac{9}{32}$-IN. AND $\frac{3}{16}$-IN. NOZZLES, OPERATING AT 45-LB PRESSURE; SPRINKLER ROTATION, 0.7 RPM

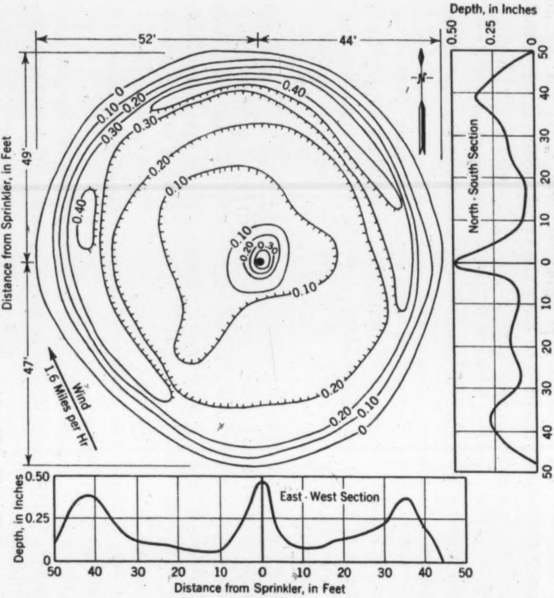

FIG. 4.—TEST 11. EFFECT OF LOW PRESSURE (20 LB PER SQ IN.) ON DISTRIBUTION OF WATER FROM SPRINKLER WITH $\frac{5}{16}$-IN. AND $\frac{5}{32}$-IN. NOZZLES; SPRINKLER ROTATION, 0.6 RPM

equal to that occupied by one tree, whereas stationary overhead sprinklers are generally spaced three to four tree rows apart each way. Consequently the distribution of water is much better for the under-tree systems, since each tree is supplied with essentially the same quantity of water, although the distribution over the area occupied by each tree may not be uniform. Very little is gained by wetting the leaves, and often this practice is detrimental in that it spreads disease. Small under-tree sprinklers operate satisfactorily on pressures of 10 to 20 lb per sq in., whereas the larger sprinklers on overhead systems require 30 to 50 lb per sq in. The low pressures can sometimes be supplied by gravity, whereas pumping plants would be required for the higher pressures.

Distribution of Water from Sprinklers

In studying the hydraulic characteristics of sprinklers, more than 300 tests were made at Davis, Calif., to determine the distribution of water from sprinklers. Most of these tests were for periods of one hour, some for ½ hour. For most of the experiments, cans were spaced 10 ft apart (or closer) in both directions over the entire area covered by the sprinkler; and, for certain tests, as many as 280 cans were used. The water was measured to the nearest cubic centimeter (equivalent to 0.005 in. in depth) in a graduated cylinder. During most of the tests, wet-and-dry bulb temperatures were taken for use in evaporation studies. To measure the wind velocities, a four-cup anemometer was mounted in an exposed position about 10 ft above the ground. By means of a return-pressure line from the base of the sprinkler, with a pressure gage mounted near the control valve, a nearly constant pressure was maintained. The plotting of the tests is illustrated in Fig. 3, which shows the distribution obtained with one sprinkler under favorable conditions (sufficient pressure, no wind, and a fairly slow and uniform rotation).

The effect of low pressure is shown in Fig. 4. With a pressure of 20 lb per sq in. most of the water was thrown to the outside edges of the area covered, with very little falling between 10 and 20 ft from the sprinkler. Fig. 5 shows the effect of wind. The area covered is offset about 2 ft for each mile per hour of wind, with a high concentration near the sprinkler, especially on the windward side.

A cause of uneven distribution is often a variable rate of rotation of the sprinklers. Every sprinkler tested varied somewhat in this respect, some much more than others. In one case (Fig. 6), the angular velocity was eight times as great when the main nozzle was discharging to the east as when it was discharging to the southwest. For a study of rotation, an anemometer recorder was converted into a rotation recorder by gearing it so that the drum rotated at a speed of one inch in 50 sec. Attached to the sprinkler was a commutator arrangement that closed an electrical circuit every 30° or 60°, as desired. In this way the actual rate of rotation for a large number of revolutions was recorded automatically. Uneven rotation is not caused by wind, as is commonly supposed.

The rate of rotation greatly affects the distribution of water. For maximum coverage, a sprinkler should rotate less than 1 rpm. Often it may rotate as

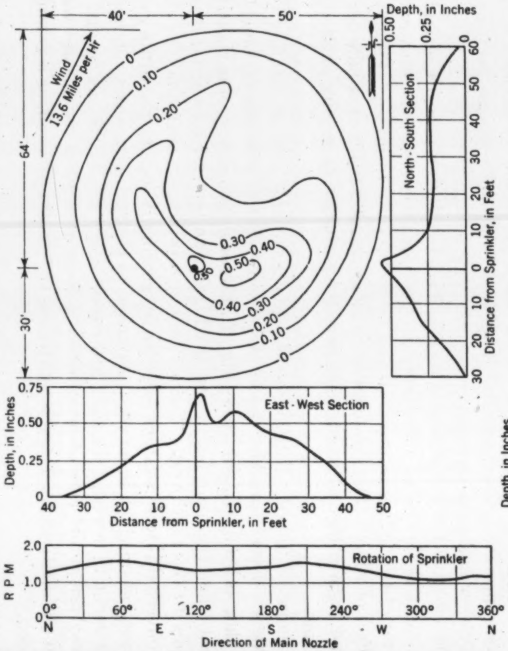

Fig. 5.—Test 112. Effect of Wind (13.6 Miles per Hr) on Distribution of Water from Sprinkler with $\frac{4}{16}$-In. Main Nozzle. Pressure, 40 Lb; Rotation, 1.3 rpm

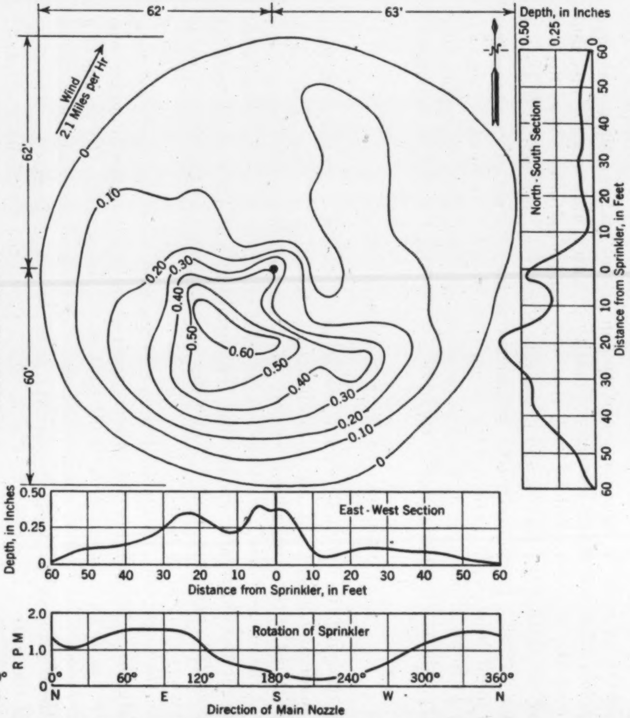

Fig. 6.—Test 103. Distribution of Water from Sprinkler with Variable Rate of Rotation; Pressure, 40 Lb per Sq In.

slowly as $\frac{1}{3}$ rpm. The slower the rotation, the larger the area covered. When improperly adjusted and allowed to rotate at 20 rpm or more, sprinklers cover only about half the area they would cover at a slow rate under the same pressure. In one instance, a sprinkler was observed to be rotating very rapidly, and a count showed the speed to be about 90 rpm. The effect of rapid rotation is shown in Fig. 7, in which case a speed of 13.6 rpm reduced the area covered to about 55% of what it would have been at 1 rpm. Unless such sprinklers are mounted closer together, the uniformity of application will be poor. In Fig. 7 the nozzles were $\frac{9}{32}$ in. and $\frac{5}{32}$ in., and the pressure was 40 lb per sq in. Under similar conditions, but with rotation less than 1 rpm, the diameter covered would have been about 115 to 120 ft.

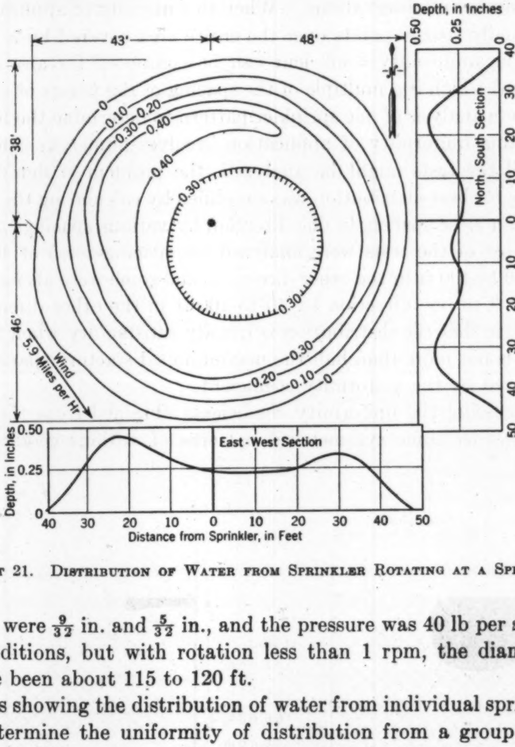

FIG. 7.—TEST 21. DISTRIBUTION OF WATER FROM SPRINKLER ROTATING AT A SPEED OF 13.6 RPM

Patterns showing the distribution of water from individual sprinklers can be used to determine the uniformity of distribution from a group of sprinklers spaced any distance apart. The resulting distribution from sprinklers with patterns corresponding to Fig. 3, for the customary spacing of 40 ft by 50 ft, is shown in Fig. 8(*a*). The variation is from about 0.7 in. to slightly more than one inch. Fig. 8(*b*) shows the resulting distribution for patterns corresponding to Fig. 4, illustrating the effect of low pressure. Here the variation is from about 0.2 in. to more than one inch. Fig. 8(*a*) illustrates the uniformity obtained under favorable conditions and Fig. 8(*b*) illustrates what occurs when pressures are inadequate.

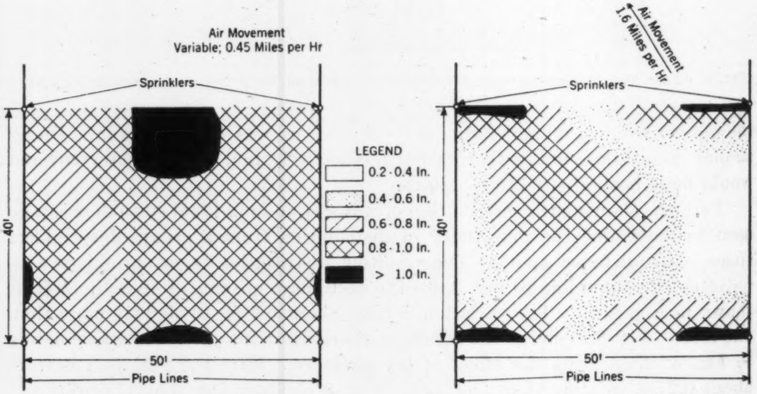
To compare sprinkler patterns and to determine how various spacings affect the resulting distribution of water, one needs a numerical expression that can serve as an index of the uniformity secured. For this purpose an expression called the uniformity coefficient was adopted. The uniformity coefficient (C_u) expressed as a percentage is defined by the equation

$$C_u = 100\left(1.0 - \frac{\Sigma x}{M\,n}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which x is the deviation of individual observations from the mean value m, and n is the number of observations. When the intensity of application at any number of equally spaced points over the entire area covered by a sprinkler is determined, the uniformity coefficient can be computed for any spacing (in either direction) which is a multiple of the spacing of the points of observation. Thus a complete analysis of one sprinkler pattern to determine the best spacing and the resulting uniformity of application involves numerous computations.

So that all the tests might be analyzed, the problem of determining the proper spacing for best distribution was simplified by calculating the uniformity coefficients for a close spacing in one direction by various spacings in the other direction. Most of the tests were analyzed for spacings of 5 or 10 ft in one direction by 40 to 100 ft in the other direction, and some were also analyzed for spacings of 40 ft in one direction by 40 to 100 ft in the other direction. The analyses indicate that the distribution is usually satisfactory when the spacing along the line is not more than half the maximum satisfactory spacing between lines as indicated by the uniformity coefficient.

Before discussing the uniformity coefficients obtained from the tests, one might well consider some symmetrical patterns of various geometric shapes



(*a*) PATTERN IN FIG. 3; 45 LB PER SQ IN. (*b*) PATTERN IN FIG. 4; 20 LB PER SQ IN.

FIG. 8.—DISTRIBUTION RESULTING FROM SPRINKLERS HAVING VARIOUS PATTERNS WHEN SPACED 40 FT BY 50 FT APART

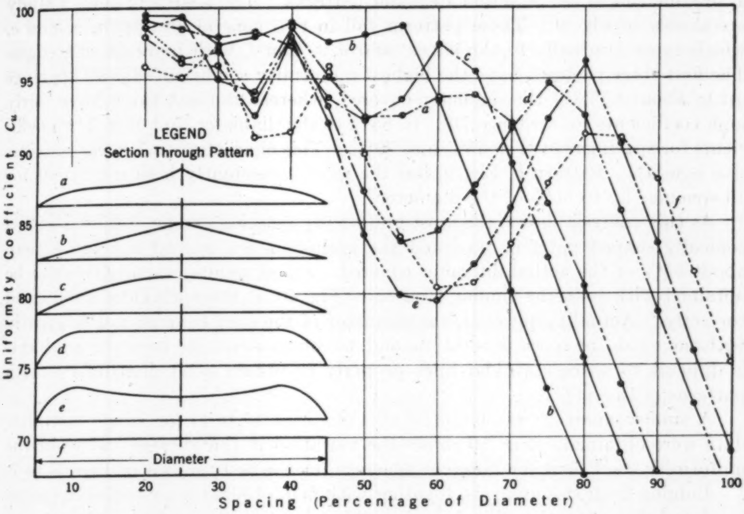


FIG. 9.—COEFFICIENTS OF UNIFORMITY FOR DIFFERENT SPACINGS OF GEOMETRICAL PATTERNS

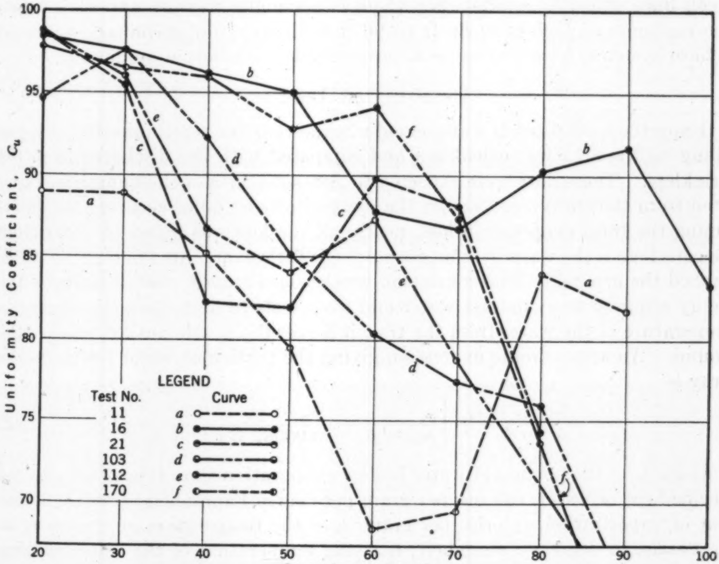

FIG. 10.—UNIFORMITY COEFFICIENTS FOR THE SPRINKLER PATTERNS SHOWN IN FIGS 3 TO 7

approximating those of actual sprinkler patterns. The results of such a study are shown in Fig. 9. These patterns fall in two general groups: *a*, *b*, and *c*, which taper gradually to the edges; and *d*, *e*, and *f*, with more abrupt edges. The first three patterns have the highest uniformity coefficients for all spacings up to about 65% of the diameter covered, whereas the last three have fairly high coefficients for spacings 70% to 85% of the diameter, but very low coefficients for spacings between 45% and 70%. This characteristic indicates excessive overlap. Pattern *b*, Fig. 9, has the most consistently high coefficient for all spacings up to 55% of the diameter.

As this analysis shows, the most uniform application can be obtained with a conically shaped pattern, provided the sprinklers are spaced not more than about 55% of the actual diameter covered. Good results, apparently, can be obtained with patterns similar to *d* or *e* (Fig. 9), if the sprinklers are spaced correctly. Actually, however, the diameter of the area covered varies greatly with the wind, the speed of rotation, and, to some extent, the pressure, so that it is difficult to space sprinkler lines properly to obtain good distribution with patterns of this type.

A similar analysis was made of all the sprinkler tests for which complete data were obtained. Fig. 10 shows the variation in the average values of the uniformity coefficient for different spacings for the tests shown in Figs. 3 to 7.

Judging from this analysis, together with field observations, sprinklers must be placed closer together than is indicated by the study of symmetrical patterns. The usual spacings of 20 ft, 30 ft, and 40 ft along the line and 50 ft to 70 ft between lines give fair results when there is adequate pressure and little wind. The customary spacings of 60 ft to 90 ft both ways for stationary overhead orchard systems, however, cause an appreciable variation in application.

EVAPORATION LOSSES

From the quantities of water caught in the cans the total quantity of water falling on the area was calculated and compared with the discharge from the sprinklers. These data were expected to give some idea of the quantity evaporated from the spray. Although the method proved quite accurate for determining the total evaporation loss, nearly all the loss was found to occur from the cans before the water was measured; very little evaporated before the water reached the ground. This conclusion was reached from a consideration of the energy required to evaporate water and from tests to determine the change in temperature of the water from the time it leaves the nozzle until it reaches the ground. An approximate expression giving the portion of water lost from the spray is

$$E = \frac{c\,(t_1 - t_2)}{L}\left[\frac{p_w - p_a}{p_w - p_a - 0.00037\,B\,(t_a - t_w)}\right]\ldots\ldots\ldots(2)$$

in which E = the portion of water loss by evaporation from the spray; c = the specific heat of water, calories per gram per degree Fahrenheit; L = the latent heat of vaporization, calories per gram; t_1 = the temperature of the water at the nozzle, in degrees Fahrenheit; t_2 = the temperature of the water striking the ground, in degrees Fahrenheit; t_w = the mean water temperature, in degrees

Fahrenheit; t_a = the air temperature, in degrees Fahrenheit; p_w = the vapor pressure of water at temperature t_w, in inches of mercury; p_a = the pressure of the water vapor in the air, inches of mercury; and B = the barometric pressure, in inches of mercury.

Evaluating the constants, and letting $c = 0.555$, $L = 585$, and $B = 30$, Eq. 2 becomes

$$E = 0.00095\,(t_1 - t_2)\left[\frac{p_w - p_a}{p_w - p_a - 0.011\,(t_a - t_w)}\right]\ldots\ldots\ldots(3)$$

One can derive a similar expression from the general evaporation formula,[4]

$$E = \frac{I - H_s - k - R_b}{L\,(1 + r)}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(4)$$

by assuming that the insolation I, the conduction k, and the back radiation R_b are negligible and can be omitted. The sensible heat, H_s, is indicated by the change in the temperature of the water. The other terms are as follows: L, the heat of vaporization; and r, the ratio of energy transfer by convection to that by evaporation (called Bowen's ratio), which is a function of the vapor-pressure deficit and of the difference in air and water temperature.

Several determinations of the temperature drop in the water between the sprinkler and the ground were made on field installations and at Davis. The evaporation losses for these tests, computed from Eq. 4, did not exceed one per cent. The drop in temperature, and therefore the evaporation loss, depends largely upon the size of drops, which in turn depends upon pressure, wind, and type of sprinkler. Apparently, however, the loss from the spray is very little, and the principal loss by evaporation is from the wet surface of soil and plants during and following the application of water.

The rate of this loss probably exceeds that from a free water surface because of the relatively larger area exposed. The rate decreases rapidly, however, as the surfaces dry, and becomes negligible after about a week, during which time the total loss may have exceeded an inch of water. In the interior valleys of California, rates of evaporation from standard Weather Bureau pans often exceed 0.40 in. per day; hourly rates frequently exceed 0.05 in., and average about 0.04 in. during the afternoon. The total evaporation loss frequently amounts to a large part of the application, especially when frequent light applications are made.

HYDRAULICS OF SPRINKLER LINES

One interesting problem in connection with sprinkler systems concerns the hydraulic losses at branch outlets along sprinkler lines. All the water does not flow through the entire line; it is distributed through side outlets equally spaced along the line. At each of these outlets there is a decrease in mean velocity in the pipe (assuming no change in pipe size) accompanied by an increase in pressure due to conversion of velocity head to pressure. There is also an hydraulic loss between the main and the sprinkler outlets. Consider a typical outlet along the line, sections 1, 2, and 3, representing, respectively, sections upstream and downstream from the outlet and in the side outlet. From Bernoulli's theorem, assuming no energy loss, one can show that

---

[4] "Evaporation as a Function of Insolation," by Burt Richardson, *Transactions*, Am. Soc. C. E., Vol. 95 (1931), pp. 996–1019.

$$p_2 - p_1 = \frac{w\,v_1^2}{2\,g}(2\,r_q - r_q^2) \qquad (5)$$

In Eq. 5, p_2 and p_1 are the pressure intensities on sections 2 and 1, respectively, v_1 = the mean velocity at section 1; g = acceleration due to gravity; r_q = ratio of $\frac{Q_3}{Q_1}$, or the proportion of water leaving the side outlet; and w = the weight of a cubic foot of water. John A. Oakey,[5] Assoc. M. Am. Soc. C. E., making a different assumption, derives an equation that can be written

$$p_2 - p_1 = \frac{w\,v_1^2}{2\,g}(3\,r_q - r_q^2) \qquad (6)$$

His experimental data, however, show that for values of r_q less than 0.7 the actual increase in pressure was approximately that given by Eq. 5. The energy loss between sections 1 and 3 can be determined only by experiment. Professor Oakey[5] gives values of K_3 from which the loss can be determined from the expression

$$e_1 - e_3 = \left(1 - r_q + \frac{K_3\,r_q^2}{r_p^2}\right)\frac{v_1^2}{2\,g} = \frac{v_1^2}{2\,g}(1 - r_q) + \frac{K_3\,v_3^2}{2\,g} \qquad (7)$$

in which e = energy; r_p is the ratio of the pipe area at section 3 to the pipe area at section 1; and K_3 is an empirical coefficient having values dependent both upon r_p and r_q. For small values of r_p, apparently, the value of the coefficient K_3 would be more nearly constant if the expression were written

$$e_1 - e_3 = \frac{v_1^2}{2\,g} + \frac{K_3\,v_3^2}{2\,g} \qquad (8)$$

Professor Oakey's data show that for $r_p = 0.0557$, K_3 varied from 0.53 for $r_q = 0.1$ to 0.36 for $r_q = 1.0$. Since values of v_3 are fairly constant along a sprinkler line and seldom exceed 8 ft per sec, the last term in Eq. 8 will seldom exceed 0.5 ft head. The conclusion reached is that the velocity in the sprinkler line has little effect on the flow in the outlets, and that the energy loss between sections 1 and 3 is of small consequence because, in comparison with the pressure required, it is appreciable only near the upper end of the line where the pressure is excessive.

Field tests were made to determine the friction factors or coefficients for the special sprinkler pipe and couplings used for portable sprinkler systems. These tests presented some difficulty because pipe-line velocities were sometimes as high as 15 ft per sec with pressures of 60 lb or more per sq in. A transverse pitot tube for measuring the flow did not prove satisfactory. The method finally adopted for these tests consisted of calibrating the sprinklers to determine the relation between pressure and discharge for all nozzle combinations and then to determine the pressure along the line by means of a pressure gage and a special fitting, slipped over the main nozzle of the sprinkler. It was necessary to correct for the increase in pressure caused by shutting off the flow of the nozzle being tested. As tests show, this correction was approximately constant along a line; one could determine it readily by noting the increase in pressure on another gage installed on the line or simply by momentarily stopping the flow of another nozzle while the gage was being used on one of the sprinklers. A pressure reading was taken on each sprinkler on a line from which the sprinkler discharge and the total discharge were determined from the calibration. The pressures were plotted on a large sheet of coordinate paper, and a smooth curve was drawn through the points. The pressure drop for each space between sprinklers was then taken from the curve and plotted against the discharge on logarithmic paper. The curve was drawn through these points, showing the relation between flow and pressure drop along the line. An interesting fact about these curves was that the best-fitting straight line showed the pressure drop to be a function of the square of the velocity in the pipe, instead of some lower power as indicated by most of the empirical formulas. For this reason the Weisbach formula,

---

[5] "Hydraulic Losses in Short Tubes Determined by Experiments," by John A. Oakey, *Engineering News-Record*, June 1, 1933, pp. 717–718.

$$h_f = \frac{f\,l\,v^2}{2\,g\,D} \qquad (9)$$

was adopted, and the average value of f for 4-in. pipe was found to be about 0.018, there being no appreciable difference between the different makes of pipe tested. (In Eq. 9, h_f = head loss due to friction; f = coefficient of friction; l = length of pipe; and D = diameter of pipe.)

However, when the values of f were computed from the pressure drops in each section of pipe between sprinklers, corrected by adding the pressure rise due to the decrease in velocity at the sprinklers to obtain the true friction loss, the values of f obtained were not constant but showed the usual form of curve when plotted against Reynolds' number.

In sprinkler problems one usually thinks of discharge in terms of gallons per minute and friction losses in pounds per square inch. For convenience the Weisbach formula can be written

$$p_f = \frac{0.0134\,f\,l\,Q_g^2}{D_i^5} \qquad (10)$$

in which p_f = the friction loss in pounds per square inch, l = the length of the line in feet, Q_g = the flow in gallons per minute, and D_i = the inside diameter of the pipe in inches.

A difficult task in the design of sprinkler systems is to determine pressure losses along a line with a large number of sprinklers. Although one can compute the loss between each two adjacent sprinklers, for long lines with twenty or more sprinklers this procedure becomes wearisome. Furthermore, in such computations one must begin at the distal end of the line and work back toward the source, beginning with an assumed pressure. A precise algebraic expression for the pressure loss in a long line of pipe with multiple outlets is very involved and therefore is of little practical value. Approximate expressions, however, from which the pressure loss can be determined quite accurately for limited conditions are very useful. If one assumes that the sprinklers are spaced *s* feet apart and that each discharges the same quantity of water (*q*),

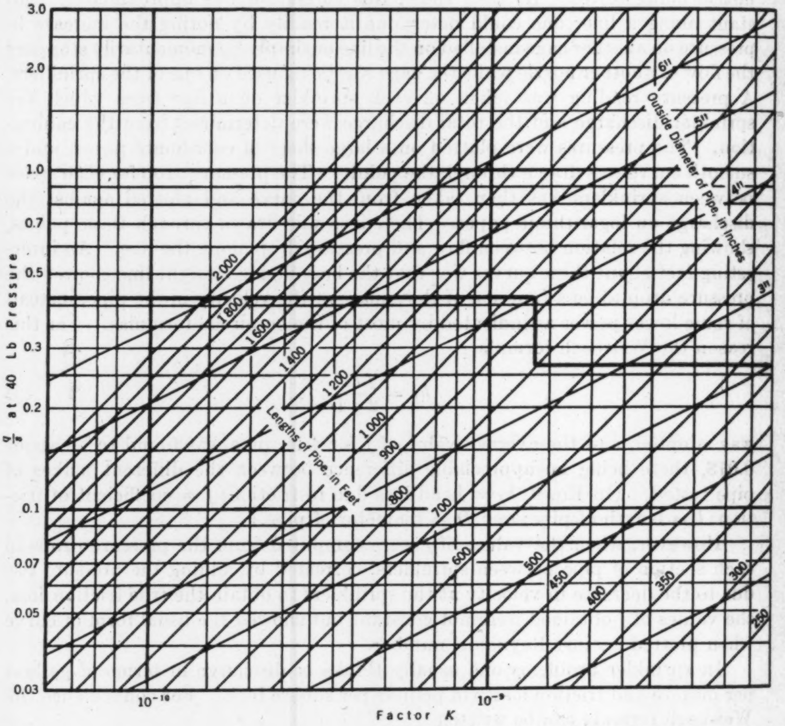

FIG. 11.—LOGARITHMIC DIAGRAM FOR DETERMINING

the total pressure loss for a line with N sprinklers and N spaces would be

$$p_f = \frac{0.0134\, f\, s\, q^2\, \Sigma N^2}{D_i^5} \qquad (11)$$

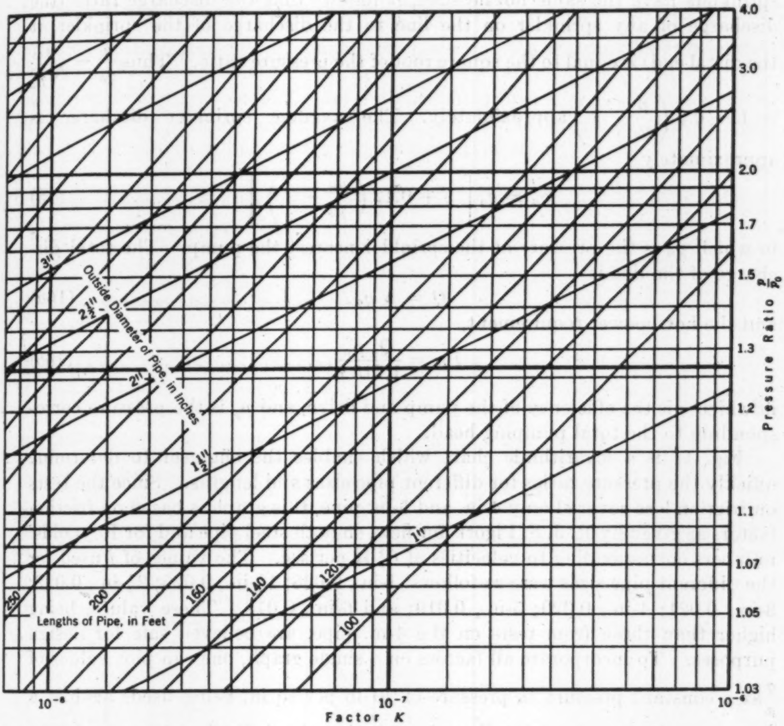
Because of the friction loss along a line, however, the sprinklers do not discharge the same quantity of water, even if the same nozzle sizes are used throughout. If the total pressure loss is relatively small, as compared with the pressure on the line, and if the computations are based on the average discharge of the sprinklers, the results will check very closely with those determined by detailed computations. The value of ΣN^2 can be determined from the expression

$$\Sigma N^2 = \frac{N^3}{3} + \frac{N^2}{2} + \frac{N}{6} \qquad (12)$$

Eq. 11 can be written

$$p_f = \frac{0.0134\, f\, L\, Q_g^2}{D_i^5}\,\frac{(\Sigma N^2)}{N^3} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

in which the first part of Eq. 13 would be the friction loss if all the water flowed through to the end of the line. From Eq. 12,



PRESSURE LOSSES IN PORTABLE SPRINKLER LINES

$$\frac{\Sigma N^2}{N^3} = \frac{1}{3} + \frac{1}{2\,N} + \frac{1}{6\,N^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

The simplest method of obtaining friction loss along a sprinkler line, therefore, is first to compute the loss, assuming that all the water flows through the entire line, and then to multiply this by a factor that depends only on the number of sprinklers. For this purpose any friction-loss table or graph applying to the pipe can be used.

The friction loss along a sprinkler line is directly proportional to the pressure at any point on the line. It has been found convenient to think in terms of pressure ratio $\frac{p}{p_o}$, the ratio of the pressure at any point on the line to the pressure at the distal end. This ratio is constant at a given point on a line regardless of the operating pressure at the pump. Assuming that all sprinklers have the same nozzle sizes, it follows that the discharge ratio (the discharge of any sprinkler on the line to the discharge of the sprinkler at the distal end) is equal to the square root of the pressure ratio. Thus $\frac{q}{q_o} = \sqrt{\frac{p}{p_o}} = 1 + 0.5\left(\frac{p}{p_o} - 1\right)$ approximately. The average sprinkler discharge is approximately

$$q_a = q_o\left[1 + 0.12\left(\frac{p_n}{p_o} - 1\right)\right] \quad \ldots\ldots\ldots\ldots\ldots (15)$$

in which p_n is the pressure at the sprinkler nearest the pump. The total discharge of the line is

$$Q = N\,q_a \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16a)$$

and the horsepower requirement,

$$P_H = \frac{Q_g\,p_p}{1{,}715\,\eta} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (16b)$$

in which η is the efficiency of the pump and drive, and p_p is the pressure corresponding to the total pumping head.

Fig. 11 is a logarithmic chart which enables the engineer to determine quickly the pressure ratios for different pipe sizes and lengths. Since the tests on friction loss covered only 4-in. and 5-in. pipe, this graph is based on friction factors as given by R. J. S. Pigott[6] for new, smooth steel pipe and for Reynolds' numbers corresponding to velocities of 6½ ft per sec. The values of f used for the different pipe sizes were as follows: 1-in., 0.028; 1½-in., 0.025; 2½-in., 0.022; 3-in., 0.021; 4-in., 0.020; 5-in., 0.019; and 6-in., 0.018. These values, being higher than those from tests on the 4-in. pipe, are believed safe for design purposes. To incorporate all factors on a single graph, one can plot values of $\frac{q}{s}$ at a constant pressure (a pressure of 40 lb per sq in. being used) against a parameter K, and then plot K against the length of the line, l, to obtain the pressure ratio $\frac{p}{p_o}$, in which p is a pressure at any distance, l, from the distal end of the line.

To use the graph one must first determine the discharge of the sprinkler at a pressure of 40 lb per sq in. If the discharge of the sprinkler at any pressure is known, the discharge at 40 lb per sq in. can be determined readily, since the discharge of the sprinkler is proportional to the square root of the pressure. For example, to find the friction loss in 800 ft of 4-in. pipe with sprinklers discharging 19 gal per min at 50 lb of pressure, spaced 40 ft apart, one must first determine the discharge at 40 lb of pressure. Thus, $q_{40} = 19\sqrt{\frac{40}{50}}$

---

[6] "The Flow of Fluids in Closed Conduits," by R. J. S. Pigott, *Mechanical Engineering*, August, 1933, pp. 497–501, and 515.

$= 17$. With sprinklers spaced 40 ft apart, $\frac{q_{40}}{s} = \frac{17}{40} = 0.425$. Entering the left side of the diagram with this value, follow to the right to the intersection with 4-in. pipe. Then drop vertically downward to the intersection with the 800-ft line, and read the pressure ratio $\frac{p}{p_o} = 1.27$ on the right margin. If the pressure at the distal end, p_o, equals 30 lb per sq in., the pressure 800 ft from the end would be $1.27\ p_o = 38.1$ lb; the pressure loss would be 8.1 lb. This diagram has proved very convenient for determining the proper pipe size under a given set of conditions or for determining the permissible length of pipe of each size in a combination line having two or more pipe sizes.

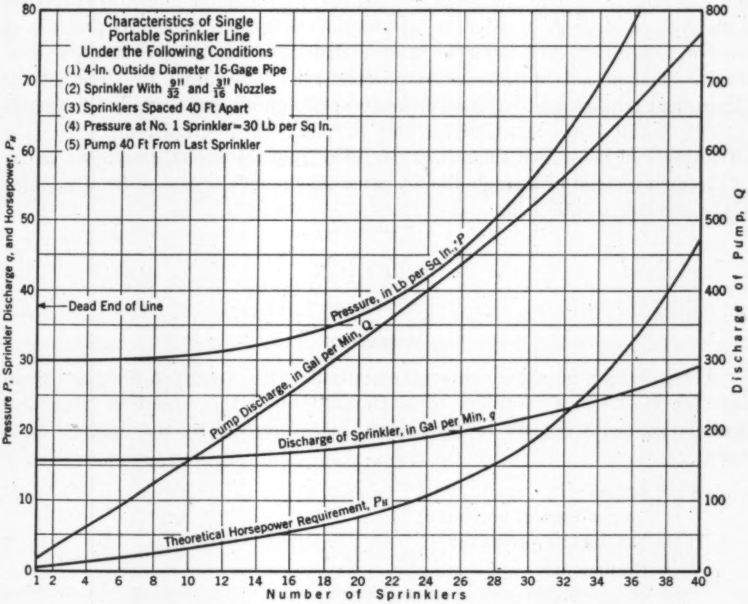


FIG. 12.—HYDRAULIC CHARACTERISTICS OF A PORTABLE SPRINKLER LINE

In designing a sprinkler system it is customary to start with an assumed value of p_o equal to the minimum pressure for which satisfactory sprinkler performance can be obtained. The dimensions of the field govern the length of the line; and since farm tractors required for other farm work are generally used as a source of power, the available power is generally known in advance. One must then ascertain the sizes of the sprinkler nozzles, the pipe, and the pump required.

When no provision is made for regulating the discharge of sprinklers along the line, it is a good practice to proportion the pipe sizes and nozzle sizes so that the over-all pressure ratio does not exceed 1.2. This arrangement limits the discharge ratio to approximately 1.1, permitting a 10% variation in sprinkler discharge along the line. On large systems it may not be advisable to limit the ratio to this value because pipe larger than 4 in. in diameter is heavy and difficult to carry. Many systems in use have pressure ratios in excess of 2; one tested had a ratio of approximately 3. Needless to say, such systems are very inefficient, and the pressure at the distal end of the line is usually far too low for satisfactory sprinkler performance. Lately, on one make of sprinkler system, the risers are provided with a shut-off cock and a pressure-valve arrangement so that the pressure on all sprinklers on the line can be determined readily and equalized.

Fig. 12 shows the hydraulic characteristics of a portable sprinkler line under the following conditions: (*a*) 16-gage pipe, outside diameter 4 in.; (*b*) sprinklers with $\frac{9}{32}$-in. and $\frac{3}{16}$-in. nozzles; (*c*) spacing of sprinklers, 40 ft; (*d*) pressure at the No. 1 sprinkler, 30 lb per sq in.; and (*e*) distance from pump to last sprinkler, 40 ft. The actual horsepower requirement is determined by dividing the theoretical requirement by the efficiency of the pump and drive. Efficiencies of 50% to 70% are assumed for this purpose. This graph emphasizes the advantages of using two short lines supplied from a source through the center of the field instead of a single line of twice that length, supplied from a source along one side of the field.

APPENDIX

NOTATION

The following notation conforms essentially with American Standard Symbols for Hydraulics compiled by a Committee of the American Standards Association[7] with Society representation and approved by the Association in 1929:

A = area:
  A_1 = area of section 1;
B = barometric pressure;
C = coefficient:
  C_u = uniformity coefficient;
c = specific heat of water;
D = diameter:
  D_i = inside diameter of pipe in inches;
E = evaporation; the portion of water loss by evaporation;
e = energy;
f = friction coefficient;
g = gravity constant;
H = heat:
  H_s = sensible heat;
h = hydraulic head:
  h_f = head loss due to friction;

---

[7] A. S. A.—*Z* 10*b*—1929.

I = insolation;
K = an emperical coefficient:
  K_3 = an emperical coefficient having values dependent on both r_p and r_q;
k = thermal conductivity; conduction;
L = latent heat of vaporization;
l = length;
M = mean value;
m = mass;
N = the total number of;
n = any number of observations;
P = power:
  P_H = horsepower requirement;
p = pressure intensity; pressure loss:
  p_a = pressure of water vapor in the air;
  p_f = pressure loss due to the pipe friction;
  p_n = pressure intensity at the sprinkler nearest the pump;
  p_o = pressure intensity at the distal end of a pipe;
  p_p = the pressure corresponding to the total pumping head;
  p_w = vapor pressure of water at t_w;
  p_1 = pressure intensity at section 1;
Q = quantity, or rate of flow:
  Q_g = flow in gallons per minute;
q = rate of flow, in gallons per minute, through a single sprinkler:
  q_a = average discharge of the sprinklers on a line;
  q_o = flow through a sprinkler at the distal end of pipe;
R = radiation:
  R_b = back radiation;
r = ratio of energy transfer by convection to energy transfer by evaporation (called Bowen's ratio):
  r_p = ratio of the pipe area at Point 3 to the pipe area at Point 1;
  $r_q = \frac{Q_3}{Q_1}$, or the proportion of water leaving the side outlet;
s = spacing of sprinklers;
t = temperature:
  t_a = air temperature;
  t_w = the mean water temperature;
  t_1 = temperature of water at the nozzle;
  t_2 = temperature of water as it strikes the ground;
v = velocity:
  v_1 = velocity at section 1;
w = weight of a cubic foot of water;
x = deviation from the mean;
η = efficiency.

DISCUSSION

Arthur F. Pillsbury,[8] Assoc. M. Am. Soc. C. E. (by letter).—In California, sprinkling systems for irrigation often have failed to perform satisfactorily because of faulty design, failure to obtain good distribution characteristics for the sprinklers with the spacings provided, and failure to interpret, properly, the limitations of the soil in absorbing the precipitation. Therefore, the excellent dissertation by Mr. Christiansen, based on a wealth of experimental evidence, is timely.

Sprinkling systems are useful where: (1) A high water level exists, and less uniform surface applications would cause that level to rise; (2) the topsoil is shallow and pervious, and less uniform surface applications would create a temporary water table above a subsoil of different texture; (3) the soil is extremely pervious resulting in waste of water in parts of a planting; (4) irrigation is infrequent, the good topsoil is shallow, and for other reasons it is not practical to establish satisfactory grades for surface irrigation; and (5) extremely light and frequent applications are desired, as with some pastures, lawns, and gardens.

In short, sprinkler irrigation is useful where surface methods cannot be economically and efficiently utilized. Its use with field crops is limited to areas of high water table, or where extremely light frequent or infrequent supplemental irrigations are desired, and with orchards to areas of shallow soil, extremely pervious soil, or unfavorable topography.

In orchard irrigation, under-tree systems are unquestionably preferable to the overhead type. The essential sprinkler objective is to improve distribution of water. With the under-tree system, the distribution is less affected by wind and by the trees, it is better adapted to operation by the usual farm laborer, and it should be less expensive.

Mr. Christiansen's data on distribution of water from sprinklers are of greatest importance with the overhead type used for field crops. With under-tree orchard irrigation, sprinklers are generally spaced only 18 to 24 ft apart, and the greatest essential is to insure approximately equal discharge of each sprinkler, rather than absolutely uniform distribution in each space bounded by four trees, which is seldom attained. A good pattern is nevertheless desirable.

For under-tree work the slow revolving sprinklers and perforated pipe systems generally are used for low-pressure (4 to 15 lb per sq in.) operation with medium to high rates of discharge (2 to 8 gal per min, or equivalent for perforated lines). Whirling sprinklers are used for intermediate pressures (10 to 20 lb per sq in.) with all usual rates of discharge (1 to 8 gal per min) and for higher pressures with low to medium rates of discharge (1 to 4 gal per min). Fixed heads are used for high pressure (20 lb per sq in. and up) with high rates of discharge (4 to 8 gal per min) and for lower rates of discharge when spacing is closer than usual or when exceptionally high pressure is available. Intermediate and high-pressure systems usually result in economies in material where sufficient pressure is available without pumping. On the other hand, low-pressure systems may eliminate the necessity of pumping, or may minimize the pumping cost.

---

[8] Asst. Prof. of Irrig., Univ. of California, Los Angeles, Calif.

The rate of application depends upon general farm practices or upon the maximum infiltration rates permissible without appreciable runoff and erosion. Infiltration rates decrease somewhat with increase in the proportion of the finer particles of a soil. More important is the physical condition of the soil. Generally, infiltration rates increase with decrease in original moisture content, but powdery dry soils may not take water readily. Organic matter, such as cover crops and manure, increases infiltration rates. Chemically "soft" waters (relatively low in calcium or with a high percentage of sodium in relation to other cations), and some inorganic fertilizers, may tend to leave a top sodium-saturated crust on the surface which is relatively impervious. Similarly, impervious crusts may be formed by physical compaction. Cultivation will improve infiltration by breaking up and mixing such crust with other soil.

Of frequent practical importance in sprinkler design is the fact that the size of sprinkler drops (with equivalent spray trajectories) is closely correlated with physical compaction ("puddling") of the surface crust. For instance, on a bare soil classified[9] as Yolo loam, with sprinkler precipitation at a constant rate of 0.59 in. per hr, a 5.4-in. depth of fine spray was applied without runoff, while with a somewhat coarser spray only 2.5 in. could be so applied. Relative size of drops was roughly checked with the Bentley technique.[10] Detailed investigations are now (1941) being conducted by the U. S. Soil Conservation Service on the effect of drop size on erosion and infiltration.[11]

In general, size of drop with a given sprinkler increases with distance from the sprinkler, and, comparing different sprinklers producing equivalent patterns, drop size decreases as pressure increases. This point is stressed because many sprinkler systems have failed due to serious runoff and erosion that developed before sufficient water could be applied. Later investigations have indicated: (1) That the soil was too heavy for satisfactory sprinkler use under the cultural practices followed, and (2) that the condition might have been prevented had sprinklers with a finer spray been used. It must be recognized, then, that low-pressure sprinklers (with a coarse spray) are sometimes not suitable for irrigation of bare soils, whereas higher pressure sprinklers would be suitable.

Mr. Christiansen's data on evaporation losses indicate that loss from the sprinkler spray is insignificant. Some increase in evaporation, as compared with furrow irrigation, may result, however, from the greater ground surface wetted and from water intercepted by plant foliage. His data on the hydraulics of sprinkler lines are quite complete. Comments on the hydraulics, having in mind the small under-tree units commonly used in Southern California, follow:

(1) The recommendations of Mr. Pigott[6] for friction loss in new steel and copper pipes are very satisfactory for use in design of $\frac{3}{4}$-in. to $1\frac{1}{2}$-in. units, as indicated by recent tests of friction losses in such pipes.

(2) Generally, the under-tree units have sprinklers at each end of the line, and are uniformly spaced. Sufficient accuracy is attained if it is conservatively assumed that friction losses will be one third the loss that would occur if the full flow of all sprinklers was carried to the end of the line.[12]

(3) Table 1 shows the maximum recommended sprinkler discharge in gallons per minute at a pressure of 20 lb per sq in. and an over-all pressure ratio of 1.2. The sprinklers are assumed to be all similar, equally spaced, and placed at each end of a unit. Spacings that are not included can be interpolated. In Table 1, approximate lengths of pipe that can be dragged readily by one man, under favorable conditions, are underlined. Assuming a maximum allowable over-all pressure ratio of 1.2, Table 1 is satisfactory for use in designing the portable units. Included are all the various types of pipe now used for such portable units. The usual steps in designing a unit are: (*a*) Select the application rate desired (generally 0.2 to 1 in. per hr); (*b*) compute the desired sprinkler discharge by the formula

$$\text{Sprinkler discharge in gal per min} = \frac{\text{Area (sq ft) per sprinkler} \times \text{rate of application (in 1 hr)}}{96.3} \quad \ldots\ldots(17)$$

(*c*) select sprinkler and operating pressure; (*d*) determine what the discharge per sprinkler would be at 20 lb per sq in. (discharge proportional to square root of pressure); and (*e*) select pipe and length of unit from Table 1. Usually sprinklers with devices for manually adjusting pressure at each sprinkler are not satisfactory for under-tree systems, but whirling sprinklers are being developed which automatically regulate discharge if pressure is greater than 8 lb per sq in. If these prove satisfactory, it will not be necessary to limit the pressure ratio when using them but simply to insure adequate pressure at the distal end of each unit.

TOM A. BITHER,[13] ASSOC. M. AM. SOC. C. E. (by letter).—This excellent paper deals with a type of irrigation that is becoming more and more extensively adopted for the irrigation of row crops, pastures, and orchards, resulting in a saving in water and more uniform distribution, as well as increased yields. It has been the good fortune of the writer to be located near Davis and the Sacramento Valley where most of Mr. Christiansen's experimental work and field tests have been conducted. The paper does not adequately indicate to the reader the vast amount of experimental work that Mr. Christiansen has done during the eight years since 1933; nor is the author able, in the space available, to cover in full the many tests on sprinklers and sprinkler lines that he has conducted during that period.

Some sprinkler lines have been sold without any consideration of the fundamental principles of design. In some cases, for example, claims have been made that a higher pressure would be obtained at the outer (distal) end of the line than at the inlet end, even though the line was to operate on level ground. It is to be hoped that with the publication of Mr. Christiansen's data and design formulas this practice can be stopped.

---

[12] "The Design of Overhead Irrigation Systems," by E. S. West and A. Howard, *Pamphlet No. 50*, Council for Scientific and Industrial Research, Commonwealth of Australia, Melbourne, 1934.

[13] With California Corrugated Culvert Co., Berkeley, Calif.

In regions where natural rainfall alone is relied upon for crop production, droughts frequently occur. Supplementary irrigation during dry periods will greatly increase crop yields and often will save valuable crops and prevent serious injury to orchards. The average seasonal rainfall is usually more than enough to grow good crops, but the rains do not always come at the right times, with the result that crops suffer if not protected by some type of supplemental irrigation. Any farmer should be able to increase production with the aid of irrigation since he can then assure himself of always having sufficient moisture available when needed. The overhead or sprinkler system of supplementary irrigation has been found to be the most suitable method for many crops and conditions. By this method, water may be applied efficiently and economically since it enables the irrigator to apply a uniform depth of water over his land regardless of topography, and without waste. This method requires less water than surface irrigation methods. Canals and ditches are eliminated, thereby doing away with seepage losses.

On uneven or rolling ground, surface methods are unsatisfactory since they result in heavy applications and water logging in the low spots, and light applications or no water at all on the high spots. A considerable quantity of water is also lost by deep percolation at the upper ends of checks and furrows where surface methods are used. The cost of preparing land for satisfactory surface irrigation is an important consideration. Extensive leveling and grading not only cost money but also have the serious objection of removing the surface topsoil from the high spots and leaving a less fertile subsoil. Where the soil is shallow, the high spots may be completely ruined by deep grading.

Expensive leveling of land is entirely eliminated where sprinkler irrigation is used to apply water. This method applies water in the form of rain and is applicable to all types of soil and to any condition of topography. It permits the utilization of a small head of water that would be entirely inadequate for surface irrigation methods. It insures a uniform distribution of water; permits keeping the soil in the best condition at all times; and, by applying water at the proper rate, prevents serious soil erosion.

Mr. Christiansen should have explained that the sprinkler distribution tests (Figs. 3 to 7) were made using sprinklers that are now considered obsolete and inadequate for agricultural work. These sprinklers were of the reaction-drive type and have been almost entirely supplanted by the impulse-drive sprinkler, a type which rotates at a uniform speed when properly adjusted. These sprinklers do not produce the unfavorable patterns shown in Figs. 3 to 7. Also, as a result of Mr. Christiansen's investigations, these later types of sprinklers produce a cross-sectional pattern approximating that shown in Fig. 9, pattern *b*. Sprinkler manufacturers have also developed agricultural sprinklers operating at lower pressures than those he describes, some of them, for under-tree work, operating at pressures as low as 2 lb per sq in. with satisfactory patterns for this work.

As a result of personal observations, the writer agrees with Mr. Christiansen that the loss due to evaporation in the spray between the nozzle and the ground is negligible. Also, the total losses incurred from the sprinkler method of irrigation are less than that from any surface method of application since water is lost neither by deep percolation at the upper ends of furrows and checks, nor from seepage from ditches.

The writer is of the opinion, as the result of field tests on operating lines, that the pressure losses determined from the logarithmic chart (Fig. 11) and from Eq. 11 are too high. This is undoubtedly due to the assumption that all sprinklers are discharging the same quantity of water, which is not the case, as indicated by Fig. 12. Although a logarithmic chart of the form of Fig. 11 is undoubtedly convenient and useful for determining pressure losses, it has been found, in the preparation of handbooks and manuals for field men, that tables are more convenient than charts. As a consequence, the writer has computed and compiled tables for various sizes of pipe and of sprinklers placed at several spacings on the line. These tables which give pressures, total line discharge, and equivalent rainfall enable the field man to determine quickly the size of pipe as well as the size and spacing of sprinklers for any particular installation, depending upon the size of the field to be irrigated, the size of the power unit or pump, the amount of water available, the type of soil, or other governing factor.

Ralph W. Powell,[14] M. Am. Soc. C. E. (by letter).—The writer wishes to comment on only one section of this interesting paper—namely, that on the hydraulics of sprinkler lines, and principally on only one phase of it, which is the recovery of pressure head in the main line of pipe when some of the flow is drawn off through a side outlet. This has been discussed in the technical press, but as Wallace M. Lansford,[15] Assoc. M. Am. Soc. C. E., has pointed out, no "complete experimental and analytical solution * * * has yet been published." Probably the most thorough experimental study of the question was made by the Bureau of Reclamation at the Fort Collins (Colo.) laboratory in 1932; but their report[16] deals primarily with the energy loss, and the only data explicitly given regarding pressure recovery seem to be those applying to points opposite the exact center of the junctions, where the recovery might be expected to be only half completed, or perhaps less than that.

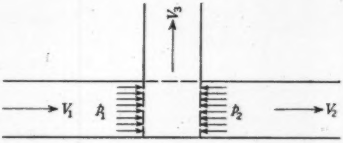

Fig. 13

For many years the writer has been puzzled by the result arising from a momentum treatment of this problem. In Fig. 13, if the unbalanced force acting in the liquid within the dashed lines is made equal to the change in momentum per second in the usual manner,

[14] Associate Prof. of Mechanics, Ohio State Univ., Columbus, Ohio.

[15] *Engineering News-Record*, April 10, 1941, p. 522. For previous discussions of the same subject, see *Engineering News-Record*, November 21, 1940, p. 697, and January 16, 1941, p. 78.

[16] "Model Studies of Penstocks and Outlet Works," *Bulletin No. 2*, Boulder Project Final Repts., U. S. Dept. of the Interior, 1938, especially pp. 49–64. (The reference, on p. 62, to a paper by the writer is unfortunate, as the paper was never published.)

$$p_2\,A - p_1\,A = \frac{w\,Q_1\,v_1}{g} - \frac{w\,Q_2\,v_2}{g} \qquad (18)$$

which reduces to

$$p_2 - p_1 = \frac{w\,v_1^2}{g}\,(2\,r_q - r_q^2) \qquad (19)$$

In Eq. 19, $p_2 - p_1$ is just twice the value given by Eq. 5. The frictional drag around the periphery of the free body has been neglected, but an approximate estimate shows that it would be negligible, and at any rate it is in the wrong direction to explain the discrepancy. One may first be tempted to state that there is a question as to whether Bernoulli's theorem applies between two points at which the quantity of flow is different, and that, since momentum considerations give an exact solution without the loss term which is required in the energy equation, Eq. 19 is more likely to be right than Eq. 5. However, when he investigates the reported experiments, he finds that the actual recovery is less than that given by Eq. 5, rather than more.

The explanation seems to lie in the unequal velocity distribution in the main pipe just downstream from the junction. Following the usual notation,[17] the momentum equation should have been written

$$p_2\,A - p_1\,A = \frac{w\,Q_1\,\beta_1\,v_1}{g} - \frac{w\,Q_2\,\beta_2\,v_2}{g} \qquad (20)$$

which leads to

$$p_2 - p_1 = \frac{w\,v_1^2}{g}\,[\beta_1 - \beta_2\,(1 - r_q)^2] \qquad (21)$$

Then, calling the ratio of recovered pressure head to original velocity head K_2:

$$K_2 = \frac{(p_2 - p_1)\,2\,g}{w\,v_1^2} = 2\,\beta_1 - 2\,\beta_2\,(1 - r_q)^2 \qquad (22)$$

Table 2 gives the average values of K_2 as reported by Professor Oakey.[1] As the author states, these agree with Eq. 5 better than with Eq. 6. Table 2 also gives the values of K_2 deduced from material published by the Reclamation Service.[18] The agreement between the two sources is very satisfactory. The measurements of the Reclamation Bureau were on a much larger scale and are

TABLE 2.—VALUES OF K_2 AND β_2

[17] "Mechanics of Liquids," by Ralph W. Powell, The Macmillan Co., New York, N. Y., 1940, p. 125. (One w is printed erroneously there as W.)

[18] "Model Studies of Penstocks and Outlet Works," *Bulletin No. 2*, Boulder Project Final Repts., U. S. Dept. of the Interior, 1938, Fig. 30 and the first equation on p. 39 (after supplying a missing parenthesis around the last three terms).

probably more accurate. The last line gives the values of β_2 necessary to make the Reclamation Bureau values of K_2 satisfy Eq. 22, β_1 being taken as 1.02.

The values of β_2 in Table 2 may seem impossibly high, but it must be realized that, when a large part of the flow is diverted to a side outlet, the remaining flow will be distributed very unequally across the pipe, possibly even to the extent of a reversal of flow on the side toward the outlet. If the velocity averaged zero over half the cross section and $2\,v$ over the other half, β would exceed 2.

It would seem to the writer that in this problem there is no hope of deducing how much head will be recovered and how much lost, but that one must depend on experiments.

Harry F. Blaney,[19] M. Am. Soc. C. E. (by letter).—Sprinkling irrigation has been used extensively in the United States for many years. The paper on this subject by Mr. Christiansen presents some excellent data but may give some readers the impression that sprinkling systems for irrigation are comparatively new. Information obtained from the 1920 Census of Agriculture, and from other sources, indicates that more than 12,000 acres were thus irrigated in 1919. As early as 1916 the U. S. Department of Agriculture made some general studies on spray irrigation and the results were published.[20] In 1924 the University of California made a study of irrigation by overhead sprinkling[21] in Southern California. However a comparison of these reports with the author's paper will indicate the change that sprinkler equipment has undergone. Tests of typical German and American sprinkler equipment in 1928 by the U. S. Department of Agriculture at the Arlington Experiment Farm under eastern conditions are also interesting.[22]

Many agricultural crops are now being successfully irrigated by portable sprinkling systems at reasonable cost, which was not deemed feasible years ago, and Mr. Christiansen's paper is a valuable contribution to engineering literature on this subject.

The writer agrees with the author's conclusions regarding evaporation losses. In the case of citrus fruits, losses by both surface evaporation and deep penetration below the root zone are unavoidable when water is applied so that the maximum tree growth is obtained. Tests made under the direction of the writer indicate that the efficiency of irrigation under the sprinkler method may not be greater than under surface irrigation. Conditions under which irrigation by sprinkling has an economic advantage over surface irrigation are those of steep or uneven topography. A higher efficiency

of irrigation can be maintained under such conditions than is possible with surface irrigation. Under sprinkler irrigation, surface runoff usually is a negligible factor if the water is properly applied.

The variations of efficiencies of irrigation under overhead sprinkling with light, medium, and heavy applications of water as determined from intensive soil moisture studies,[23] San Diego County, California, 1926, are shown in Table 3.

During the season of 1939 the Division of Irrigation, in cooperation with the Los Angeles Bureau of Water Works and Supply, conducted experiments on applying irrigation water with low-head sprinklers and by furrows. The average efficiency of irrigation under the sprinkler system was 49% and with the furrow method 47%. Two types of sprinklers were used with pressures varying from 8 to 18 lb per sq in.

J. E. CHRISTIANSEN,[24] ASSOC. M. AM. SOC. C. E. (by letter).—The interest shown in this paper is appreciated sincerely. Professor Pillsbury has contributed greatly to the subject, especially with respect to undertree sprinkler systems for orchards. Although the writer fully agrees with Professor Pillsbury's statements in regard to the conditions under which sprinkling is useful, he also believes that sprinkling will be satisfactory on most crops, and under most conditions, provided sufficient water is applied, at the proper rates. Exceptions are found in crops adversely affected by fungi or bacterial diseases; sprinkling may aggravate such trouble or make control more difficult. Grapes, a typical example, are not sprinkled because of mildew. Sprinkling is simply a method of irrigation in which the operator has good control over the water. If he applies the water at such a rate that the soil can absorb it, he can apply as little or as much as he wishes and can secure any depth of penetration desired.

The primary limitation is one of economics—that is, the cost of sprinkling as compared with other methods of irrigation. In general, sprinkling costs more; and unless the results, as measured by increased returns, are better, it cannot be considered economical. Since only 1% or 2% of the total irrigated area in California is sprinkled, evidently most farmers are either satisfied with their present methods, or do not believe that increased returns will compensate for higher costs.

Mr. Bither lists many advantages of sprinkling. An increased return resulting from one or another of these advantages will sometimes more than offset higher costs, but not always. One crop grown extensively in California that thrives under sprinkling is Ladino clover. Being shallow rooted, it requires rather frequent irrigation—that is, every week or 10 days for best results. Most of it is grown on rather poor, shallow, undulating soil, where extensive leveling is objectionable. It is generally irrigated by the border-strip flooding method, and considerable water is wasted. Nevertheless, thousands of acres of clover are grown profitably, mainly for fattening lambs, where the gross return averages about $25 per acre. This total gross return, however, would scarcely pay the cost of applying water with sprinklers; and so, although the production might be appreciably increased, sprinkling would apparently not be feasible. The economic phases of this subject do not seem pertinent in this paper and are covered in another report.[25]

[24] Irrig. and Drainage Engr., U. S. Regional Laboratory, U. S. Dept. of Agriculture, Riverside, Calif.

All the tests illustrated in Figs. 3 to 7 were made on sprinklers that have been replaced by later models. However, many tests on types now generally used indicate that the uniformity of application usually is no better than that produced by the pattern shown in Fig. 3. Furthermore, the new sprinklers are similarly affected by wind and to some extent by low pressure. They do rotate at a fairly steady, uniform rate and cannot be thrown out of adjustment so that they rotate rapidly. The uniformity of application of water by sprinklers is the subject of a paper published early in 1941.[26]

The logarithmic diagram (Fig. 11) for determining pressure losses in portable sprinkler lines is based upon coefficients slightly more conservative than those obtained from the field tests on sprinkler pipe. This diagram was prepared as a guide for designing sprinkler lines with all types of couplings. Although tests on several makes of lines indicate rather small differences in friction factors, some allowance was made for deterioration in carrying capacity caused by increasing roughness of the pipe with age. This allowance was very small as compared with standard engineering practices in designing pipe lines. The assumption that all sprinklers discharge equal quantities of water does not result in higher losses, provided proper friction factors are used and provided the total friction loss is not excessive. The writer recognizes the advantage of tables for the purpose mentioned. In this paper, however, tables would be impracticable because of the space required to cover the many combinations of pipe and sprinkler sizes in use.

In deriving Eq. 19 by the momentum treatment, Professor Powell does not consider the pressure difference on the upstream and downstream sides of the side outlet near the main pipe. Undoubtedly there is a zone of high pressure on the downstream side of the outlet pipe, and a zone of low pressure on the upstream side. Whether or not the net downstream thrust on the outlet pipe is sufficient to harmonize Eqs. 5 and 19 is not known. As Professor Powell states in private correspondence with the writer, the effect of this unequal pressure on the sides of the outlet pipe is to reduce the values of β_2 given in Table 2. It is surprising that such an intriguing problem in hydraulics has not been investigated more completely. The writer was concerned principally with the effect of the pressure recovery on the friction loss in the pipe. The friction factor f, computed on the basis of pressure and elevation difference at two points on a sprinkler line, with differences in velocity neglected, was found to remain rather constant for large differences in Reynolds' number. When corrections were made for the pressure recovery at each outlet, however, the customary relation between f and R was obtained. In other words, the pressure recovery at a side outlet increases the exponent of V to approximately 2 in an empirical formula for flow of water in pipes, the magnitude of the effect depending upon the spacing and number of outlets on the pipe. For this reason the Weisbach formula, with constant value for *f* of each pipe size, was used as a basis for the friction-loss diagram.

The writer thanks Mr. Blaney for emphasizing that sprinkling is not a new practice. Portable systems of the types now common, however, are relatively new; and their use has greatly extended the acreage irrigated by this method. As Mr. Blaney also states, sprinkling does not always increase irrigation efficiencies; many installations are very inefficient, mainly because of poor equipment, poor design of the system, and improper operation. In the writer's opinion, however, it is possible to obtain higher irrigation efficiencies by sprinkling than are generally possible by surface methods, although this is not always accomplished. Farmers seldom understand the hydraulics of sprinkler systems; and often some minor change in equipment or in methods of operation will improve the efficiency of the system materially.

PLASTIC THEORY OF REINFORCED CONCRETE DESIGN

By Charles S. Whitney,[1] M. Am. Soc. C. E.

With Discussion by Messrs. L. E. Grinter, Basil Sourochnikoff, R. W. Stewart, George C. Ernst, Homer M. Hadley, Robert W. Abbett, Paul Andersen, R. A. Caughey, Roberto Contini, A. A. Eremin, Jaroslav J. Polivka, Paul W. Abeles, O. G. Julian, and Charles S. Whitney.

Synopsis

It is the purpose of this paper to present a realistic method for the design of reinforced concrete members that should result in more efficient use of the materials. The theory of elasticity has proved satisfactory for the determination of the forces acting on the various sections of continuous frames or arches and much attention has been devoted to various methods of its application. The result has been a general extension of its use and a marked improvement in the understanding, by designers, of the action of reinforced concrete structures.

Corresponding progress has not been made in proportioning the members of a structure after the external forces have been determined. The theory of elasticity, as applied to design of sections, is too inflexible and inaccurate to be entirely satisfactory. The writer proposes the adoption of the plastic theory which recognizes the true characteristics of the material determined by research since the standard "straight-line theory" was adopted about a generation ago. The plastic theory takes into account the plasticity of the material and is in itself sufficiently "plastic" to be adjusted empirically to actual conditions. It has already been given recognition in the general adoption of the standard column formula, and the formulas proposed herein by the writer extend the same theory to beams, eccentrically loaded columns, and arch ribs. The equations are much simpler than the standard formulas and agree better with test results. They are based on the cylinder strength of the concrete and the yield strength of the steel without the use of modular ratio n. A number of

attempts[2,3,4] have been made since 1936 to eliminate the modular ratio, n, but none of them is as practical or as well adapted to American practice as that given herein. The writer has previously published parts of this theory,[5,6] but has now improved and extended the equations so that he hopes they may be recognized as forming a satisfactory basis for practical design and further research.

INTRODUCTION

There are three general steps in the design of an efficient structure:

(1) The determination of service conditions depending on the purpose and location of the structure, such as the nature and intensity of loading, the foundation conditions, and the exposure to deteriorating influences;

(2) The computation of the external forces to which the various sections of all the members will probably be exposed during the life of the structure; and

(3) The proportioning of the different parts of the structure so that the limits of their useful strength may be reached, but not exceeded, under the loading specified.

Step 1 leads an experienced designer to the selection of materials and a preliminary layout of the structure. It has been demonstrated by many investigations that, in the case of frames or arches of reinforced concrete, the external forces can be computed satisfactorily (Step 2) by means of the theory of elasticity, based on the assumption of direct proportionality of stress to strain. In spite of the plasticity of concrete this is true within the limits of the useful strength of the structure, except in some special cases where cracking at certain sections sufficient to cause redistribution of moments might not be detrimental. In such special cases, advantage might be taken of the increased strength due to redistribution of moments, but this must be done with caution.

A number of tests since about 1936[7] have shown that the maximum strength of a redundant structure is not determined by the first section to reach its maximum strength but by the combined strength of the redundant and primary members or sections, as explained in 1939 by J. A. Van den Broek,[8] M. Am. Soc. C. E.

Ordinarily, in reinforced concrete structures, the useful load limit of the structure occurs when the first section reaches its allowable limit, as determined by the permissible cracking or yielding of the concrete while the steel stress is still considerably below its yield point. For this reason, it is best to design the

structure so that, as nearly as practicable, all the sections involved may reach their allowable limits without exceeding them under the service loading.

Under such a condition, the theory of elasticity is the best guide to the forces acting on the different sections.[7] The probable redistribution of moments caused by yielding under higher loads than the design loads will effect the factor of safety of the structure against collapse and aid in the selection of the proper allowable limits of the strengths of the different sections.

The third step in the design is the proportioning of the different parts of the structure so that the limits of their useful strength may be reached but not exceeded under the loading specified. In dealing with a plastic material such as concrete, this limit can best be determined by a theory that recognizes its true characteristics. The plastic theory is based as closely as practicable on the actual behavior of concrete in combination with steel and makes possible the determination of the useful strength of concrete members with more accuracy than the present standard straight-line stress theory. The strength and reliability of the present-day concrete, and the detailed knowledge gained by practical research certainly justify a complete re-examination of the methods of design.

THE STRESS-STRAIN CHARACTERISTICS OF CONCRETE

The behavior of concrete under stress is extremely complex because it is influenced by combinations of so many variables that even under well-controlled conditions the prediction of true unit stress is not possible.

The classic conception of the stress-strain curve is that of a parabola with its lower part approximately straight and ending at the top tangent to the horizontal. The lower third of the curve being nearly straight, it formed the basis of the straight-line formula in which working stresses are used. The entire curve was used in the parabolic formula based on ultimate strength. Both of these formulas involve Young's modulus of elasticity of the concrete, which has been proved inaccurate by exhaustive research because the stress-strain relation is an indeterminate variable depending on the concrete, the manner and intensity of loading, and on time. Change in strain with time is due to plastic flow and shrinkage.

After years of extensive researches, R. E. Davis, M. Am. Soc. C. E., H. E. Davis, Assoc. M. Am. Soc. C. E., and Elwood H. Brown state that[9]

> "* * * it is not yet possible quantitatively to state with any degree of certainty what is likely to be the magnitude of either plastic flow or shrinkage under the conditions which surround any given concrete structure; nor is it possible quantitatively to state with accuracy what is the effect of plastic flow and shrinkage upon the magnitude and distribution of stresses."

It has been shown that deformations of stressed concrete change with time, and that stresses in a restrained member are greatly affected by plastic flow.[10] Even short-time measurements are affected by plasticity. On account of the variability of this stress-strain relation, it is not possible to determine the unit stresses at any particular point in the concrete member by measuring strains, except to a very limited degree.

---

[9] "Plastic Flow and Volume Changes of Concrete," by R. E. Davis, H. E. Davis, and Elwood H. Brown, *Proceedings*, A. S. T. M., Pt. II, Vol. 37, 1937, p. 318.

[10] "Plain and Reinforced Concrete Arches," by Charles S. Whitney, *Journal*, Am. Concrete Inst., March, 1932.

The modulus of elasticity of concrete used in design formulas is an empirical value assumed because it appeared to make them give satisfactory results. However, the results cannot be made entirely satisfactory, even by this method of choosing n.

An almost universal misconception of the behavior of concrete in flexure is the assumption that at maximum load the highest unit stress is at the outer surface. The descending branch of the compression stress-strain curve has been generally disregarded because it is difficult to measure and has been considered of no particular interest.

Fig. 1 shows some typical stress-strain curves for concrete cylinders selected from those measured in 1938 by O. G. Kiendl and J. A. Maldari.[11] It will be noted that the maximum stress occurs at a strain of approximately 0.002 in. per in., and that the failure does not occur suddenly but that the stress is reduced gradually as the strain continues to increase.

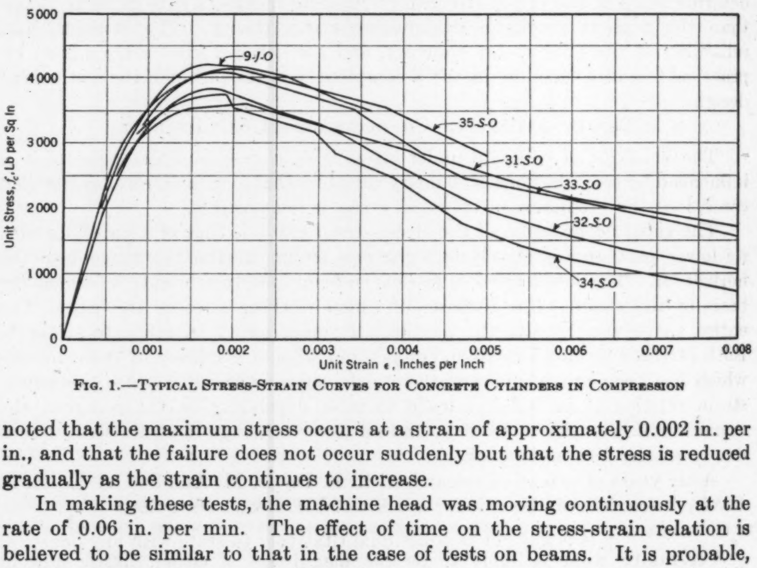

FIG. 1.—TYPICAL STRESS-STRAIN CURVES FOR CONCRETE CYLINDERS IN COMPRESSION

In making these tests, the machine head was moving continuously at the rate of 0.06 in. per min. The effect of time on the stress-strain relation is believed to be similar to that in the case of tests on beams. It is probable, therefore, that these curves indicate the form of compressive stress distribution in a beam at ultimate load in the concrete in the zone where the unit strain exceeds about 0.002 in. per in. In the case of a beam under partial load for a long time, plastic flow will modify the stress-strain relation so that the descending portion of the curve is perhaps of no significance. It is the writer's purpose in this paper to present a method of predicting ultimate strengths. No attempt will be made to determine actual stresses.

In considering the effect of the large strains occurring in a beam as the maximum load is approached it should be remembered that, under favorable circumstances, concrete strained beyond its point of maximum resistance will regain its strength after a rest.[12]

---

[11] "A Comparison of Physical Properties of Concrete Made of Three Varieties of Coarse Aggregate," a thesis by Oscar G. Kiendl and Joe A. Maldari, presented to the University of Wisconsin, Madison, Wis., in 1938, in partial fulfilment of the requirement for the degree of Bachelor of Science in Civil Engineering.

Because the straight-line formula applied to test results indicates that the concrete stress at maximum load in an over-reinforced beam is much higher (about 50%) than the cylinder strength, and because the maximum strain in the beam is much higher than that in the cylinder at maximum load, it has been concluded quite generally that the concrete does not behave the same in the beam and in the cylinders. Although there is undoubtedly some difference due to the shape of the unit and the distribution of stress, it will be shown that this difference may not be substantial and that the behavior in the compression side of the beam may be fully explained by the stress-strain characteristics of the cylinder.

It is obvious from a comparison of the different curves of Fig. 1 that even in controlled tests there are such great differences in the strains that no very refined theory can be justified. There are general characteristics, however, that form the basis of the plastic theory and indicate the form of the equations, leaving certain empirical constants to be determined by actual tests on beams. In this manner, simple formulas can be derived that have a more satisfactory theoretical basis than the present standard formulas and that give more accurate results.

The ideal stress-strain curve in Fig. 1 was derived from cylinder tests of concrete with a strength of about 4,000 lb per sq in. It has been proved that the strain in the compression side of a beam increases practically in direct proportion to the distance from the neutral axis. Therefore, the ideal curve to the left of any particular ordinate corresponding to the strain at the outer surface of the beam will represent the variation of unit compression stress in the concrete. If the strain in the steel is known, the location of the neutral axis and the resisting moment of the beam can be computed. The tension in the concrete will be neglected because the effect is small at high loads and the error is on the side of safety.

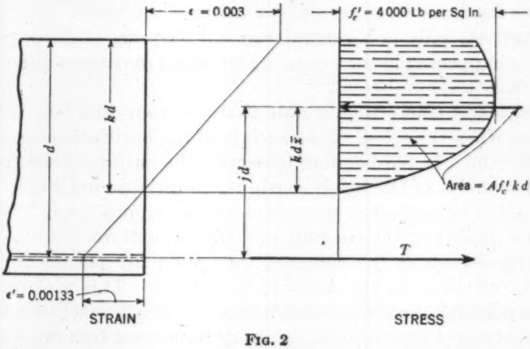

Fig. 2

---

[12] "Autogenous Healing of Concrete," by M. W. Loving, Assoc. M. Am. Soc. C. E., *Bulletin No. 13*, Am. Concrete Pipe Assoc., 1936; and "Autogenous Healing of Cement and Concrete," by Leslie Turner, London, International Assoc. for Testing Materials, April, 1937.

As an example, Fig. 2 shows the distribution of stress in the beam assuming a unit strain of $\epsilon = 0.003$ at the face of the concrete and $\epsilon' = 0.00133$ at the steel corresponding to a steel stress of 40,000 lb per sq in.

The computed value of k is $\frac{\epsilon}{\epsilon + \epsilon'} = 0.692$. By integrating the stress-strain curve from zero to the ordinate where the strain ϵ is 0.003, it is found that the area is $0.803\,\epsilon f_c'$ in which f_c' is the maximum concrete stress and ϵ is the maximum strain. Furthermore, the center of gravity of the area is $\bar{x}\,\epsilon = 0.571\,\epsilon$ from the origin. Applying this area to the depth of the beam above the neutral axis, substituting $k\,d$ for ϵ, the area represents the total compressive force in the beam; and it equals $C = 0.803 f_c'\,k\,d = 0.556 f_c'\,d$. Then the moment arm from the steel to the center of compression is $j\,d = d - k\,d\,(1 - 0.571) = 0.703\,d$. The bending moment for a unit width of beam is then:

$$M = 0.556 f_c'\,d \times 0.703\,d = 0.391 f_c'\,d^2 \ldots\ldots\ldots\ldots (1)$$

Corresponding values of moment have been computed for other concrete and steel strains (see Fig. 3(*a*)), using the formula

$$\frac{M}{f_c'\,b\,d^2} = k\,A\,(1 - k + k\,\bar{x}) \ldots\ldots\ldots\ldots (2)$$

in which

$$A = \frac{\int f_c\,d\epsilon}{f_c'\,\epsilon} \ldots\ldots\ldots\ldots (3a)$$

and

$$\bar{x} = \frac{\int \epsilon\,dA}{A\,f_c'\,\epsilon^2} \ldots\ldots\ldots\ldots (3b)$$

In these computations, the values of distance $\bar{x}$ and area A given in Fig. 3(*b*) were used, based on the ideal stress-strain curve. The maximum ordinates in Fig. 3(*a*) give the maximum resisting moments of the beam. They are significant quantitatively only in a general way but they are of great value in indicating what is happening in the beam. The actual maximum value can best be determined from tests on beams.

It is particularly interesting to note that the maximum bending moment is not developed when the stress at the surface of the beam reaches the maximum cylinder strength. As the bending increases, the surface stress decreases but the resisting moment of the beam continues to increase until the strain at the surface is roughly twice that of the cylinder at maximum load. This ratio will vary with the quality of the concrete and the steel strain.

These large strains in the concrete are principally plastic and result in a redistribution of stress as the moment is applied. This yielding brings the center of the compressive stress much nearer the tensile steel than indicated by the standard straight-line formula. A very important feature of this redistribution of stress is that it apparently does not affect the fatigue limit of the beam adversely. Tests made by J. L. Van Ornum,[13] M. Am. Soc. C. E., on heavily reinforced beams that failed in compression showed that the fatigue limit at which beams failed under repeated loading was between 50% and 60% of the static strength and practically the same percentage as the fatigue limit of cylinders under repeated compression. The strength of the beams under 1,000 repetitions was about 70% of the static strength.

---

[13] "The Fatigue of Concrete," by J. L. Van Ornum, *Transactions*, Am. Soc. C. E., Vol. LVIII, June, 1907, p. 294.

Referring to the ideal curve in Fig. 3, it will be seen that a moment of 50% of the ultimate may produce initially a stress greater than 80% of the cylinder strength. It might be expected that a repetition of such load would cause failure, but the plasticity of the concrete at such a high stress causes a readjustment before failure takes place. This is important because it indicates that although the stress in the outer portion of the beam may be higher than the fatigue limit as shown by cylinders, there is a redistribution of stress in the beam so that the fatigue limit of the beam is more than 50% of the ultimate static strength of the beam.

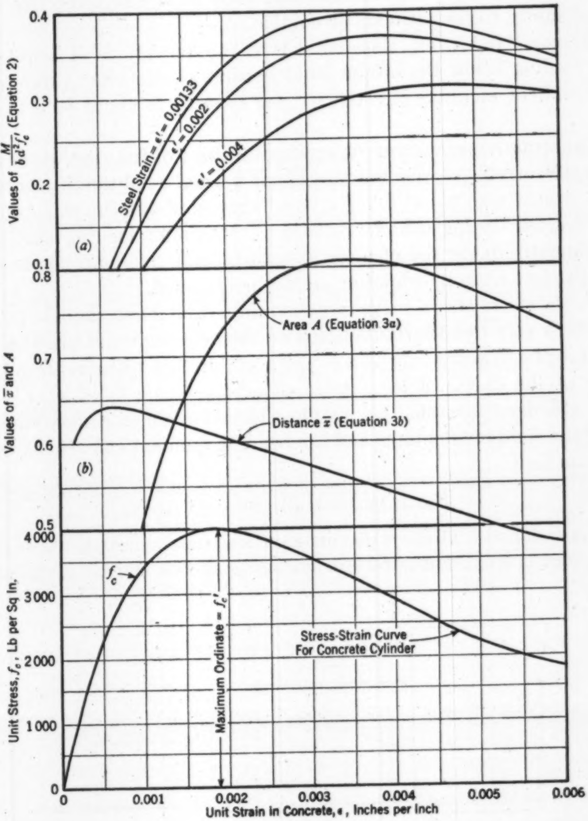

Fig. 3

It has been proved that plastic flow is approximately proportional to stress at low stresses, but for higher stresses the plastic strain increases much more rapidly than the stress.[14] This is to be expected from the shape of the ordinary stress-strain curve.

It is obvious that if the fatigue limit is a reasonably definite percentage of the ultimate strength, the ultimate strength is itself a better measure of the useful strength of the beam than is the unit stress calculated by the standard straight-line formula based on an arbitrary value of the modulus of elasticity. The useful strength can then be determined most effectively by applying a factor of safety to the ultimate strength.

Professor Van Ornum also found that the deflections of beams under repeated loading below the fatigue limit became elastic after a number of repetitions, and the modulus of elasticity was reduced to about 80% of the initial value.

No information is at hand regarding the effect of full reversal of loading on heavily reinforced sections, but this is not a usual condition in concrete structures. Beams with about 0.3% of steel showed about the same fatigue limit under reversed loading as under repeated. Maximum loading conditions occur so infrequently in the life of most structures that this may not be important ordinarily; but more information should be obtained.

Since the stress-strain curves are so variable and indeterminate (as indicated by Fig. 1), a very exact formula based on this relation is not practical. Fortunately it is practicable to derive a simple formula that will give the approximate location of the center of the compression force more satisfactorily than the present standard formula. A simple expression for the maximum limiting value of the compression force and the bending moment can also be determined from beam tests.

RECTANGULAR BEAMS AND SLABS

If it is assumed that the stress distribution in a concrete beam at failure has the shape of the cylinder stress-strain curve shown in Fig. 4, the total compression, C, is the area bounded by the curve. The line of action of C lies through the center of gravity of this area. From an examination of the ideal stress-strain curve in Fig. 3, it is found that, if the actual area is replaced by an equivalent rectangular area of width equal to $0.85 f_c'$ and depth equal to a (as shown in Fig. 4), the location of the center of gravity of this rectangle corresponds closely with that of the actual area.

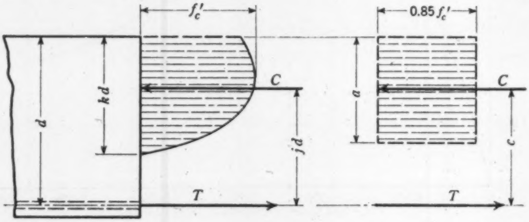

FIG. 4

---

[14] "Short-Time Creep Tests of Concrete in Compression," by R. S. Jensen and F. E. Richart, M. Am. Soc. C. E., *Proceedings*, A. S. T. M., Pt. II, Vol. 38, 1938, p. 417.

In other words, the actual irregular stress block is replaced for simplicity with a rectangular stress block of equal size that has an average stress intensity equal to $0.85 f_c'$. This does not mean that this method is based on the assumption of rectangular stress distribution. The use of the rectangle is merely a mathematical device to approximate the effect of the true distribution. It would be possible to use any curved shape that would give the same area and center of gravity, but the rectangular area appears to be entirely satisfactory and gives the simplest possible mathematical solution. This conception forms the basis of all the following formulas, and they give good agreement with tests. The assumption of a concrete stress equal to $0.85 f_c'$ corresponds to the actual strength in columns and permits a consistent treatment through the full range from pure flexure (eccentricity $e = \infty$) to axial load ($e = 0$).

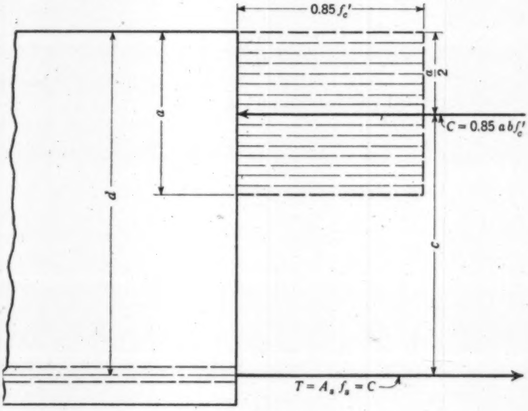

FIG. 5

It should be noted that the depth a does not correspond with the depth to the neutral axis, $k d$, and it bears no definite relation to it. The value of $k d$ is determined by the strains at the top and bottom of the beam but a is determined by the strengths of the materials.

For practical purposes, the action of the beam may now be described as follows (see Fig. 5):

If the beam is under-reinforced so that the primary failure will occur in the tensile steel, the concrete will crack as the steel stretches, and the equivalent depth of the beam in compression, a, will decrease until the average effective concrete stress reaches the maximum. The concrete will then fail progressively, reducing the lever arm of the steel and causing failure of the beam.

Therefore[14b]:

$$a = \frac{A_s f_s}{0.85\, b f_c'} = \frac{A_s m}{b} \qquad (4a)$$

or

$$\frac{a}{d} = p\, m \qquad (4b^*)$$

[14b] Equation Nos. marked with an asterisk (*) indicate essential design formulas.

in which: A_s = area of tensile steel; f_s = yield point stress of steel (or in the case of steel without a definite yield point, the stress producing a total unit strain equal to 0.004 in. per in.); b = width of beam; f_c' = standard concrete cylinder strength; the steel percentage is

$$p = \frac{A_s}{b\,d} \quad \text{(5a)}$$

and

$$m = \frac{f_s}{0.85\,f_c'} \quad \text{(5b)}$$

The lever arm of the steel reinforcement is then

$$c = d - \frac{a}{2} = d - \frac{A_s\,m}{2\,b} \quad \text{(6a)}$$

or

$$\frac{c}{d} = 1 - \frac{p\,m}{2} \quad \text{(6b*)}$$

The ultimate resisting moment of the beam as controlled by steel failure can be written:

$$M = c\,A_s f_s = A_s f_s \left(d - \frac{A_s\,m}{2\,b} \right) \quad \text{(7a)}$$

or

$$\frac{M}{b\,d^2} = p\,f_s \left(1 - \frac{p\,m}{2} \right) \quad \text{(7b*)}$$

Also, for under-reinforced beams,

$$M = 0.85\,f_c'\,a\,b \left(d - \frac{a}{2} \right) \quad \text{(8)}$$

from which

$$\frac{a}{d} = 1 - \sqrt{1 - \frac{2.35}{f_c'} \frac{M}{b\,d^2}} \quad \text{(9a*)}$$

and

$$\frac{c}{d} = \frac{1}{2} \left(1 + \sqrt{1 - \frac{2.35}{f_c'} \frac{M}{b\,d^2}} \right) \quad \text{(9b*)}$$

The foregoing expressions are extremely simple and are independent of n. It should be noted that all of the equations in this paper apply only to ultimate load conditions and are not intended to predict stresses under working loads.

The required steel area is

$$A_s = \frac{M}{c\,f_s} \quad \text{(10*)}$$

In case the moment is less than that required to cause a primary compression failure in the concrete, from Eq. 7b

$$p = \frac{1}{m} - \sqrt{\frac{1}{m^2} - \frac{2}{f_s\,m} \frac{M}{b\,d^2}} \quad \text{(11*)}$$

The limiting value of the depth of equivalent compression, a, for equal concrete and steel strengths in flexure can best be determined experimentally. If there is at least sufficient steel to fully develop the strength of the concrete, additional steel does not materially increase the strength of the beam.

The limiting value of $\frac{a}{d}$ computed from tests reported by Inge Lyse, and the late W. A. Slater,[15] Members, Am. Soc. C. E., is given in Table 1. Eliminating four groups of beams that appear erratic, the mean value of $\frac{a}{d}$ is 0.537 and $\frac{c}{d}$ is 0.732. The corresponding ultimate resisting moment is given by the expression

[a] These values not included in average.

$$\frac{M}{b\,d^2} = 0.85\,f_c'\,\frac{a}{d}\left(1 - \frac{a}{2\,d}\right) = \frac{f_c'}{3} \quad \text{(12*)}$$

For comparison, Table 1 gives the maximum moment for the test beams as computed from the American Concrete Institute (A.C.I.) formula and from the parabolic formula[16] using the measured value of n. The standard deviation is practically the same in the three cases indicating that there is no advantage in using a formula involving n.

Fig. 6 shows the value of $\frac{M}{b\,d^2\,f_c'}$ given by 36 beams tested by Professors Slater and Lyse,[17] and 33 beams tested by the late Richard L. Humphrey, M. Am. Soc. C. E., and Louis H. Losse[18] which had sufficient steel to cause a primary compression failure. The Humphrey beams, with stronger concrete, were not included because there was not sufficient reinforcement to develop such high concrete strength fully although they may have been reported as compression failures.

[17] *Loc. cit.*, p. 850.

[18] "The Strength of Reinforced Concrete Beams," by Richard L. Humphrey and Louis H. Losse, *Technological Paper No. 2*, National Bureau of Standards, 1912.

Confusion no doubt exists because it is difficult to differentiate between primary steel or concrete failures unless the steel percentage is considerably less than the critical required to develop full concrete strength. The difference cannot be detected by measuring the maximum strain in the concrete as it may be as large in either case. A slight stretching of the steel will reduce the concrete compression area and will cause, in an under-reinforced beam, what appears like a concrete compression failure.

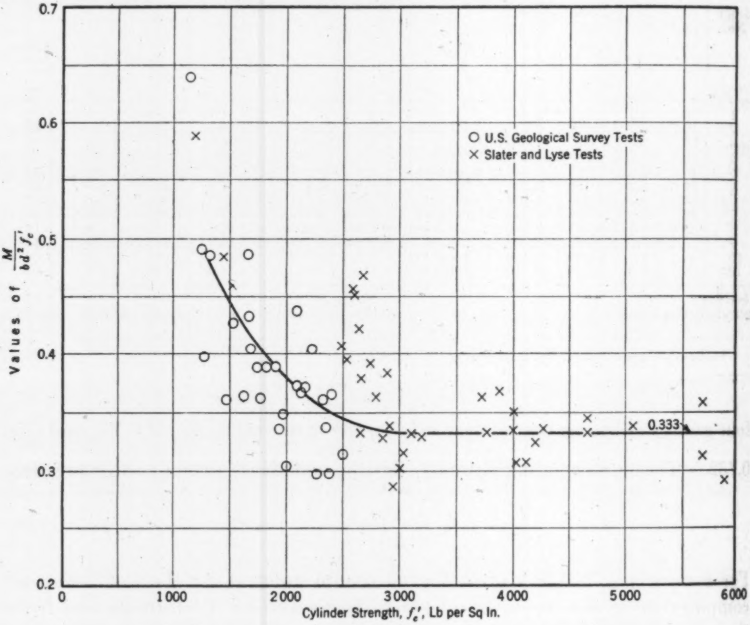

FIG. 6.—VALUE OF $\frac{M}{b\,d^2 f_c'}$ FROM TESTS OF BEAMS

The value of $\frac{M}{b\,d^2 f_c'}$ shown in Fig. 6 is unaffected by the concrete strength between 3,000 and 6,000 lb per sq in., although it rises about 50% for weaker concretes from 3,000 to 1,000 lb per sq in. With present methods and materials it is not probable that structural concrete will have a strength less than 2,500 or 3,000 lb per sq in., and if a weaker concrete is used, a greater factor of safety is appropriate. Therefore, it appears that a value of 0.333 for $\frac{M}{b\,d^2 f_c'}$ can be used generally.

The critical percentage of steel required to develop the full compressive strength of the concrete is (see Eq. 4):

$$p_0 = \frac{0.537}{m} = 0.456\frac{f_c'}{f_s} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13^*)$$

For beams with less steel, the allowable bending moment is given by Eq. 7. Table 2 shows the results of the application of Eq. 7 to 72 beams of the series

[a] Three beams each item.

[b] Determined by concrete strength, Eq. 12.

tested by Messrs. Humphrey and Losse[18] except Item 21 for which Eq. 12 controls because of low-concrete strength. The average ratio of actual maximum moment to that given by Eq. 7 is 1.071 to 1. Eliminating the low-strength cinder concrete beams (Table 2(*d*)), the ratio is 1.062 to 1. Classified according to age, the ratio is 1.052 to 1 at 4 weeks, and 1.09 to 1 at 52 weeks.

According to percentage of steel, it is 1.117 for $p = 0.0049$, 1.054 for $p = 0.0098$, and 1.042 for $p = 0.0196$, showing the increasing influence of the tension in the concrete as the percentage of steel is reduced. There appears to be no correlation between the modulus of elasticity of the concrete and the accuracy of Eq. 7.

The value of the steel lever arm, $\frac{c}{d}$, from Eq. 6 shows a substantial improvement over the j-value given by the standard formula. This is clearly shown by the aforementioned tests.[17, 18] The general trend of the comparative values is shown in Table 3 computed for different percentages of steel in a beam with 3,000 lb per sq in. concrete and 50,000 lb per sq in. yield point steel. It will be noted that, for the smaller percentages of steel, $\frac{c}{d}$ is larger than j and this increase is fully justified by the Humphrey tests. As the percentage of steel increases to more than that commonly used, $\frac{c}{d}$ becomes subtantially smaller than j. The importance of this reduction is shown in the tests by Messrs. Slater and Lyse[15] who reported that the steel stresses at failure of the beams were considerably higher than the theoretical values. Table 4 gives a comparison for four series of beams for which strains were measured close to the ultimate load. The values of j at failure have been estimated from the observed values. It is seen that the actual j was much lower than the theoretical and corresponds very well with $\frac{c}{d}$ as given by Eq. 6.

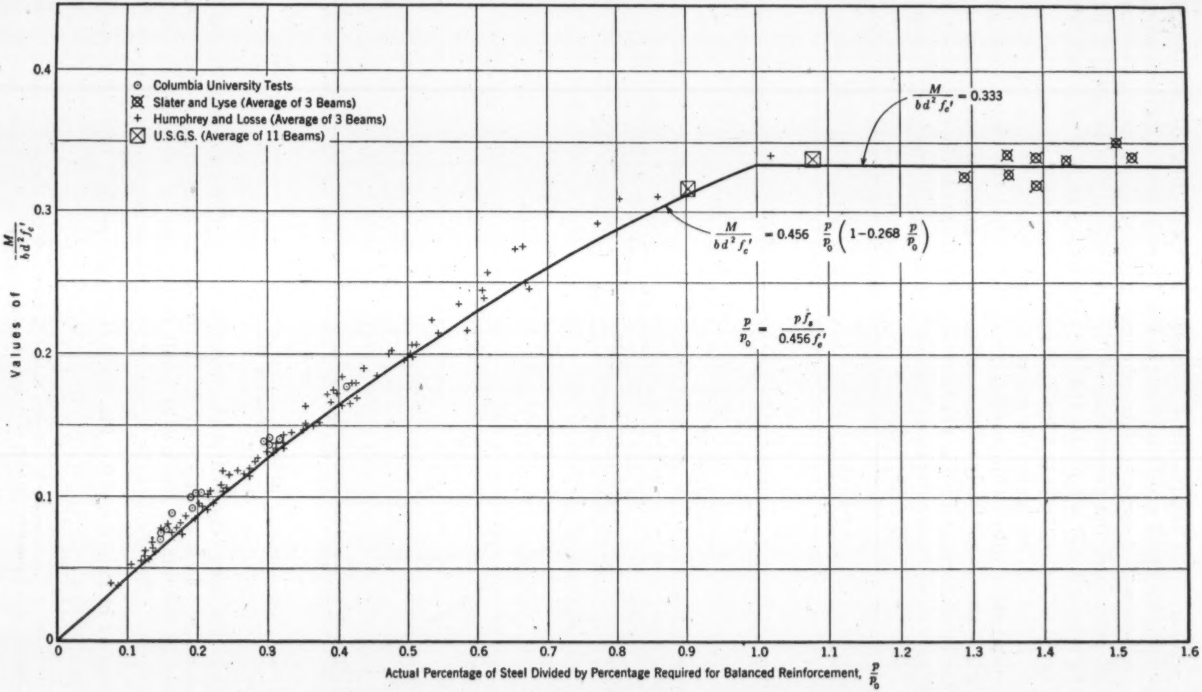

FIG. 7.—COMPUTED ULTIMATE STRENGTH OF CONCRETE BEAMS COMPARED WITH THE RESULTS OF 309 TESTS

A comparison of the results of 309 beam tests with the ultimate strength values given by Eqs. 7 and 12 is shown in Fig. 7 (see Appendix for description). Only well-controlled series of tests have been included and European tests are omitted because of the uncertainty of the translation of cube strength into cylinder strength. It is probable that the cylinder is a more satisfactory index of strength of the concrete in a beam or column than is the cube.

Eq. 7 does not recognize the excess strengths that have been reported in beams and slabs with small percentages of steel,[19] but the use of small percentages of steel is not likely to be as satisfactory in practical construction as it is in the laboratory, and it has not been demonstrated that the excess strength will not disappear under repeated loading. Considerable cracking of slabs in buildings has been observed in the past few years. This is evidently due to shrinkage and lack of plasticity in the relatively high-strength and rapid-hardening concrete, so the use of small percentages of steel should not be encouraged. The effect of the foregoing formulas on rectangular beam design is indicated in Figs. 8 and 9. Fig. 8 shows the allowable $\frac{M}{b\,d^2}$ given by Eqs. 7 and 12 for different values of p with a factor of safety of $2\frac{1}{2}$ as compared with

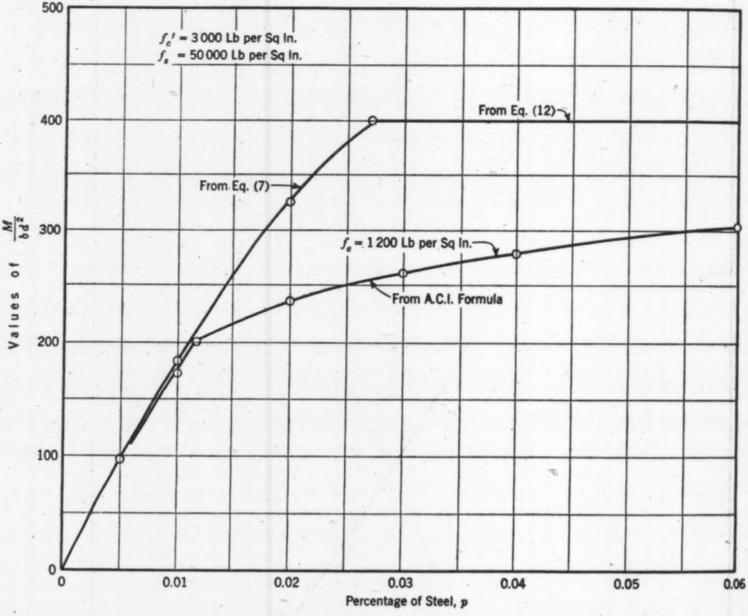

FIG. 8.—COMPARISON OF RESISTING MOMENT OF RECTANGULAR BEAMS COMPUTED FROM VARIOUS FORMULAS

the standard formula of the American Concrete Institute when $f_c' = 3{,}000$ lb per sq in. and $f_s = 50{,}000$ lb per sq in. The new formulas raise the critical percentage of steel from 0.0113 to 0.0273, and the allowable $\frac{M}{b\,d^2}$ from 197.5 to 400.

---

[19] "A Study of Reinforcement in Concrete Slabs," by Inge Lyse and George R. Wernisch, *Journal*, Am. Concrete Inst., September–October, 1936, p. 1.

Fig. 9 is a universal design diagram giving values of $\frac{M}{b\,d^2}$ and p for all grades of concrete and steel. The advantage of the simplicity of the basic formulas is obvious, and since the equations conform so well to tests covering the full range of steel and concrete strengths used in practice, there appears to be no reason that they should not be used for design.

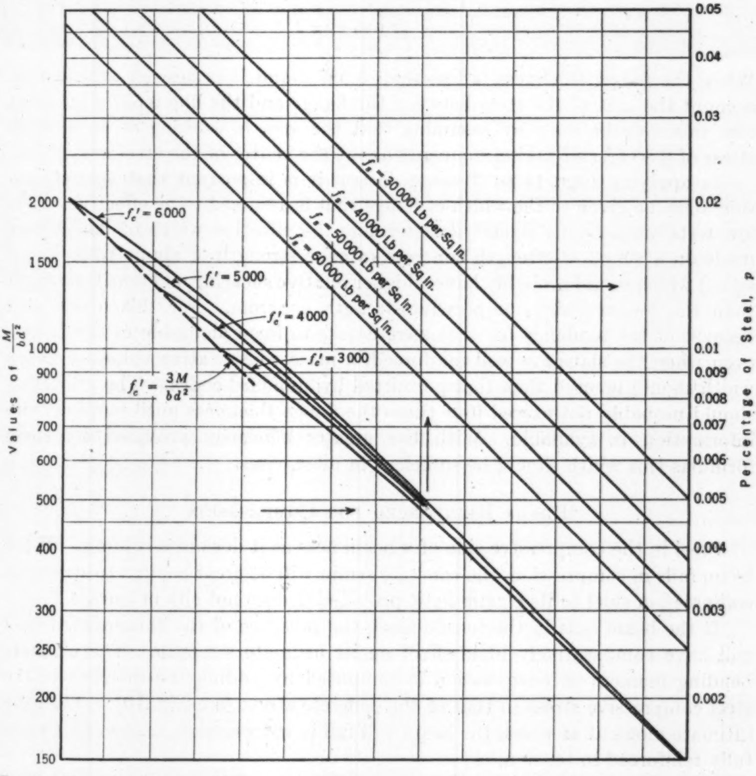

FIG. 9.—ULTIMATE BENDING MOMENT AND PERCENTAGE OF STEEL FOR RECTANGULAR BEAMS, BASED ON EQS. 7 AND 12

DESIGN OF T-BEAMS

The foregoing formulas for rectangular beams (Eqs. 7 and 12) can be directly applied to T-beams when the depth of compression, a, does not exceed the flange thickness t. For larger moments, when t is less than 0.537 d, it can be assumed that the entire flange area is working at an average stress of 0.85 f_c' with the resultant at the center depth of the flange. Then the ultimate moment is given by

$$\frac{M}{b\,d^2} = 0.85\,f_c'\left(1 - \frac{t}{2\,d}\right)\frac{t}{d} \tag{14a*}$$

and

$$A_s = \frac{M}{f_s\left(d - \frac{t}{2}\right)} \tag{14b*}$$

When the flange thickness is less than 0.537 d and it is desired to take into account the area of the stem between the flange and the line 0.537 d from the top, this may be done by assuming that the area is working at an average stress of 0.85 f_c' and taking moments about the center of the steel area.

In applying Eqs. 14 to T-beam design, it is important that special consideration be given to the width of flange that is assumed to be effective. The few tests made by C. Bach[20] to determine the effective width of flange were made on a very low-strength concrete (a cube strength of about 1,700 lb per sq in.) which would probably have a higher relative shearing and tensile strength than the modern high-compressive-strength concrete. For this reason and because of the tendency for shrinkage cracks to form alongside of the beams, even when the slabs are well reinforced, a more conservative value for flange width should be used than that permitted by standard codes. The projection should probably not exceed four times the flange thickness until more definite information is available. With the greater efficiency provided by these formulas this width should be sufficient in most cases.

Beams Reinforced for Compression

Steel in the compressive side of a beam acts as it does in a column. If the beam fails in compression, the concrete strain will be great enough to stress the compression steel to its elastic limit provided it does not slip or buckle.

If the beam fails in the tensile steel, the presence of the compression steel will have comparatively little effect on its ultimate strength. The ultimate bending moment in compression is computed by adding the moment of the steel compressive stress to that of the concrete stress (see Fig. 10). Then the ultimate moment at which the beam will fail in compression, assuming it to be fully reinforced in tension, is

$$M = \tfrac{1}{3}\,b\,d^2 f_c' + d'\,A_s'\,f_s \tag{15a*}$$

or

$$\frac{M}{b\,d^2} = \frac{f_c'}{3} + \frac{d'}{d}\,p'\,f_s \tag{15b*}$$

in which A_s' is the area of the compression steel, and d' is its lever arm. If the yield point of the compressive steel has a value of f_s' different from f_s, it can be taken into account in the equation by changing the value of A_s' used in Eq. 15a to the value of $\frac{f_s'}{f_s} A_s'$ without changing the equation. This applies to all equations involving compressive steel.

---

[20] "Versuche mit Eisenbetonbalken," von C. Bach and O. Graf, *Mitteilungen über Forschungsarbeiten auf dem Gebiete des Ingenieurwesens*, Heft 90 and 91, Berlin, 1910.

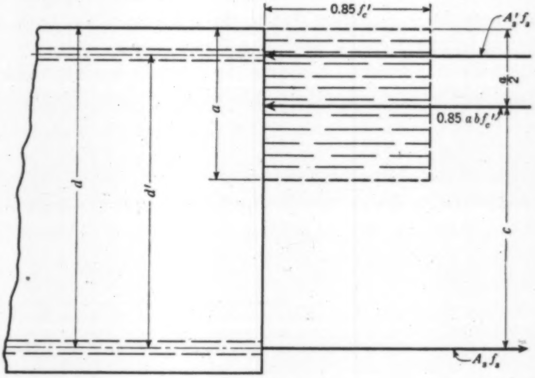

FIG. 10

When the beam is under-reinforced in tension, the lever arm of the tensile steel can be computed as if the compressive steel is stressed to its elastic limit and the remainder of the compression is on the concrete. The calculation is made as if the tensile steel were in two parts, one to balance the compressive steel and the other to balance the stress on the concrete. The ultimate tensile moment is then

$$M = d' A_s' f_s + (A_s - A_s') \left[d - \frac{(A_s - A_s') m}{2 b} \right] f_s \ldots\ldots (16^*)$$

or

$$\frac{M}{b d^2} = \frac{d'}{d} p' f_s + (p - p') \left[1 - \frac{(p - p') m}{2} \right] f_s \ldots\ldots\ldots (17^*)$$

and the tensile steel required is

$$p = p' + \frac{1}{m} - \sqrt{\frac{1}{m^2} - \frac{2}{f_s m} \frac{M - d' A_s'}{b d^2}} \ldots\ldots\ldots\ldots (18^*)$$

Eqs. 16 and 17 assume that A_s is greater than A_s'. If A_s' is the greater, the lever arm of the tensile steel can be taken as d' and Eq. 16 becomes:

$$M = d' A_s f_s \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

Eqs. 15 to 18 have been checked against the results of tests with satisfactory agreement provided that failure is not caused by shear or bond. The results of tests of beams with compressive steel made by C. Bach and O. Graf at Stuttgart, Germany, and reported by Fritz von Emperger[21] are of interest because they show the danger of bond failure. The full yield point stress of 35,000 lb per sq in. was developed in compression, but with bars of 60,000 lb per sq in. yield point the failure was in bond before the full strength was developed.

---

[21] "Handbuch für Eisenbetonbau," by Fritz von Emperger, Vol. 1, 3d Ed., p. 225.

Tests made with twin twisted bars in the compression side of beams[22] indicate that, because of buckling due to the twisting of the bars, they are not as fully effective in compression as they are in tension.

It is extremely important, of course, to provide against failure by bond, shear, and buckling in highly reinforced beams.

Flexure and Direct Load on Rectangular Sections

The strength of the compression side of the section will be the same when the member is subjected to bending and direct load as it is under flexure alone. Therefore, Eq. 15*a* can be used to predict the resistance to compression failure of an eccentrically loaded rectangular section.

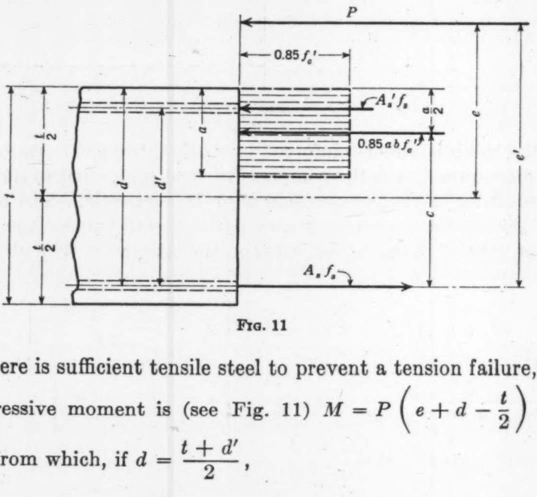

Fig. 11

When there is sufficient tensile steel to prevent a tension failure,[23] the ultimate compressive moment is (see Fig. 11) $M = P\left(e + d - \frac{t}{2}\right) = \frac{1}{3}bd^2f_c' + d'A_s'f_s$ from which, if $d = \frac{t + d'}{2}$,

$$P = \frac{2A_s'f_s}{\frac{2e}{d'} + 1} + \frac{btf_c'}{\frac{3te}{d^2} + \frac{6dt - 3t^2}{2d^2}} \quad \ldots\ldots\ldots\ldots\ldots (20^*)$$

Eq. 20 gives the theoretical value when the eccentricity of the load is greater than the eccentricity of the resisting forces in the compression side of the section. Because of its derivation it has no theoretical meaning for smaller eccentricities but it can be adjusted to the smaller range by making *P* approach the proper value for an axially loaded column as *e* approaches zero. The first term giving the steel strength needs no adjustment because it equals $2\,A_s'f_s$ when e equals zero. It is known that the concrete strength is $0.85\,b\,t\,f_c'$ for axial load so the second term becomes $\dfrac{b\,t\,f_c'}{\dfrac{3\,t\,e}{d^2} + 1.178}$, and with this change, Eq. 20 becomes:

---

[22] "Versuche über Zielsichere Betonbildung und an druckbewerten Balken," by Rudolf Saliger, *Beton und Eisen*, January 20, 1935.

[23] "Plain and Reinforced Concrete Arches," Report of Committee 312, by Charles S. Whitney, Chairman, *Proceedings*, Am. Concrete Inst., September, 1940.

$$P = \frac{2\,A_s'f_s}{\dfrac{2\,e}{d'} + 1} + \frac{b\,t\,f_c'}{\dfrac{3\,t\,e}{d^2} + 1.178} \ldots\ldots\ldots\ldots\ldots\ldots (21^*)$$

which gives the strength of the rectangular member as controlled by compression strength. Eq. 21 gives values which agree satisfactorily with tests, as will be shown subsequently.

The formula for the strength of the member as controlled by ultimate tensile strength of the steel for the larger eccentricities will now be derived. If the member is over-reinforced on the compression side so that the compression steel is sufficient to take the total compression force without help from the concrete, the value of the ultimate load can be expressed by taking moments, and

$$P = A_s f_s \frac{2\,d'}{2\,e - d'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22^*)$$

When there is not sufficient compression steel to take all the compression force, it may be assumed for practical purposes that both the tension and compression steel will be stressed to the yield point at ultimate load, and the remainder of the compression load on the section acts on the compression side of the concrete over an equivalent depth equal to a. This total compression on the concrete is then $0.85\,a\,b\,f_c'$ and it follows that $P + A_s f_s = A_s' f_s + 0.85\,a\,b\,f_c'$ or, $0.85\,a\,b\,f_c' = P + (A_s - A_s')\,f_s$ and $a = \dfrac{P}{0.85\,b\,f_c'} + (A_s - A_s')\,\dfrac{m}{b}$, in which $m = \dfrac{f_s}{0.85\,f_c'}$.

Then taking moments about the tension steel,

$$M = P\left(e + \frac{d'}{2}\right) = d'A_s'f_s + 0.85\,f_c'\,a\,b\left(\frac{d'}{2} + \frac{t}{2} + \frac{a}{2}\right) \ldots\ldots (23)$$

Substituting the previous values and solving for P, we find: $P = 0.85\,t\,b\,f_c' \times$

$$\times\left\{\sqrt{\left[\frac{e}{t} - 0.5 + (p - p')\,m\right]^2 + \frac{2\,d'}{t}\,p'\,m + (p - p')\,m\left[\frac{d'}{t} + 1 - (p - p')\,m\right]}\right.$$

$$\left. - \left[\frac{e}{t} - 0.5 + (p - p')\,m\right]\right\} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24a^*)$$

For the symmetrical reinforcement, when $p = p'$, this reduces to

$$P = 0.85\,t\,b\,f_c'\left\{\sqrt{\left(\frac{e}{t} - 0.5\right)^2 + \frac{d'}{t}\,p_t\,m} - \left(\frac{e}{t} - 0.5\right)\right\} \ldots (24b^*)$$

in which, $p_t = p + p' = \dfrac{A_s + A_s'}{b\,t}$. When there is no compressive steel, $p' = 0$ and the ultimate load equals

$$P = 0.85\,t\,b\,f_c' \left\{ \sqrt{\left(\frac{e}{t} - 0.5 + p\,m\right)^2 + \left(\frac{d'}{t} + 1 - p\,m\right) p\,m} - \left(\frac{e}{t} - 0.5 + p\,m\right) \right\} \ldots\ldots (24c^*)$$

On account of the assumption that the steel on the side of the column away from the load is in tension, Eqs. 24 have no significance when e is very small. That case is covered by Eq. 21.

When the value of $\frac{e}{t}$ is large, it is difficult to obtain satisfactory accuracy in solving Eqs. 24 with a slide-rule. Formulas can be derived in another form to cover the same case in the same manner as Eqs. 16 and 17. This can be done most conveniently in terms of e', the eccentricity measured from the tensile steel.

Assuming the compressive steel to be working at yield-point stress, the percentage of tensile steel required to balance it will be $A_s'\left(1 - \frac{d'}{e'}\right)$. Subtracting this quantity from A_s, the percentage of tensile steel that is dependent on the development of compression in the concrete for its fulcrum to work against is determined. The value of P that can be resisted by these two portions of the tensile steel can be written and combined as follows:

$$P = f_s \left[A_s - A_s' \left(1 - \frac{d'}{e'}\right) \right] \frac{\beta}{e' - \beta} + \frac{d'}{e'} A_s' f_s \ldots\ldots (25^*)$$

in which

$$\beta = \frac{1}{2} \left\{ d + e' - \sqrt{(e' - d)^2 + \frac{2\,e'\,m}{b} \left[A_s - A_s' \left(1 - \frac{d'}{e'}\right) \right]} \right\}$$

When the reinforcement is symmetrical, $A_s' = A_s$ and Eq. 25 reduces to

$$P = \frac{2\,d'\,A_s\,f_s}{e' - d + \sqrt{(e' - d)^2 + \dfrac{2\,d'\,A_s\,m}{b}}} \ldots\ldots (26a^*)$$

When there is no compression steel $A_s' = 0$ and this becomes

$$P = A_s\,f_s \frac{e' + d - \sqrt{(e' - d)^2 + \dfrac{2\,e'\,A_s\,m}{b}}}{e' - d + \sqrt{(e' - d)^2 + \dfrac{2\,e'\,A_s\,m}{b}}} \ldots\ldots (26b)$$

Tables 5 and 6 compare the values of ultimate load given by Eqs. 21 to 26 with the actual loads found in several series of tests by Messrs. Bach and Graf,[24] F. E. Richart and T. A. Olson,[25] and A. G. Hayden,[26] M. Am. Soc. C. E. In the case of the Bach and Graf tests (Table 5), it was necessary to translate the cube strength into cylinder strength, and it is assumed the strength of the 30 cm cube per sq in. is 1.13 times that of the standard 6-in. by 12-in. cylinder.[27]

[a] Two tests each; all other determinations based on three tests each.

The Bach and Graf tests (Table 5) show very close agreement with the formulas for the full range, with the actual strengths slightly larger in all cases. They were made on 49 columns about 16 in. square with an equivalent cylinder strength of 2,830 lb per sq in. The steel had yield strengths of 53,700 lb per sq in. and 50,900 lb per sq in. with p equal to 0.005 and 0.0095, and p' equal to zero, 0.005, and 0.0095. The tests therefore covered a very significant range. The details of the sections, and the agreement between the actual and theoretical strengths, have been presented elsewhere.[28]

The Richart and Olson tests (Table 6(*a*)) on knee frames[25] show excellent agreement with the exception of No. 9 which had about 3% of tensile steel and failed at about 85% of the load given by Eq. 26*b*. Cracks formed before failure parallel to the compression face at the knee, indicating that it may have been caused by high shearing stresses due to the sharp curvature of the line of compression stress around the angle of the knee. The other frames with about 1% of steel failed primarily in tension and indicated no weakness in compression due to the concentration of stress at the knee when the ordinary percentage of reinforcement is used. More information is needed regarding the knee effect with higher steel percentages.

[a] In Col. 6, e' is measured perpendicular to the axis of the leg of the member. [b] Average of two frames. [c] $P\sqrt{2}$. [d] Possible shear failure. [e] Part (*a*) refers to footnote 25; and part (*b*) refers to footnote 26.

Eqs. 21 to 26 give the ultimate strengths of rectangular members for the full range of conditions from axially loaded columns to beams under flexure alone. Since it is customary to provide a greater factor of safety for axially loaded columns than for beams, it is necessary to modify some of these formulas for use in design. Without changing their form they can easily be adjusted to any desired combination of beam and column factors of safety.

For instance, in the case of the compression control Eq. 21, it would be reasonable to assume that the factor of safety should vary from that now provided by the present standard formula for axially loaded columns to $2\frac{1}{2}$ for the case of pure bending. When plotted with P as ordinate and $P\,e$, as abscissa, Eq. 21 is a straight line, and it can be adjusted by lowering the y-axis intercept to any desired point.

The standard formula for the axially loaded column is

$$P = 0.4\, A_{st}\, f_s + 0.225\, A_c\, f_c' \quad \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

in which A_{st} is the total area of longitudinal steel; and A_c = area of concrete in compression. Eq. 21 can be adjusted so that P will be $2\frac{1}{2}$ times this value when e is zero and it then becomes

$$P = \frac{2\, A_s'\, f_s}{\frac{2\, e}{d'} + 1} + \frac{A_c\, f_c'}{\frac{3\, t\, e}{d^2} + 1.775} \quad \ldots\ldots\ldots\ldots\ldots\ldots (28^*)$$

Eq. 28 can be used as an ultimate strength formula and will provide the desired variation in factor of safety. The relation between Eqs. 21 and 28 is

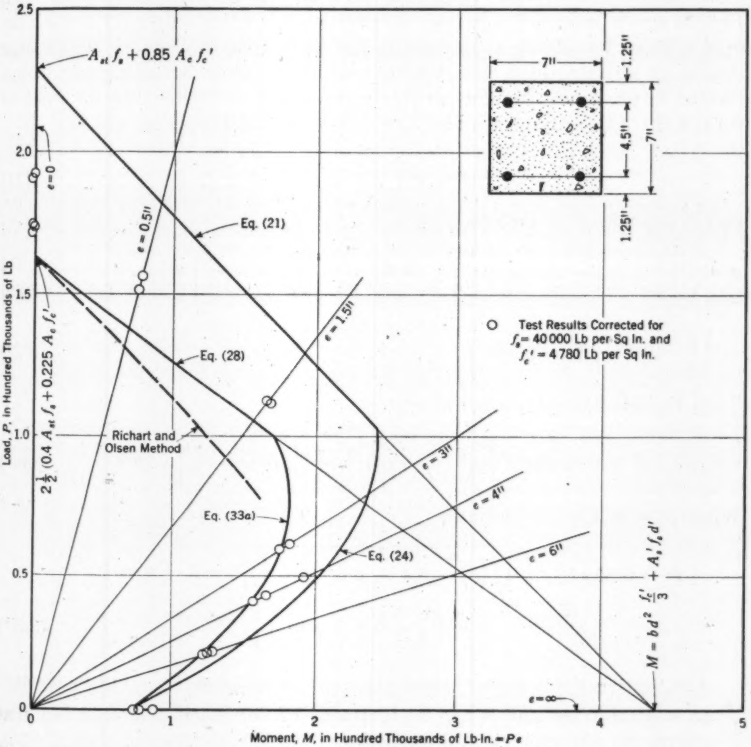

FIG. 12.—TEST RESULTS, SERIES F E, CORRECTED FOR f_s = 40,000 LB PER SQ IN. AND f_c' = 4,780 LB PER SQ IN.

shown by Fig. 12, assuming: d = 5.75 in.; d' = 4.5 in.; $A_s = A_s'$ = 0.392 sq in.; f_s = 40,000 lb per sq in.; f_{cu} = 6,250 lb per sq in.; and f_c' = 4,780 lb per sq in.

The allowable axial load for rectangular tied columns, according to standard practice, is

$$P = 0.8\,(0.4\,A_{st}\,f_s + 0.225\,A_c\,f_c') \ldots\ldots\ldots\ldots\ldots (29)$$

and the allowable eccentric load when the reinforcement is symmetrical may be obtained by multiplying Eq. 28 by $\frac{0.8}{2.5}$ which gives

$$P = \frac{0.32\,A_{st}\,f_s}{\dfrac{2\,e}{d'} + 1} + \frac{0.18\,A_c\,f_c'}{\dfrac{1.69\,t\,e}{d^2} + 1} \ldots\ldots\ldots\ldots\ldots (30^*)$$

Eq. 30 covers the case of the rectangular tied column when compression controls. When the eccentricity is so large that the tension in the steel controls the load, Eqs. 24 can be modified to provide an additional factor of safety for the smaller eccentricities by adding a constant to the eccentricity. Because of the large strains at ultimate load, the deflection of the column (assuming the length limited to ten times t) might possibly increase the eccentricity by as much as $0.1\,t$, and if this amount is added to e used in the derivation of Eq. 24*a*,

$$M = P\left(e + \frac{t}{10} + \frac{d'}{2}\right) \ldots\ldots\ldots\ldots\ldots (31)$$

and it becomes: $P = 0.85\,t\,b\,f_c' \times$

$$\times\left\{\sqrt{\left[\frac{e}{t} - 0.4 + (p - p')\,m\right]^2 + \frac{2\,d'}{t}\,p'\,m + (p - p')\,m\left[\frac{d'}{t} + 1 - (p - p')\,m\right]} - \left[\frac{e}{t} - 0.4 + (p - p')\,m\right]\right\} \ldots\ldots (32^*)$$

Then Eq. 24*b* becomes, when $p' = p$—

$$P = 0.85\,t\,b\,f_c'\left\{\sqrt{\left(\frac{e}{t} - 0.4\right)^2 + \frac{d'}{t}\,p_t\,m} - \left(\frac{e}{t} - 0.4\right)\right\} \ldots (33a^*)$$

When $p' = 0$, Eq. 24*c* becomes

$$P = 0.85\,t\,b\,f_c'\left\{\sqrt{\left(\frac{e}{t} - 0.4 + p\,m\right)^2 + \left(\frac{d'}{t} + 1 - p\,m\right)p\,m} - \left(\frac{e}{t} - 0.4 + p\,m\right)\right\} \ldots\ldots\ldots (33b^*)$$

The comparison of Eqs. 33*a* and 24*b* are shown by Fig. 12. The addition of $\frac{t}{10}$ to e is arbitrary and it can be increased or decreased if desired but that amount appears to give good results as compared with tests. Eqs. 25 and 26 are only used for large eccentricities and need no reduction.

The writer has compared[6] the ultimate loads computed from Eqs. 28 and 33*a* with the actual loads found in tests made by Messrs. Richart and Olson[29] and F. G. Thomas.[30] The test results by Mr. Thomas are generally lower than the values computed from Eqs. 21 and 24*b* but higher than Eqs. 28 and 33*a*. This is consistent with his tests on axially loaded columns in the same series and the low strength appears to be due to the design of his test specimens. The reinforcing steel did not extend to the bearing plates but was embedded in enlarged ends which were smaller than those that proved unsatisfactory in the Illinois and Lehigh tests.[31] The test results indicated a slipping of the compression steel. The results of one series of tests are plotted in Fig. 12.

---

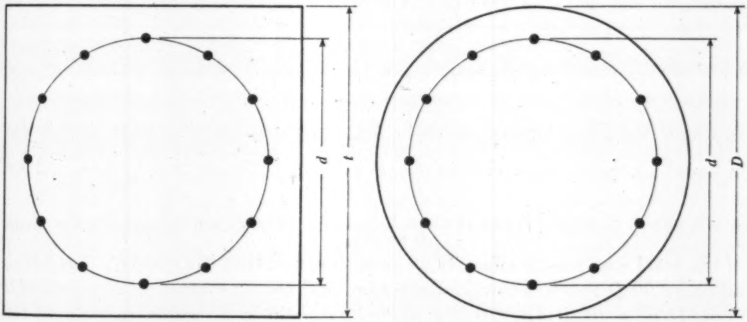
[29] "The Resistance of Reinforced Concrete Columns to Eccentric Loads," by F. E. Richart and T. A. Olson, *Journal*, Am. Concrete Inst., March–April, 1938, p. 401 (see especially Tables 2 and 4).

The results of the Richart and Olson tests[29] on 10-in. square columns also lie between the two sets of equations, but for some reason the axially loaded columns also failed to develop their expected strength. Messrs. Richart and Olson stated:[32]

> "Comparing the axially loaded columns of this series with previous tests in which 'flat-ended' columns were used, it appears that these 'hinged-ended' columns are weaker by roughly 15 per cent. It seems reasonable that the eccentrically loaded columns of this series are similarly weaker than columns rigidly framed into other members of a building frame."

COLUMNS WITH ROUND CORES

The writer has derived formulas for the strength of round cored columns and they will be given herein, although further tests may show that the empirical constants can be improved.



(*a*) SQUARE COLUMN (*b*) ROUND COLUMN

FIG. 13.—COLUMNS WITH ROUND CORES

Square Columns.—When, in a square column (Fig. 13(*a*)), the longitudinal reinforcement is distributed around the circumference of a circle with a diameter *d*, Eqs. 28 and 33 can be adapted by substituting for the value of d' the equivalent effective steel distance in terms of d. The equations seem to agree quite well with tests when $0.67\,d$ is used, and assuming half the steel effective on each side of the section, Eq. 28 becomes, for ultimate load producing compression failure:

---

[30] "The Strength and Deformation of Reinforced Concrete Columns Under Combined Direct Stress and Bending," by F. G. Thomas, *Studies in Reinforced Concrete No. VI*, Building Research Station, London; see also, *Concrete and Constructional Engineering*, March, 1938, p. 165.

[31] "First Progress Report on Column Tests at Lehigh University," by W. A. Slater and Inge Lyse; and "Second Progress Report on Column Tests at the University of Illinois," by F. E. Richart and G. C. Staehle, *Journal*, Am. Concrete Inst., Vol. 27, 1931.

[32] "The Resistance of Reinforced Concrete Columns to Eccentric Loads," by F. E. Richart and T. A. Olson, *Journal*, Am. Concrete Inst., March–April, 1938, p. 406.

$$P = \frac{A_{st} f_s}{\dfrac{3\,e}{d} + 1} + \frac{0.85\,A_c f_c'}{\dfrac{10.2\,t\,e}{(t + 0.67\,d)^2} + 1.51} \quad \text{(34}a^*\text{)}$$

With a factor of safety of 2½ Eq. 34*a* approaches $P = 0.4\,A_{st} f_s + 0.225\,A_c f_c'$ as e approaches zero. Making the same substitution in Eq. 33, it becomes, for ultimate load producing tension failure:

$$P = 0.85\,t^2 f_c' \left[\sqrt{\left(\frac{e}{t} - 0.4\right)^2 + 0.67\,\frac{d}{t}\,p_t\,m} - \left(\frac{e}{t} - 0.4\right) \right] \quad \text{(34}b^*\text{)}$$

Round Columns.—To adapt Eq. 34*a* for compression failure to the case of the round column with round core, the effective depth of the concrete section, t, can be changed to $0.8\,D$ and Eq. 34*a* becomes

$$P = \frac{A_{st} f_s}{\dfrac{3\,e}{d} + 1} + \frac{0.85\,A_c f_c'}{\dfrac{8.16\,D\,e}{(0.8\,D + 0.67\,d)^2} + 1.51} \quad (35)$$

For the case of tension failure, a new equation can be derived in the same manner as Eq. 24*b*. For this purpose the distance from the center line of the section to the center of gravity of the area of concrete in compression can be expressed with sufficient accuracy as

$$\bar{x} = 0.211\,D + 0.293\left(0.785\,D - \frac{2\,A}{D}\right) \quad (36)$$

in which A is the compression area. Assuming that the total steel compression is equal to the total steel tension: $P = 0.85\,A\,f_c'$; or, $A = \dfrac{P}{0.85\,f_c'}$. Then $\bar{x} = 0.211\,D + 0.293\left(0.785\,D - \dfrac{2\,P}{0.85\,D\,f_c'}\right)$. Then assuming that four tenths of the total steel area is effective on each side, and that the effective d' is $0.75\,d$, adding $0.09\,D$ to e to allow for deflection, and taking moments: $P\,(e + 0.09\,D + 0.375\,d) = (0.40\,A_{st} \times 0.75\,f_s\,d) + P\,(\bar{x} + 0.375\,d)$ which reduces to the following equation for the ultimate load causing tension failure in a round column with a round core:

$$P = 0.85\,D^2 f_c' \left[\sqrt{\left(\frac{0.85\,e}{D} - 0.3\right)^2 + \frac{d\,p_t\,m}{2.5\,D}} - \left(\frac{0.85\,e}{D} - 0.3\right) \right] \quad (37^*)$$

Although some of the assumptions used in deriving these equations may be questioned as being contrary to present conceptions based on the elastic theory, they may nevertheless be sufficiently close to the true conditions at failure so that the simple and convenient form of the equations will prove satisfactory in practice. A comparison[6] with the tests reported by Messrs. Richart and

Olson[29] indicates that this is true, although the writer feels that sufficient tests have not been made to show whether or not the empirical constants in the equations can be improved. The equations appear to be more convenient than any others that have yet been proposed.

METHOD OF DESIGN AND FACTOR OF SAFETY

The foregoing equations provide a simple and consistent treatment for the full range of conditions from axially loaded columns to beams under flexure alone. Designers who follow current methods are inconsistent in applying the plastic theory to axially loaded columns, and at the same time attempting to combine it with the theory of elasticity as soon as the eccentricity is introduced. Messrs. Richart and Olson[29] suggest that design of eccentrically loaded columns for the range of eccentricities with e less than $0.25\,t$ should be based on the transformed section modulus of the uncracked section, involving the modular ratio. They propose the use of the standard straight-line stress formulas for large eccentricities. For the allowable unit stress, they propose an empirical variation from $0.225\,f_c'$ for a concentric load to $0.4\,f_c'$ for larger eccentricities. Fig. 12 shows the relative strength computed by their method.

The method suggested by Thomas[30] using the present formulas based on the straight-line no-tension theory is similar to the method proposed by Messrs. Richart and Olson. Thomas introduces an empirically varying allowable concrete stress only in the range between $e = 0$ and $0.5\,d$. As applied to the full range of eccentricities such a method merely forms an empirical transition between the standard plastic treatment of the axially loaded column and the standard straight-line working stress treatment for beams, which is not as realistic nor as simple as the method proposed by the writer.

The equations of this paper, except Eq. 30, are ultimate strength equations. They are not intended to be used to predict stresses under working loads.

Actual stresses under working loads are affected by so many conditions that they are quite indeterminate. It has been proved[33] that shrinkage and plastic flow entirely upset stress computations based on the elastic theory but they have little effect on ultimate strength because before failure the strains are great enough to cause redistribution of stress.

This is also true of pre-stressed reinforcement which has been shown to have no appreciable effect on ultimate strength although it does increase the load at which tension cracks appear in the concrete.[34]

The factor of safety should obviously depend on the nature of the structure and its loading. It may be desirable to provide different factors for different kinds of loads in some cases. Reasonably well-controlled concrete is such a reliable material at present that the use of any factor of safety to provide for sub-standard concrete can be eliminated by using f_c' as the minimum cylinder strength instead of the mean. With care, sufficient concrete strength can readily be provided and the concrete can be placed on the same design basis as steel.

---

[33] "Effect of Time Yield in Concrete Upon Deformation Stresses in a Reinforced Concrete Arch Bridge," by W. M. Wilson, M. Am. Soc. C. E., and R. W. Kluge, Assoc. M. Am. Soc. C. E., *Bulletin No. 275*, Eng. Experiment Station, Univ. of Illinois, 1935.

[34] "Cracking in Reinforced Concrete," by F. G. Thomas, *The Structural Engineer*, July, 1936, p. 298.

If the minimum fatigue strength of reinforced concrete members, under load repeated thousands of times, is more than 50% of the ultimate static strength as indicated by tests, it will be still higher under loads repeated as infrequently as the maximum loading conditions in an ordinary structure. As a general proposition it appears that allowable dead plus live loads could be four tenths of the ultimate loads; and, for extreme combinations of dead and live loads, and wind, temperature, and shrinkage effects, one half of the ultimate might not be excessive. This is premised on the use of the elastic theory (and not the principle of moment redistribution based on yielding) to determine moments and thrusts so that the actual forces will not exceed the useful limit of the strength of the member. Each case should be given careful consideration and it is obvious that the designer should have as correct an understanding as possible of the true action of structures.

There is one important peculiarity of members subjected to both bending and direct load which has not been properly recognized. As can be seen from Fig. 12, when the tensile strength controls (Eq. 24*b*), the bending moment that can be resisted increases with the direct load. Therefore, it is possible for a reduction of direct load without change in moment to cause failure. It may not be safe, therefore, to consider that in case of overload, both the direct thrust and the moment will increase proportionately. It is obvious that in the case of a bridge arch, where the thrust is due largely to dead load and the bending moment due to live load, an increase in bending is much more probable than an increase in thrust. The use of ultimate strength formulas makes it possible to design a member for any combination of multiples of the thrust and moment. Instead of using a simple factor of safety as for an axially loaded column or a beam, in the case of a member subjected to both direct load and bending, consideration should be given to probable combinations to which the member might be subjected. A further analysis of the desirable factor of safety of arch ribs has been made by the writer.[23]

COMPARISON OF PLASTIC THEORY WITH THE STANDARD THEORY

The plastic theory proposed by the writer for the design of concrete members is based on three assumptions: (1) No tension in the concrete; (2) linear variation of strains; and (3) a simple equivalent stress block which closely approximates the effect of the real distribution at maximum load. It differs from the ordinary straight-line stress distribution theory only in that it recognizes the plastic action of concrete at failure instead of attempting to predict the stresses at working loads.

The objections that may be raised to the adoption of the plastic theory are about as follows: (*a*) It is unfamiliar and untried; (*b*) it is an ultimate strength method instead of a working stress method; (*c*) the present method has given satisfactory service for years and could be modified to permit higher stresses if they are justified; and (*d*) it may lead to the use of beams and slabs that are too shallow and cause excessive deflections.

Each of these ideas will be discussed in order, as follows:

(*a*) The application of the plastic theory is much simpler than the present method, and it is as well supported by tests as the latter. In fact, its closer agreement with tests is one of its greatest advantages. It can be taught as easily as the present method and will lead designers to a better understanding of the actual structural action.

(*b*) In spite of the designer's familiarity with the working-stress method of design and his preference for it, the ultimate-strength method is superior if it is a better guide to the useful strength of members and provides a more consistent factor of safety against damaging overload. Tests indicate that the useful strength bears a more definite relation to the ultimate strength than to theoretical working stresses given by the standard formulas.

(*c*) The present method has been useful during a time when knowledge and experience with reinforced concrete were being accumulated. It provides, in some cases, what is now an excessively high factor of safety against concrete failure. It leads to uneconomical design and inconsistent factor of safety. It is actually based on an empirical value of $\frac{E_s}{E_c}$ which could be modified together with the allowable stresses to give practically the same results as the new theory as far as the resisting moment of the concrete in compression is concerned. This would lead to the use of nominal working stresses which would appear unreasonably high; but, more serious than that, as previously stated, the method does not give as satisfactory values of the steel lever arm as the new method. This would lead to the use of more steel in lightly reinforced beams and a reduction in factor of safety against steel failure in heavily reinforced beams as compared with the new method. Table 7 shows the average unit concrete stress, at failure, of the test beams reported by Messrs. Slater and Lyse,[15] as computed by seven different methods. The last column indicates the consistency with which the formula might predict the results of the tests if the correct unit stresses were used in the formula.

TABLE 7.—COMPARISON OF CYLINDER STRENGTH WITH MAXIMUM UNIT STRESS IN OVER-REINFORCED BEAMS

Item No.	Value of *n* in the formula	Ratio[a] $\frac{f}{f_c'}$	Mean variation from the average
	By the Straight-Line Formula:		
1	American Concrete Institute, 1928[b]	1.57	±0.045
2	Joint Committee, 1924[c]	1.50	±0.059
3	Actual	1.62	±0.075
	By the Parabolic Formula:		
4	American Concrete Institute, 1928[b]	1.10	±0.034
5	Joint Committee, 1924[c]	1.07	±0.041
6	Actual	1.05	±0.035
7	By the plastic theory, Eq. 12[d]	1.05	±0.037

[a] Computed unit stress divided by the cylinder strength.

[b] "Reinforced-Concrete Building Regulations and Specifications," *Proceedings*, Am. Concrete Inst., Vol. XXIV, 1928, Section 601.

[c] "Standard Specifications for Concrete and Reinforced Concrete," Report of Joint Committee, *Proceedings*, Am. Soc. C. E., October, 1924, Section 103.

[d] Ratio for Item 7 is the computed unit stress divided by 0.85 f_c'.

It is interesting to note that the straight-line formula with the actual value of *n* (Item 3, Table 7) gave the poorest results, and that the parabolic formula

(Item 6) and the plastic formula (Item 7) gave the best results. The plastic theory appears more desirable than a modified straight-line theory.

(*d*) The new formulas permit the use of more slender members, which is an advantage in structures for which dead weight and temperature or shrinkage moments are important. It will also be beneficial at the haunches of T-beams. It is always important to guard against excessive deflections, no matter what method is used, and it is always necessary to design carefully for shear and bond. It will not generally be found economical to use maximum percentages of steel in beams and slabs; but the designer will be given more freedom in design, and, having simpler tools with which to work, he can pay more attention to other important considerations.

APPENDIX

DESCRIPTION OF TESTS PLOTTED IN FIG. 7

The tests by Messrs. Humphrey and Losse[18] were made on 333 8-in. by 11-in. beams of gravel, limestone, granite, and cinder concrete varying in strength from 1,500 to 5,700 lb per sq in. Reinforcement varied from 0.49% to 1.96% of steel with a yield point averaging about 40,000 lb per sq in. Of the total, 84 beams are not plotted in Fig. 7 because the concrete cylinder strength exceeds the testing machine capacity and, therefore, f_c' was not determined. The cylinders tested are 8 in. by 16 in. and f_c', the strength of 6-in. by 12-in. cylinders, is calculated as $\frac{100}{95}$ times the reported value. Each point plotted represents the average of three beams.

The U. S. Geological Survey Tests[35] were made at St. Louis, Mo., in 1908 on a series of 8-in. by 11-in. beams of gravel concrete with 3.02% of steel with an average yield point strength of 38,210 lb per sq in. Only beams with concrete strengths greater than 2,000 lb per sq in. are included, and because individual steel strengths are not reported, only the averages are plotted for two groups of eleven beams each, one under-reinforced and one over-reinforced. The concrete cylinders were 8 in. by 16 in. and f_c' is calculated to be $\frac{100}{95}$ times the reported strengths.

The Columbia University tests[36] were made on thirteen rectangular 12-in. by 13-in. beams reinforced with ordinary steel and twin twisted bars with yield points from 34,800 lb per sq in. to 58,250 lb per sq in. and areas varying from 0.451% to 1.245%. The concrete strengths varied from 2,510 to 3,443 lb per sq in. The yield point of the twin twisted bars was taken as the stress producing a unit strain of 0.004.

The tests by Messrs. Slater and Lyse[37] are those previously quoted. The four sets excluded from the averages in Table 1 are not plotted. Each point represents the average of a group of three beams.

DISCUSSION

L. E. Grinter,[38] M. Am. Soc. C. E. (by letter).—The procedure for the structural design of reinforced concrete that is proposed in this paper is certain to receive repeated and probably favorable consideration in the coming years. There is reason to question if the knowledge of the action of reinforced concrete frames under ultimate loads is adequate today to answer the question as to whether the author's procedure is logical in all cases; and, of course, the proposed method of allowing for plasticity is but one of many possible procedures. It is true, however, that designers have already taken certain steps in this direction—notably, the adoption of a column formula that omits consideration of relative moduli of elasticity by basing load capacity upon the yield strength of the steel. On the other hand, this step was a much more obviously acceptable one in that high steel stresses in columns are known to exist as a normal condition even under ordinary working loads. Elimination of the term n in present formulas for the design of reinforced concrete beams presupposes flow beyond conditions ordinarily normal in concrete structures.

The author's castigation of the use of the ratio n in reinforced concrete design nevertheless seems justified by many recent findings. It is true that measured strains in concrete cannot be transferred into stresses of great significance, and yet one cannot question that the stress corresponding to a given strain will bear a relation, however complex, to the modulus of elasticity. The directness of this relationship may be expected to reduce as the load is increased beyond working conditions. As shown clearly by Fig. 1, the straight-line relationship between stress and strain may be expected to exist up to one half of the ultimate strength, and engineers do not plan to design structures for working stresses of even this magnitude. On the other hand, Fig. 1 does not express the stress-strain relationship as it is influenced by time yielding since this influence seems largely restricted to dead-load conditions.

Evidently, then, the acceptability of any method of design by means of a theory of plasticity should be studied in the light of one's belief in design for failure. After most careful study, the writer has concluded that, in many instances, a steel structure can be designed far more logically if failure is accepted as the basis. By failure is meant a condition of deformation dependent upon the passing of the elastic limit, not necessarily a condition of exaggerated distortion. Similarly, in reinforced concrete design, it would seem logical to design the structure like the famous "shay" so that it would fail simultaneously in all of its parts. A criterion, then, is whether the proposed plastic theory will achieve this condition more closely than use of the ordinary straight-line formulas for the design of reinforced concrete beams.

In order that a continuous frame may fail simultaneously at many places (and nearly all concrete structures are continuous frames of some type or other), the designer must not only consider plasticity in the design of the individual sections but also plasticity for the distribution of moments. This is precluded in the author's procedure by his belief that "* * * the theory of elasticity is the best guide to the forces acting on the different sections." It is precluded in the writer's opinion by the simple fact that engineers do not know enough about the influence of plasticity upon structural action to predict properly the influence of time yield or of plastic flow upon moments.

---

[38] Vice-Pres. and Dean, Graduate School, Illinois Inst. of Technology, Chicago, Ill.

The other point that deserves consideration is the fact that the parts of a structural frame include columns, beams, slabs, and their joints. To be better than the present methods, a new theory must predict the failure of each of these parts more accurately than standard procedures, and this must be true even if concrete of different strengths (and different moduli of elasticity) are used in the several parts of the structure. In early attempts at analysis, the factor *n* was introduced consistently for columns, beams, and slabs, and perhaps within reasonable limitations designers achieved uniformity of action under light loads for which elastic conditions obtained. The realization, however, that column rods picked up additional stresses through time flow in the concrete spoiled this apparent consistency and has led the author to attempt a readjustment of beam design to parallel the now accepted method of column design. Some revision of beam design seems desirable, one reason being that the factor of safety is probably greater in beam design than in column design by present methods. A problem for consideration is that present column formulas are justified by time yielding, whereas the proposed beam formulas depend upon plastic flow near failure. Evidently these are quite different conditions.

As was mentioned earlier, there are many ways that plasticity can be introduced into design. One procedure would be to accept the parabolic stress distribution curve seriously proposed in the early days of reinforced concrete. The author's rectangular stress pattern, being non-physical in its aspects, can be justified only by simplicity, and, actually, it does not seem to simplify, greatly, the common methods of design. Hence, although the writer agrees with the probable desirability of considering failure as a criterion for design, he finds it difficult to justify a procedure resulting in an entirely artificial stress-distribution relationship for the concrete above the neutral axis. It seems unfortunate that one dimension of the stress diagram does not represent the maximum concrete stress and that the other dimension is not associated with the depth of the beam in a physically significant manner.

It must not be forgotten, when theories are proposed for introduction into standard codes, that these theories must be presented to undergraduate students. It is always feasible to teach facts that may be substantiated in any reasonable way. It is also possible to present hypotheses that have some reasonable connection with observed phenomena and to develop theories from such hypotheses. It is simply not reasonable, however, to ask students to accept theories that do not follow physically observable phenomena or even the accepted hypothesis as to physical action. An example of this is the possible use of a stress diagram for compression in the concrete that is inconsistent with the hypothesis of a straight-line variation of strain throughout the depth of the beam. Such an inconsistency would militate against the logical use of any formulas that might be developed, irrespective of their simplicity or other desirable features.

The author's paper will serve a most valuable purpose in pointing out the present inconsistencies in the design of reinforced concrete structures. His proposal will call forcefully to the attention of structural engineers the desirability of basing design procedures for all members of a structure upon a single hypothesis. The importance of plasticity both as an influence upon the stress distribution at a section and upon the moment distribution throughout the structure will be reweighed as to its importance. Time yielding at low loads will be reconsidered and compared in its significance with plastic flow beyond normal working stresses. The many possibilities of stress distribution over the beam cross section may be reconsidered again to advantage. Finally, the purpose to be achieved by any theory of stress analysis that is known to be far from exact in its representation of conditions in a material that is neither homogeneous nor even continuous must be re-evaluated. The author's excellent paper will bring each of these matters again to the attention of structural engineers.

Basil Sourochnikoff,[39] Esq. (by letter).—In order to simplify computations, Mr. Whitney replaces the curvilinear stress distribution with a rectangular stress block. This appears to be quite satisfactory, as the results of formulas obtained by using this approximation check very closely with experimental data. However, it may be of interest to establish formulas based directly on the curvilinear stress distribution without using any simplifying device. Of course, these formulas cannot be expected to be more exact than the stress-strain curve on which they are based. A comparison of results thus concluded with the experimental data may show just how closely the idealized stress-strain curve represents actual conditions.

Under-Reinforced Beams.—From the conditions of equilibrium of any cross section it follows that

$$\kappa = \frac{f_s'}{f_c'} \times \frac{p}{A} \ldots\ldots\ldots\ldots\ldots\ldots (38a)$$

and

$$\frac{M}{f_c'\,b\,d^2} = \kappa\,A\,[1 - \kappa\,(1 - \bar{x})] = \frac{f_s}{f_c'}\,p\left[\,1 - \frac{f_s'}{f_c'}\,\frac{p}{A}\,(1 - \bar{x})\,\right] \ldots . (38b)$$

in which, in addition to the author's notation, f_s' is the yield stress in steel. When the steel is strained above the yield point, f_s' remains practically constant and independent of ϵ'. Then, for each particular beam, the resisting moment will vary with $\frac{1 - \bar{x}}{A}$ alone. The maximum resisting moment will correspond to the minimum of $\frac{1 - \bar{x}}{A}$. This last quantity, for each given grade of concrete, depends on the stress curve only. For curves of Fig. 3:

---

[39] Registered Structural Engr., St. Paul, Minn.

$1{,}000\,\epsilon$	$\frac{1 - \bar{x}}{A}$
1.0	0.710
1.5	0.585
2.0	0.540
2.5	0.538
3.0	0.538
3.5	0.543
4.0	0.575
4.5	0.602
5.0	0.638

Therefore, if the steel is overstressed, the resisting moment increases until the strain in the concrete reaches a value of about 0.00275. Then it would decrease if the strain exceeds this value. The ultimate strain in the concrete is therefore about 0.00275 and does not depend on the percentage of steel. The ultimate resisting moment is determined from the expression:

$$\frac{M}{f_c'\, b\, d^2} = \frac{f_s'}{f_c'}\, p \left[1 - 0.538 \frac{f_s'}{f_c'}\, p \right] \ldots\ldots\ldots\ldots\ldots\ldots (39)$$

which is of the same form as Eq. 7*b*. The coefficient $\frac{m}{2}$ in Eq. 7*b* is $\frac{f_s'}{2 \times 0.85\, f_c'} = \frac{0.59\, f_s'}{f_c'}$. For $f_c' = 4.000$, $f_s' = 6.000$ and $p = 3\%$. This means a difference of only 3.2% on the ultimate moment. Assume that, at the yield point, the steel is strained to 0.002. Since, in the present case, the steel is overstressed, $\epsilon' > 0.002$. Then, if the concrete fails after the steel is overstressed, failure occurs at $\frac{\epsilon'}{\epsilon} > \frac{0.002}{0.00275}$ or 0.73. From Eq. 38*a* this is possible only if $p < \frac{0.46\, f_c'}{f_s'}$. Therefore, in the present case, it seems that $\frac{0.46 \times 4{,}000}{60{,}000}$ or 3% is the limiting ratio of reinforcement. The beam would be under-reinforced if $p < 3\%$, and over-reinforced if $p > 3\%$. This again checks with results obtained by Mr. Whitney.

Over-Reinforced Beams.—From the conditions of equilibrium it follows again that:

$$f_c'\, A \frac{\epsilon}{\epsilon + \epsilon'} = E\, \epsilon'\, p \ldots\ldots\ldots\ldots\ldots\ldots (40)$$

Therefore,

$$\frac{\epsilon'}{\epsilon} = \tfrac{1}{2} \left(\sqrt{1 + \frac{4\, f_c'\, A}{E\, p\, \epsilon}} - 1 \right) \ldots\ldots\ldots\ldots\ldots\ldots (41)$$

and

$$C = \frac{M}{f_c'\, b\, d^2} = A\, \kappa \left[1 - \kappa \left(1 - \bar{x} \right) \right] \ldots\ldots\ldots\ldots\ldots\ldots (42)$$

Using again the curves of Fig. 3, the constants for different steel ratios are given in Table 8. This shows that the ultimate resistance occurs for $\epsilon = 0.003$, approximately. The quantity $C = \dfrac{M}{f_c'\, b\, d^2}$ depends on p and increases asymptotically to 0.455. This result is at variance with that obtained by Mr. Whitney, as it seems to show that for over-reinforced beams the ultimate resistance does increase with the steel ratio, although the rate of increase is slow.

TABLE 8.—CONSTANTS FOR VARIOUS STEEL RATIOS

$1{,}000\,\epsilon$	STEEL REINFORCEMENT (FOR $p = \infty$—$\epsilon' = 0$; $\kappa = 1$; AND $C = A\,\bar{x}$)									
	3%			4%			5%			∞
	$1{,}000\,\epsilon'$	κ	C	$1{,}000\,\epsilon'$	κ	C	$1{,}000\,\epsilon'$	κ	C	C
1	1.105	0.474	0.203	0.905	0.525	0.220	0.78	0.563	0.233	0.330
2	1.75	0.535	0.310	1.44	0.582	0.330	1.21	0.624	0.346	0.442
3	2.10	0.590	0.352	1.71	0.638	0.370	1.44	0.678	0.384	0.455
4	2.28	0.640	0.362	1.84	0.686	0.375	1.56	0.720	0.385	0.431
5	2.35	0.681	0.348	1.86	0.730	0.362	1.60	0.760	0.368	0.392

It should be reemphasized that the numerical results cannot be more exact than the stress-strain curve from which they are derived.

R. W. STEWART,[40] M. AM. SOC. C. E. (by letter).—Many tests cited by the author, and other published tests not cited,[41] show that the concrete stress in a reinforced concrete beam is substantially lower at rupture than the value computed by the straight-line stress distribution assumption that is used almost universally for design purposes. This proves that the tensile steel is the weak partner and that by increasing the steel percentage a beam of given thickness can be made suitable for carrying substantially heavier loads. The author makes this situation very clear and proposes a method of analysis which he demonstrates to give accurate results. This method eliminates the modular ratio n that is recognized as an arbitrary factor if the stress-strain ratio for concrete does not plot as a straight line or some known mathematical curve. However, factor n can be eliminated only by the introduction of some other arbitrary device, and the author has selected the rectangular stress block, which he describes.

Flexure formulas for ultimate loads have been published heretofore on the assumption that the stress deformation curve for the concrete is a parabola.[42] The author's investigation shows, however, that a parabola of higher order than the second degree must be used to represent the stress distribution in the concrete in order to compute with accuracy the ultimate resisting moment of a beam. Table 9(a) indicates a sequence of beam sections, each of which has the proper amount of tensile steel to fix its neutral axis at the same percentage of its depth as the beam analyzed by the author and illustrated by Fig. 2. Item 4 shows the relative moment-resisting capacity of each of the beam sections. It is to be noted that the ideal curve for concrete stress distribution, presented by the author, will permit a beam, if sufficiently reinforced, to carry 47% more load than if designed by the usual straight-line formula. It may be noted also that using the fourth-degree parabola will give very nearly the same

result. The cubic parabola, with a small error on the side of safety, appears to the writer to be a suitable curve to use. It is pictorially superior to a rectangular stress block in representing the actual condition of fiber stress and involves less departure from established procedure.

A comparison of costs of slabs designed by the proposed method and by the straight-line formula was not included in the paper. Such data are presented in Table 9 (*b*), which shows the make-up of a series of slabs, each one designed to resist the same bending moment using the same fiber stresses. The differences in slab thicknesses and percentage of reinforcing steel are due to the different assumptions as to stress distribution as shown by Table 9 (*a*). It is noted that, although the author's proposed concrete stress distribution and the higher order of parabolic distributions show saving in concrete, the increased cost of the additional steel required will more than offset this saving so that some special inducement to use thin slabs is required in order to justify, economically, the abandoning of the straight-line theory of concrete stress distribution. The cost of forms is properly excluded from the cost of concrete in this comparison, so it is seen that, unless the unit cost of the concrete is considerably higher than the usual bid prices, the straight-line stress distribution formula will give the most economical result.

It may be noted also that Fig. 1 indicates that the stress-strain graph for the tests of concrete reported appears as a straight line up to a unit stress of 2,000 lb per sq in.

GEORGE C. ERNST,[43] ASSOC. M. AM. SOC. C. E. (by letter).—The rational approach to the design of reinforced concrete members, as presented in this paper, has interested the writer since its introduction in 1937.[5] The straightforwardness shown in the concept of the action of the two combined materials is refreshing and should be welcomed by engineers engaged in the structural field.

It is important to note in Fig. 12 that the results of the series of tests by F. G. Thomas,[30] in which high-strength mixtures were used, do not conform to the proposed formulas although the tests of Bach and Graf[24] with a medium-strength mixture show good agreement. The Thomas tests on specimens of low-strength concrete also agree well with the formulas as shown in Table 10, but the author has suggested that the lack of agreement shown in Fig. 12 for the higher strength concrete appeared to be due to the use of enlarged ends on the specimens and slipping of the compression steel. (The use of the minimum concrete strength in Table 10 is consistent with the author's suggestion under "Method of Design and Factor of Safety." Manipulations with average, minimum, nominal, or maximum concrete or steel strengths, however, do not affect the relative positions of the groups.) The design of the ends of the specimens in the low-strength group, however, was the same as for the high-strength group. It is apparent also that the lack of agreement is just as evident for the larger eccentricities where the effect of the enlarged ends and slipping of the compression steel are virtually negligible. It is inconceivable to the writer that the design of the eccentrically loaded specimens affected the results to any noticeable degree unless it is due to the smallness of the cross section (about one sixth the area of the Bach and Graf test columns) when used with the higher strength mixtures. In this connection it is to be noted that the 10-in. square test columns of Richart and Olson had an area of only about one third of the Bach and Graf specimens. Although Messrs. Richart and Olson suggest the possibility that about a 15% reduction in the capacity of "hinged-ended" columns exists as compared to "flat-ended" columns, nevertheless the tests of Thomas fail to confirm this belief when enlarged ends are used. Since the effect of the enlarged ends should be essentially the same for "hinged" and "fixed" ended specimens, the tests by Professor Thomas are definitely inconclusive in this matter (see Table 10). With regard to the five points plotted in Fig. 12 on the ordinate $e = 0$, the lowest value and the next to the highest value are for "fixed-ended" conditions, whereas the remaining three are "hinged-ended." Two other "hinged-ended" columns, not shown would fall above the entire diagram although the concrete strengths of these

[a] Minimum f_c' and average f_s used in each group. [b] Tested with fixed ends. All others tested with knife-edge end bearings. [c] The cylinder strength (converted) exceeded the average by 17.5%.

two were only 17.5% above the average of the group. Furthermore, it is difficult to attribute the lack of strength in the tests of Messrs. Richart, Olson, and Thomas to hinged ends if the Bach and Graf tests are considered as hinged-ended for the eccentrically loaded conditions.

All evidence points to a reduction in relative capacity due to the use of the higher strength mixtures, although it must be recognized also that the size of the specimens of Bach and Graf are comparable to actual construction, whereas those of Thomas are somewhat small. It would seem best to the writer to place a limit on the concrete strength at approximately 3,000 lb per sq in. for the proposed formulas until more conclusive tests have been conducted using the higher strength mixtures under combined bending and direct stress.

Although Table 6(*a*) is entitled "Rapid and Long-Time Tests," the frames subjected to long-time loading by Messrs. Richart and Olson are not tabulated and it would prove of value if the author would supply the missing information for the purpose of showing that the effect of sustained loading is negligible. The writer believes, also, that much of the value of Table 6(*a*) is lost unless the frame details are described briefly to show the effect of various sizes of fillets and chamfers. Such details raise a question as to the position of the critical section, and in so far as the writer has been able to determine it occurs, for these frames, just inside the fillets, whether circular or straight. Chamfering the back corner may bring the critical section into the corner if the effective section at the corner is reduced sharply, although this does not appear to be the case for frames 6 or 7.

5[d,e,f,g]	2.67	4,800	4,960	0.97

[a] One test for each item. [b] No hinges. [c] Constant 6-in. depth and 3.5-in. width. [d] Bases hinged. [e] Hinged at crown. [f] Verticals varied from 6 in. at the knee to 3 in. at each base hinge. [g] Top horizontal varied from 6 in. at the knee to 3 in. at the hinges.

Tests on rectangular frames made at the University of Maryland in 1940 (Table 11) show good agreement with the proposed formulas, but it must be noted that the concrete mixture was of low strength. Tests upon frames very closely approximate actual conditions of restraint in the application of the eccentric load.

The important feature revealed by the comparison of the author's formulas with test results seems to be the need for additional information on rectangular and circular sections subjected to eccentricities from zero to pure bending and covering a wide range of concrete strengths. Until such additional tests are made it would be exceedingly difficult for the writer to justify the use of the proposed formulas without an upper limit of 3,000 lb per sq in. placed upon the concrete cylinder strength.

HOMER M. HADLEY,[44] ASSOC. M. AM. SOC. C. E. (by letter).—There are several matters concerned with the fundamentals of Mr. Whitney's proposed theory of design on which it is hoped additional information will be furnished.

(1) Fig. 1, from which the proposed theory is developed, shows six curves, one of which terminates at a unit strain of 0.0036 in. per in., a second at a unit strain of 0.005 in. per in,, whereas the remaining four are shown extending unbroken to the right-hand edge of the diagram. Standard 6-in. by 12-in. cylinders being used, the unit strain 0.005 in. per in. gives a total deformation of 0.06 in. The text states (see heading "The Stress-Strain Characteristics of Concrete") "the machine head was moving continuously at the rate of 0.06 in. per min." On this basis the range of stresses shown in the diagram occurred in slightly more than 1½ min. It is most immediate, practically instant, plasticity that is disclosed.

These are highly unusual stress-strain curves for concrete cylinders. Ordinarily the attainment of maximum stress is closely followed by failure. For a few seconds while it holds together the load drops off rapidly; then the cylinder shatters and breaks into fragments. In Fig. 1, however, the cylinders do nothing of the kind. After maximum stress has been attained (that is, after maximum load has been applied) they do not fracture but simply deform with reducing unit stress. It might almost be said that they are made to deform by taking load off of them, which, of course, is an improper statement. The truth is that they are made to deform uniformly and they offer sustained but decreasing resistance. Complete details regarding these tests and such anomalous behavior are most desirable.

(2) Under the foregoing heading is the statement that

> "The effect of time on the stress-strain relation is believed to be similar to that in the case of tests on beams. It is probable, therefore, that these curves indicate the form of compressive stress distribution in a beam at ultimate load in the concrete in the zone where the unit strain exceeds about 0.002 in. per in."

Considering that the cylinder test is one of direct stress over a full section, whereas the beam is a case of flexure with fibers at varying distances from the neutral axis; and considering the highly unusual character of the curves in Fig. 1, the writer hopes there will be further exposition of these statements. Has it definitely been "proved" or has it definitely been assumed "that the strain in the compression side of a beam increases practically in direct proportion to the distance from the neutral axis"?

(3) When the stress distribution in a beam has been explicitly stated to be "probably" like those of the cylinder curves of Fig. 1, why should the direct

---

[44] Regional Structural Engr., Portland Cement Assn., Seattle, Wash.

declaratory form of statement subsequently be used regarding this stress distribution—for example, in the second paragraph following Eq. 3*b*? The validity of an assumption is not established simply by its being postulated and formulated.

(4) Why was the particular form of stress curve shown in Fig. 4 selected? This curve appears to be identical with the curve of Fig. 2 which is definitely stated to be based on an ϵ value of 0.003. If it is assumed that the four curves of Fig. 1 do indeed terminate at the margin of the diagram at a unit deformation of 0.008 in. per in., then the average value of ϵ of the six curves would be 0.0068—say, 0.007. If this average value of the anomalous evidence were used, as apparently it might well be, then a different stress distribution in the beam would result with a different position of the center of gravity, etc. Of all the "fibers" (so-called) in a beam, the extreme topmost one is most advantageously placed with respect to the centroid of tensile stresses for developing resistance to external forces. In view of this fact is there not an inherent improbability in the assumption that a less advantageously placed fiber with a substantially lesser lever arm carries a higher stress than the topmost fiber? In the general economy of nature things do not work in this fashion.

This matter of so-called "plastic flow" in concrete is an annoying one. There is a nucleus of truth in the term. A certain slight amount of increased deformation does occur at early ages under sustained load; but how this is to be separated and distinguished from the deformation that occurs when concrete dries out and shrinks in plain, common every-day fashion is difficult to determine. The concrete knee-frame tests under sustained load, reported by Messrs. Richart and Olson,[25] had the specimens continuously wet until placed under load and it was while under load that they dried out. So likewise continuously wet until placed under load were the specimens of the A. C. I. column tests at Lehigh University, Bethlehem, Pa., and the University of Illinois, Urbana, Ill. Plastic flow is such an easy explanation of other things. Some one forgets to put camber in a bridge span and it settles slightly. "Plastic flow" is the immediate whispered explanation. Embarrassing deflections from some other cause—insufficient reinforcement, for example—develop and—"Oh, that's plastic flow in the concrete. All the research laboratories are studying it these days"—and so on. It is worthy of note that most concrete structures, if they are any the worse for it, do not reveal that fact to any appreciable extent. In a publication of Northwestern Technological Institute of Northwestern University dated February 1, 1941, Prof. G. A. Maney,[45] M. Am. Soc. C. E., reaches the conclusion that "Concrete is not an appreciably plastic material under working stresses and the time changes, in volume and dimension, of concrete under working loads are not due to plastic flow but to shrinkage." Mere change of nomenclature, of course, does not eliminate the volume change but it does simplify matters; it does eliminate obscurantism.

The standard concrete compression-test specimen, a cylinder 6 in. in diameter and 12 in. high, is an interesting object to consider. It is necessary to have some means of comparing various mixtures of concrete made at different places and at different times; and it has come to pass that the standard cylinder is the generally accepted means of making such comparisons; but, out of the complete widespread acceptance of this cylinder and of its unit compressive strength as a basis of comparison, has developed the attribution to it of wholly unwarranted powers. Of these none is more lacking in substantial basis than the assumption that it measures, directly, the flexural strength of its concrete when that concrete is put in a beam or slab and its ultimate fiber stress is computed by the straight-line theory with some one of the various values of n. Just why it should be a cylinder 6 in. in diameter and 12 in. high that should do this rather than some other cylinder 6 in. in diameter and of a different height is not, on earnest consideration, apparent. In Europe concrete is tested in 6-in. cubes and has some other unit strength than it has in America. Let no one think that shape of test specimen and conditions of testing do not have a pronounced effect upon the nominal unit strength of concrete. Some years ago S. H. Woodard, M. Am. Soc. C. E., tested numerous cylinders and prisms with sheets of blotting paper, impregnated with heavy grease, introduced between the ends of the specimens and the heads of the testing machine. By so doing he assuredly did not change the inherent properties of the concrete but he eliminated conical and pyrimidal breaks completely and caused their strengths to drop markedly below those of companion specimens tested without the blotting paper.[46] The paper by H. F. Gonnerman,[47] M. Am. Soc. C. E., indicates that the height of the 6-in. diameter cylinder should be about 4 in. to have it measure, directly, the flexural strength of the Slater-Lyse and other test beams when computed by the straight-line theory.

---

[45] "'Warping' or Non-Uniform Shrinkage Over Cross-Section Found to Be Source of All Time Yield in Loaded Concrete Members," *Studies in Engineering—No. 1*, Northwestern Technological Inst. of Northwestern Univ., Evanston, Ill.

However, when it is possible to multiply the unit strength of the standard 6 by 12 cylinder by 1.5 and thereby obtain a value that reasonably approximates the flexural unit strength of the concrete in test beams, what could be simpler than to do that? The writer is not especially "enamored" of the straight-line theory, but on the other hand it is to be recognized that it has the virtue of great simplicity. Furthermore, it is the established and practically world-wide basis for designing reinforced concrete and has been taught continuously in all engineering schools and colleges ever since there has been a standard method of design. It is not to be lightly abandoned and put aside.

Therefore, as a constructive proposal it is suggested that the ordinary cylinder values be multiplied by 1.5 to obtain flexural values conservatively less than the ultimate flexural strength, that the straight-line theory be retained, and that working stresses be based on the flexural, not on the cylinder, strength. Certainly there is need for a revision of concrete design practice to effect a more reasonable and more economical use of the material than at present obtains. Fundamentally such a revision will make it permissible for concrete structures to carry greater loads than now allowed. That is what concrete structures are for—to carry loads. To make them do that effectively, economically, and in reasonable conformity with their potential abilities means the revision of various "books of rules" and a marked increase in present maximum permissible stress values.

[46] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 1091.

[47] *Proceedings*, A. S. T. M., 1925, Pt. 2, p. 237.

ROBERT W. ABBETT,[48] M. AM. SOC. C. E. (by letter).—The theory proposed in this paper, for proportioning structural members of reinforced concrete, is based on the assumptions that: The material is plastic; stress is not proportional to strain; and, in the case of gradually applied loads, the material will fail at a stress intensity less than maximum. These conditions are known to exist when the order of magnitude of compressive stress in the concrete is near the ultimate. Therefore, the author's theory should give an accurate indication of the behavior of a reinforced concrete member at the point of impending failure, provided that the strength of the concrete is critical and that the applied loads are of long duration.

In the case of loads suddenly applied and quickly removed, the stress-strain curve for concrete is not very similar to the ideal curve in Fig. 3 in that failure usually occurs near the point of maximum stress. This is true even when the ratė of load application is that usually adopted as standard for the testing of cylinders in the laboratory. Frequently, in laboratory tests of cylinders, the failure is in the nature of a sudden explosion at or near the point of maximum stress.

If the reinforcement of a beam is under-designed, presumably ultimate failure will occur because of yielding of the steel when the concrete stress is at some point below the maximum for the material. When this occurs the concrete stress is likely to fall in a region of the stress-strain curve which is a closer approximation of the properties of an ideal elastic material than those of an ideal plastic material. In this connection it should be noted that, even when the design is perfectly balanced, failure will usually occur because of yielding of the reinforcement, and that under any circumstances a compression failure of the concrete is very rare. Furthermore, when a factor of safety of 2 or more is used in the design, the working stresses in the concrete are in the elastic range of the stress-strain curve as in the case of the under-reinforced beam at the point of failure.

In view of the foregoing conditions, the writer has drawn the following conclusions with regard to the plastic theory:

(1) In the case of structural members for which the greater part of the load to be carried is dead load or live load permanently fixed in position, the plastic theory gives a better indication of the ultimate strength of the member than the present standard theory based on the theory of elasticity. Typical of such members are the column, footing, arch rib, and floor girder.

(2) When movable live load comprises the greater part of the total load to be carried, the plastic theory may give an erroneous indication of the strength and behavior of the member, and the elastic theory is to be preferred. Included in this class of members are most building floors, bridge decks, beams, and stringers.

---

[48] Asst. Prof., Civ. Eng., Columbia Univ., New York, N. Y.

(3) The plastic theory gives very little indication as to what is occurring in a member working at the average, or design, stresses when the factor of safety is 2 or more. On the other hand, the elastic theory gives results that are relatively close approximations for a large class of structures.

(4) The prediction of deflections under working conditions, although very uncertain with the elastic theory, is virtually impossible with the plastic theory.

(5) There are uncertainties in the behavior of reinforced concrete members that are ignored by both the plastic and elastic theories. These are probably the cause of greater variations than those due to the two theories mentioned. Typical of these uncertainties are the effect of tension resistance in the concrete, variation in effective moment of inertia, and stress conditions in both the concrete and steel in the vicinity of the small cracks which are always present in a stressed beam.

(6) Apparently the balance is about even when it comes to a choice of the two theories with a slight advantage in favor of the elastic theory simply because it is in agreement with the procedure standardized for other materials. However, the entire idea of "working stress" as a basis for design is questionable. There is a growing tendency to think of design in terms of useful limiting load but until this becomes universal there is no reason why the plastic theory should not be adopted for the class of structures for which it is most suitable. This has been done already in the case of columns.

Finally, the writer would like to pay his respects to the author, whose paper has contributed so much to the theory of reinforced concrete structures.

Paul Andersen,[49] Assoc. M. Am. Soc. C. E. (by letter).—The conventional method of designing reinforced concrete is unsatisfactory. Attempts have been made to eliminate from the analysis the modular ratio, *n*. At present, columns concentrically loaded are analyzed by means of formulas that carefully avoid this quantity. If, however, the load is moved slightly off center so as to produce combined flexure and compression, the analysis is immediately changed to one that makes extensive use of the modular ratio. Therefore, the author should be congratulated upon his efforts in correcting these contradicting procedures and presenting methods of analysis consistent for all types of members.

The plastic theory encourages the use of much higher steel percentages than the usual straight-line theory. According to the former theory, the critical percentage of steel required to develop the full compressive strength of the concrete is expressed by Eq. 13.

According to the straight-line theory this percentage can be found by equating total tension and total compression; thus: $\frac{1}{2} k\, j\, b\, d^2 f_c' = A_s f_s\, j\, d$, and

$$p_0 = \frac{A_s}{b\,d} = \frac{k}{2} \times \frac{f_c'}{f_s} = \frac{n f_c'}{2(n f_c' + f_s)} \qquad (43)$$

To compare Eqs. 13 and 43 to actual tests, six beams with varying steel percentages were made up and tested at the age of 28 days in the Materials

---

Testing Laboratory of the University of Minnesota, Minneapolis, Minn. In each beam the bottom reinforcement differed, as shown in Table 12. The

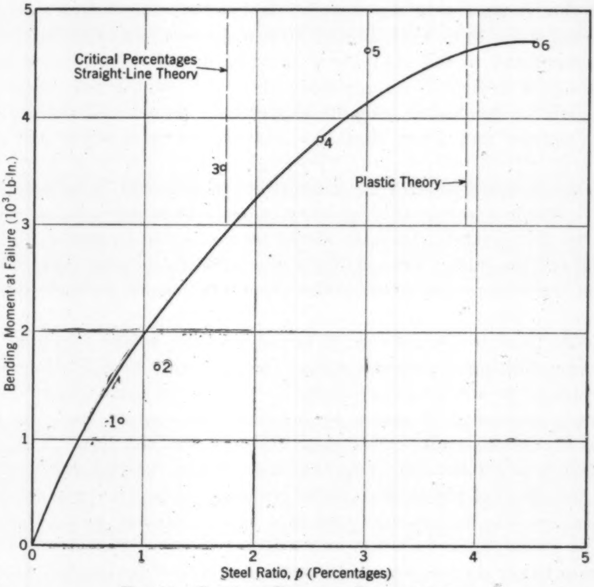

FIG. 14.—TESTS ON BALANCED REINFORCEMENT

compressive strength of the concrete (average of two cylinders) was 4,060 lb per sq in.; the secant modulus of elasticity at 75% of ultimate strength was 3.67×10^6 lb per sq in.; and the yield point of the reinforcement was 47,000 lb per sq in. Bending moments at failure plotted against steel ratios are shown in Fig. 14. Critical steel percentages according to Eqs. 13 and 43 are indicated. These tests, together with those cited by the author, support the contention that the conventional theory does not permit percentages of steel sufficient for balanced design.

The question that will arise immediately after the adoption of a plastic theory for the proportioning of reinforced concrete sections is whether the determination of moments and shears should not be by a procedure based on limit design rather than elastic theory. If the different parts of the structure are designed for forces existing prior to failure it appears logical to determine the distribution of these forces on the same basis.

R. A. CAUGHEY,[50] M. AM. SOC. C. E. (by letter).—The attention of the engineering profession has been directed to a problem that should receive serious attention and that should call forth various suggestions for the improvement of certain phases of reinforced concrete design. The writer, however, feels that the problem is not finally solved and that certain details should, and will, receive attention before the proposed method is considered for general use.

From the viewpoint of an engineering teacher, the writer feels that, in beam design, it would be very difficult to substitute a rectangle for the present stress diagram and to tell students that "The use of the rectangle is merely a mathematical device to approximate the effect of the true distribution." Most students in reinforced concrete classes have tested cylinders in concrete materials courses and know that the relation between stress and strain in concrete is a difficult problem; but they might reasonably expect a stress-strain curve closer to the results of the laboratory than would be afforded by this "device." Table 1 seems to suggest that, outside of the method suggested, a return to the parabolic formula would be a solution in the case of beams; but designers generally, recognizing the variations in the material, uncertainties in the flexural behavior of the beam, etc., would scarcely desire such a change.

It should be noted in the case of beams that the author's comparisons are made between ultimate-strength values (see Tables 1 and 2) when what the engineer desires to consider in concrete design is what the concrete does under working stresses. Fig. 1 seems to indicate that, up to half the ultimate strength, the stress-strain curve approaches a straight line. True enough, plastic flow is not taken into account, but neither does the author's method consider the effect of plastic flow under working loads. It seems to the writer that designers have had enough test data and experience with design, by the method of straight-line variation and working stresses, to warrant confidence in design but they do need some information on the effect of plastic flow under working loads. Mr. Whitney attempts to make allowance for the plastic flow by use of the rectangle but confines his attention to consideration of ultimate loads.

---

[50] Prof. of Structural Eng., Dept. of Civ. Eng., Iowa State Coll., Ames, Iowa.

It will be noted that all of the formulas of the paper are based on ultimate strengths. At first this would seem to be desirable in these days of rigid frames but the designer still has the moments of inertia of the members of frames to deal with in determining bending moments; and it would seem to offset, to some extent, the advantages of an ultimate-strength method to use moments of inertia which, in turn, infer straight-line variation in concrete stresses.

Dropping the use of working stresses would also be objectionable because members of all other structural materials are designed on that basis. Most designers have regarded the abandonment of the ultimate-strength method of design as a very desirable step and would scarcely welcome a return to that method. Concrete design at present, with available curves, tables, etc., compares well in simplicity with design of other materials; and this simplicity with similarity in design methods to methods used in other materials is very desirable.

What the writer has stated thus far applies principally to beams. It is a generally recognized fact that structural engineers have gone far in considering plastic flow in formulas for columns[51] carrying concentric loads. Stress distribution over the section of a concentrically loaded column, however, is a problem that differs from the case of a beam. The unit stress in the concrete is practically the same over the entire section whereas, in the case of the beam, it presents a major problem. The writer feels that more tests of columns under combined direct stress and moment should be made, with the idea of determining strain distribution under working loads. With the distribution of strains determined, it might be possible to extend the work of J. R. Shank,[52] M. Am. Soc. C. E., and others to the determination of stresses with plastic flow taken into account.

The aforementioned method might be used in the case of beams, possibly by arriving at some method of adjusting the value of n so that the present convenient method of design might be more satisfactory.

Roberto Contini,[53] Jun. Am. Soc. C. E. (by letter).—Although the method of ultimate strength for purposes of design appears very logical and satisfactory, the developments for the determination of the strength of structural members seem to be rather uncertain. All the computations are based on the consideration that the equivalent rectangular stress diagram at failure must have a height equal to 0.85 f_c' in order for the center of gravity of that rectangle to coincide with the center of gravity of the actual stress diagram.

This develops, it seems, from the shape of the stress-strain diagram for concrete and from the fact that the maximum bending moment is developed when the maximum concrete strain is about twice the one causing the maximum stress. However, as the author himself states (see paragraphs following Eq. 3),

---

[51] Final Report of Committee 105, Reinforced Column Investigation, *Proceedings*, Am. Concrete Inst., Vol. 29, p. 275.

[52] "The Mechanics of Plastic Flow of Concrete," by J. R. Shank, *Loc. cit.*, Vol. 32, pp. 149–180.

[53] Graduate Student, Columbia Univ., New York, N. Y.

"This ratio will vary with the quality of the concrete and the steel strain." As the height of the rectangular equivalent diagram is certainly correlated with that ratio, the value of 0.85 f_c' appears questionable.

Moreover, even if that value is satisfactory for concrete at failure, it could be erroneous, to some extent, in case of under-reinforced beams. In this case, in fact, the full concrete strength is not yet developed when the steel yields. The concrete stress diagram has a different shape than the one at maximum concrete strength, and its center of gravity is in a different position, so that the lever arm of the steel is different.

The case of under-reinforced beams is to be given consideration, because very often the size of a beam is controlled by a large bending moment confined to only a part of it, or by conditions other than the maximum bending moment. When this occurs, it would be wasteful to provide the full percentage of reinforcement required to balance the section, at least for some parts of the beam.

The writer thinks, however, that it is possible to avoid the use of uncertain values such as 0.85 f_c', and to proceed, instead, with the analysis of reinforced concrete members by simple considerations very similar in principle to the ones used in the usual theory of reinforced concrete. Such analysis, outlined hereafter, leads to the plotting of diagrams that are very easy to use.

The study is limited to simple bending of rectangular and T-beams, with tensile reinforcement only; but, if the system should prove satisfactory, it should not be difficult to extend it to any type of load and reinforcement. The following assumptions are made: (*a*) The strain distribution is linear through the entire depth of the beam; (*b*) the tensile action of concrete is negligible; (*c*) the stress-strain characteristics for concrete are well known and can be represented by means of a curve such as Fig. 3; and (*d*) the steel follows Hooke's law to the yield point—that is, to failure.

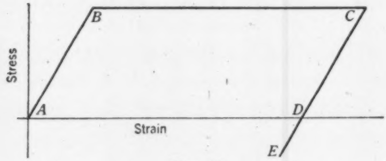

FIG. 15

The first assumptions are made also by the author. In order to justify assumption (*d*) the writer refers to a paper by J. A. Van den Broek, M. Am. Soc. C. E., in which a stress-strain diagram[54] for structural steel is plotted as shown in Fig. 15. Professor Van den Broek states:

> "Although the curve [Fig. 15] may appear idealized, this is not necessarily the case to any great degree. To be sure, stress-strain curves frequently are recorded with a bulge instead of the sharp angle shown at Point *B* * * *. It must be noted that the things tested are specimens and not filaments. For example, an ordinary steel bar suffers a differential stress between material in the outside and the center of the bar due to the cooling of the core (on the cooling bed) after the outside of the bar is already black and hardened. Furthermore, the rate of running the testing machine affects the curve. In other words, variations from stress-strain curves of mild steel, as shown in the figure, may frequently be assigned to the test specimen rather than to the material. In several

---

[54] "Theory of Limit Design," by J. A. Van den Broek, *Transactions*, Vol. 105 (1940), Fig. 2, p. 640.

hundred tests reported in 1918[55] the writer found the horizontal part of the curve very pronounced and coincident with the proportional limit."

It must be noted that Professor Van den Broek refers to tests made by strain control method, which is the one used for determining the stress-strain curve for concrete given by the author.

Rectangular Beams.—On these assumptions the following relations can be written (using the author's notation): From the linear strain relation—

$$\epsilon' = \frac{1 - k}{k} \epsilon \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44a)$$

Because of Hooke's law for steel—

$$T = A_s f_s = A_s \epsilon' E \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44b)$$

in which E = Young's modulus up to yield point. Since $T = C = A f_c' k b d$:

$$A_s \epsilon' E = A f_c' k b d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44c)$$

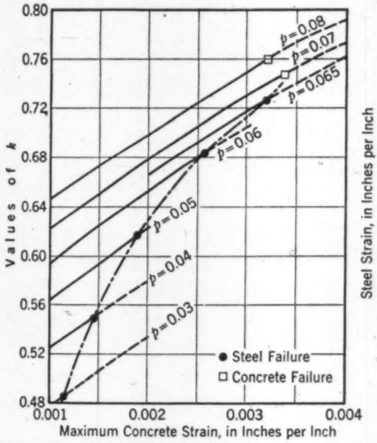

FIG. 16

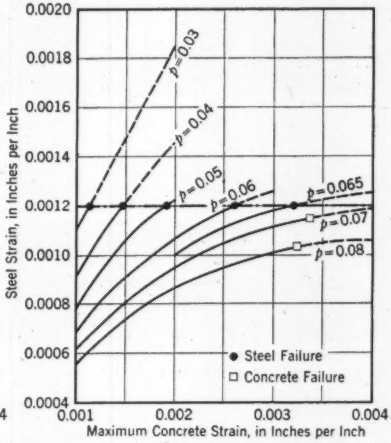

FIG. 17

Eliminating ϵ' from Eq. 44c by means of Eq. 44a:

$$A_s \frac{1 - k}{k} \epsilon E = A f_c' k b d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45a)$$

Therefore,

$$k^2 + k \frac{A_s \epsilon E}{A f_c' b d} - \frac{A_s \epsilon E}{A f_c' b d} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45b)$$

and

$$k^2 + k \frac{p \epsilon E}{A f_c'} - \frac{p \epsilon E}{A f_c'} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45c)$$

from which, by solving for k and taking the positive root:

$$k = -\frac{p \epsilon E}{2 A f_c'} + \sqrt{\left(\frac{p \epsilon E}{2 A f_c'}\right)^2 + \frac{p \epsilon E}{A f_c'}} \ldots\ldots\ldots\ldots\ldots\ldots (46)$$

---

[55] "The Effect of Cold Working on the Elastic Properties of Steel," Carnegie Scholarship *Memoirs*, Iron and Steel Inst., Vol. IX, 1918; see, also, *Engineering*, July, 1918.

For any value of ϵ, the corresponding value of A can be selected from Fig. 3(*b*). Therefore, everything being known concerning the right side of Eq. 46, it will be possible to plot a series of curves k against ϵ for different values of p (see Fig. 16) and, by using Eq. 44*a*, to plot ϵ' against ϵ. All the elements are now available to plot $\frac{M}{f_c'\,b\,d^2}$ against ϵ by using Eq. 2. The curves given in Fig. 17 were plotted by using the following characteristics of the materials: (*a*) For concrete, the curves given by the author, in Figs. 3(*b*) and 3(*c*) with $f_c' = 4{,}000$ lb per sq in. (The limit of x when ϵ approaches zero should be 0.667.) (*b*) For steel, $E = 30{,}000{,}000$ lb per sq in. and f_s' = yield point stress = 36,000 lb per sq in.; consequently, ϵ_y' = strain at which yield begins = 0.0012.

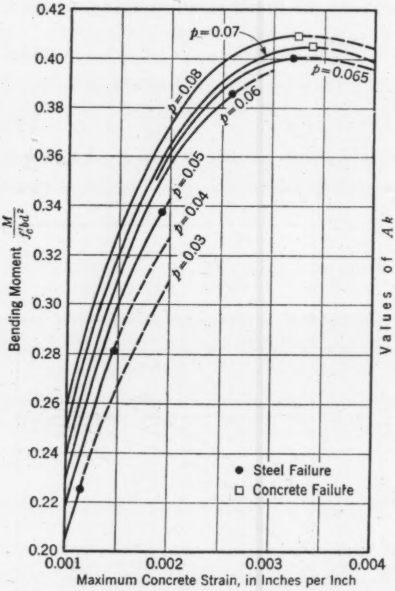

FIG. 18

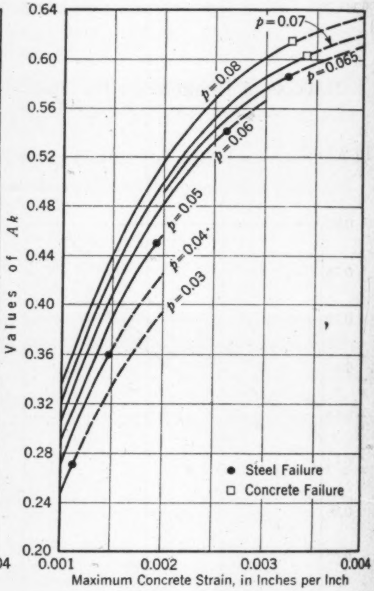

FIG. 19

The curves were plotted as if the steel followed Hooke's law indefinitely; therefore they are of no significance beyond the point at which the steel strain reaches the value $\epsilon_y' = 0.0012$ (dotted parts of curves). As shown by Figs. 17 and 18, for small values of p the beam fails by tension in the steel, because the steel strain reaches the value ϵ_y' before the full strength of the concrete is developed. If p is high, the maximum resisting moment, as controlled by concrete, is reached when the steel strain is still less than ϵ_y' and the beam fails by compression in concrete.

A "balanced" design is obtained when the maximum resisting moment, as controlled by concrete, is reached at the same time that the steel strain reaches the value ϵ_y'. At that point the beam is on the verge of failure both by compression in concrete and by tension in steel.

For the selected characteristics of the materials, the value of p for balanced design happens to be a little more than 0.065. For under-reinforced beams the value of ϵ, corresponding to ϵ_y', can be found also (in addition to the foregoing) by plotting the curve $A\,k$ (Fig. 19) and noting that $T_{max} = \epsilon_y'\,E\,A_s$. This quantity is known; and, as $T = C$, one can write: $\epsilon_y'\,E\,A_s = A\,f_c'\,k\,b\,d$; or,

$$\frac{\epsilon_y'\,E\,p}{f_c'} = A\,k \quad \text{(47)}$$

in which the left term is known. The value of ϵ, corresponding to the value of $A\,k$ found by means of Eq. 47, is read from the curves.

In Fig. 20 the value of the maximum resisting moment is plotted against p. This, therefore, is the fundamental diagram for design purposes. Also the value of k at failure is plotted.

T-*Beams.*—For T-beams with tensile reinforcement (using the notation of Fig. 21), if $k < t$, the formulas found for rectangular beams apply as well.

The author states that, in his theory, formulas for rectangular beams apply directly to T-beams if the compression depth a is less than the thickness of the flange. It seems, however, that in any case the length $k\,d$ should be considered instead of a; otherwise it becomes implicitly assumed that the stress distribution is rectangular, which, on the contrary, is sharply denied by the author.

If $k > t$, the total compressive force will be the same as for a rectangular beam of width b, less the part corresponding to the shaded area in Fig. 21(a). If: $\frac{b - b'}{b} = s$; C_1 = compressive force for rectangular beam of width b; C_2 = compressive force corresponding to the shaded area, to be subtracted; and $C = C_1 - C_2$ = effective compressive force; then:

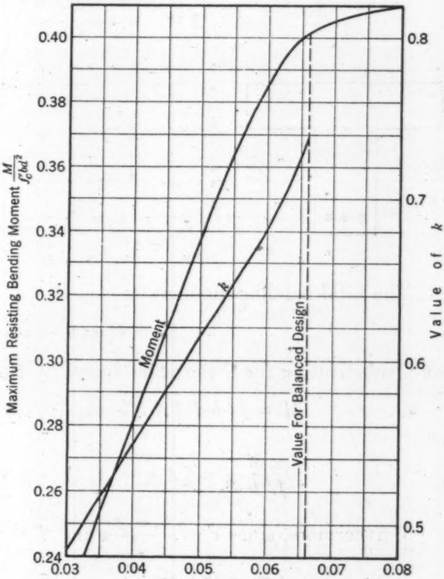

FIG. 20

$$C_1 = A\,f_c'\,k\,b\,d \quad \text{(48a)}$$

$$C_2 = A_2\,f_c'\,(k - t)\,b\,d\,s \quad \text{(48b)}$$

and

$$C = C_1 - C_2 = f_c' \, b \, d \, [A \, k - A_2 \, (k - t) \, s] \quad \text{..........} (48c)$$

Area A is read from Fig. 3(b) in relation to ϵ, maximum concrete strain, and A_2 is read in relation to ϵ_2, the concrete strain at the lower face of the flange. The linear strain distribution yields the relation:

$$\epsilon_2 = \frac{k - t}{k} \, \epsilon \quad \text{........................} (49)$$

Assume that: $\bar{x}_1 \, k \, d$ = distance of the line of action of C_1 from the neutral axis; and $\bar{x}_2 \, k \, d$ = distance of the line of action of C_2 from the neutral axis. The moment of $C = C_1 - C_2$ about the neutral axis will then be:

$$(C_1 - C_2) \, \bar{x} \, k \, d = C_1 \, \bar{x}_1 \, k \, d - C_2 \, x_2 \, (k - t) \, d \quad \text{..........} (50)$$

in which $\bar{x} \, k \, d$ is the distance of the line of action of C from the neutral axis. Solving for $\bar{x}$:

$$\bar{x} = \frac{C_1 \, \bar{x}_1 - C_2 \, \bar{x}_2 \left(1 - \frac{t}{k}\right)}{C_1 - C_2} \quad \text{.................} (51)$$

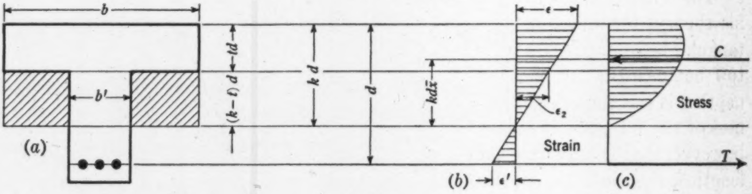

FIG. 21

The total bending moment is:

$$M = C \, d \, (1 - k + k \, \bar{x}) \quad \text{...................} (52)$$

and, substituting for C the value found by Eq. 48c:

$$M = f_c' \, b \, d^2 \, [A \, k - A_2 \, (k - t) \, s] \, (1 - k + k \, \bar{x});$$

or,

$$\frac{M}{f_c' \, b \, d^2} = [A \, k - A_2 \, (k - t) \, s] \, (1 - k + k \, \bar{x}) \quad \text{..........} (53)$$

Furthermore, since $\epsilon' = \frac{1 - k}{k} \, \epsilon$ and $T = A_s \, f_s = A_s \, \epsilon' \, E = C$:

$$A_s \, \epsilon' \, E = f_c' \, b \, d \, [A \, k - A_2 \, (k - t) \, s] = A_s \, \epsilon \, E \, \frac{1 - k}{k} \quad \text{......} (54)$$

That is:

$$\frac{p \, \epsilon \, E \, (1 - k)}{f_c' \, k} = A \, k - A_2 \, (k - t) \, s \quad \text{.............} (55a)$$

or

$$k^2 \, (A - A_2 \, s) + k \left(\frac{p \, \epsilon \, E}{f_c'} + A_2 \, s \, t\right) - \frac{p \, \epsilon \, E}{f_c'} = 0 \quad \text{......} (55b)$$

If $s = 0$, Eq. 55*b* becomes the formula for rectangular beams; if $s = 1$ the action of the compressed part of the web is neglected.

Eq. 55*b* is not as simple as the one for rectangular beams, and actually is not solvable for k by simply assigning values to ϵ, as in the case of rectangular beams, because A_2 is unknown. This quantity, in effect, is read from Fig. 3(*b*), the determination of which, by means of Eq. 49, requires a knowledge of k. Therefore Eq. 55*b* can be solved either by trial or graphically. In this latter case, for each value of ϵ, A_2 should be plotted against k both by means of Eq. 55*b* and by means of Eq. 49 and Fig. 3(*b*). The intersection of the two curves gives the value of k corresponding to the inherent value of ϵ.

Once k has been plotted against ϵ for given values of t and s and for a series of values of p, all the elements are available for plotting the following curves (all with ϵ as abscissas): ϵ_2, by means of Eq. 49; A_2, from Fig. 3(*b*); $\bar{x}$, from Eq. 51 after having determined $\bar{x}_1$ and $\bar{x}_2$ from Fig. 3(*b*); and finally, for determining the maximum resisting moment as controlled by concrete $\frac{M}{f_c' \, b \, d^2}$ by means of Eq. 53.

For steel failure ϵ' will be plotted against ϵ, by means of Eq. 44*a*, and the designer can proceed in the determination of the resisting bending moment as he did for rectangular beams.

All these curves are plotted for a series of values of p. Finally, the resisting moment can be plotted against the steel ratio p; and, here again, this will be the fundamental curve for purposes of design.

In conclusion, sets of diagrams should be plotted for each combination of steel and concrete; in the case of T-beams, a set of diagrams would be necessary for each combination of t and s. As a matter of course, the suggested method should be tested with experimental results. The writer has attempted to show that, for purposes of design, it is not necessary to rely on formulas based on more or less empirical and uncertain data, when it is possible to devise diagrams for easy application, based on simple and fundamental considerations. In this sense, the discussion is an attempt to support and improve the arguments presented by Mr. Whitney.

A. A. EREMIN,[56] ASSOC. M. AM. SOC. C. E. (by letter).—It is well known that the modulus of elasticity for compression in concrete varies with its stress, age, and physical qualities. Attempts were made in this paper to develop the equations for stresses, considering variation of the modulus of elasticity.

Interesting equations were developed by Fritz J. von Emperger in 1936 for a beam with a rectangular section.[57] He considered the variation of the modulus of elasticity in terms of the ratio "n," which he computed for the maximum stresses in concrete and steel, and the percentage of reinforcement in the section. Mr. von Emperger expressed variation of stresses in the rectangular section by a trapezoid with the maximum stresses at the top of beam section continued to a depth of $\frac{2}{3}$ a and varied according to a straight line from the maximum stresses to zero stresses at the neutral axis, a being a distance from the top of beam to the neutral axis (Fig. 22). Mr. von Emperger has shown that, in a reinforced concrete beam with light reinforcement, a variation of the ratio "n" has a slight effect on the stresses. Furthermore, like the author, he reached the conclusion that varying the ratio "n" and the percentage of reinforcement in a beam section made it possible to increase the maximum stresses in concrete and steel.

[57] "Der Beiwert '*n*,'" by Fritz J. von Emperger, *Beton und Eisen*, October, 1936, p. 324.

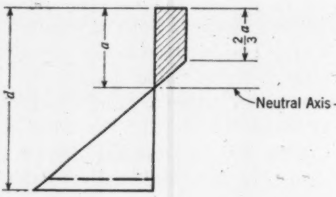

FIG. 22.—DISTRIBUTION OF STRESSES

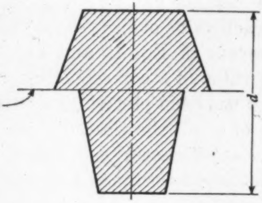

FIG. 23.—EQUIVALENT SECTION

In his formula for stresses (Eq. 3), instead of varying the ratio "n," Mr. Whitney assumed the maximum strains in concrete and steel. Furthermore he assumed that the stresses in the rectangular section vary as a rectangular prism with the total resulting stresses concentrated in center. Evidently the resulting equations may produce an economic design of reinforced concrete beams with small ratio of depth to span length. However, deep girders designed according to the author's formulas will require an excessive percentage of reinforcement.

To insure further accuracy in the equations for stresses in reinforced concrete beams, the influence of the section width should be taken into account. J. Melan has shown that the distribution of stresses in deep sections is not the same as in wide sections.[58]

Interesting equations for computation of stresses in concrete beams were developed by Rudolf Kern.[59] Like the author, Mr. Kern based his equation on the stress and strain curve obtained from a cylinder test. However, instead of assuming a rectangular prism distribution of stresses, Mr. Kern computed an equivalent trapezoidal section for the rectangular section of a beam, Fig. 23. Stresses in the equivalent trapezoidal section of a beam may be computed with standard formulas based on a straight-line variation. It is interesting to note that the equivalent beam sections determined by Mr. Kern may be used also for the computation of the elastic properties in rigid frames. Mr. Kern applied his equations in the computation of stresses in reinforced concrete arch ribs.

The equations of this paper should be modified to make them strictly applicable to the analysis of stresses in rigid frames or arches.

JAROSLAV J. POLIVKA,[60] **M. AM. SOC. C. E.** (by letter).—The characteristics of the plastic flow of concrete just before the failure of a structural member are different from those at working loads,[61] and more research is needed to prove whether, and how far, the stage preceding the failure can be considered as a reliable basis for reinforced concrete design. The adoption of the plastic theory is very attractive for its simplicity of analysis and design, compared with the generally accepted theory using the modular ratio n. A further simplifying step is suggested that may be extended for analysis and design of any irregular shape of the concrete section having unsymmetrical reinforcement and subject to any kind of loading.

Eq. 12 may be derived, assuming the value a equal to the distance between the centroidal axis of the prismatic cross section and the compression face:

$$a = \frac{t}{2} \qquad (56)$$

When the value a is substituted in the equation of equilibrium,

$$M = C_f \times f_c' \times a\, b \times c \qquad (57)$$

the ultimate resisting moment of the beam as controlled by concrete failure (Eq. 12) becomes equal to $\frac{f_c'}{3}$, maintaining the coefficient $C_f = 0.85$ and setting $d = 0.93\,t$. Then, $a = 0.538\,d$ and $c = 0.731\,d$, which values check very well with those computed from tests reported by Professors Slater and Lyse[15] (0.537 d and 0.732 d).

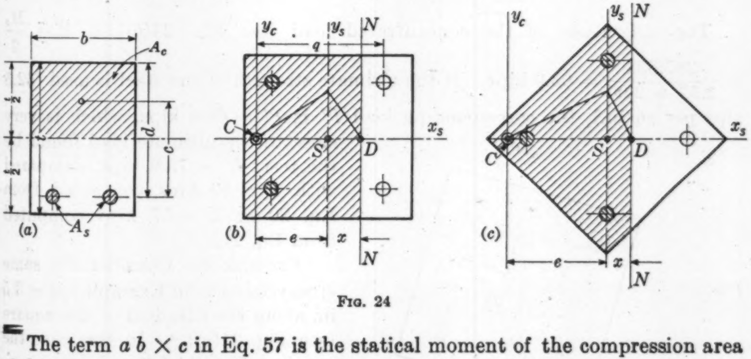

FIG. 24

The term $a\, b \times c$ in Eq. 57 is the statical moment of the compression area of the cross section with respect to the centroidal axis of the reinforcement:

$$M_c = A_c\, c = a\, b\, c \qquad (58)$$

This principle may be adopted for any shape of the cross section, considering the area of compression as acted upon by a uniformly distributed imaginary stress $C_f f_c'$. The compression area is determined by the neutral axis of the full homogeneous cross section (section of concrete). For pure bending the neutral axis is defined as a centroidal axis of the cross section, conjugate to the plane of bending. For eccentric loading the neutral axis is the antipolar of the point of application of the concentrated load with respect to the ellipse of inertia of the homogeneous cross section.

---

[60] Research Associate, Univ. of California,; Cons. Engr., Berkeley, Calif.

[61] "Design of Concrete Columns Reinforced by Steel of High Strength," by J. J. Polivka, *Stavitelské Listy* (*Structural Journal*), Vol. 29, 1933, Prague, pp. 175–178 and 188–191; see also "Le Béton Translucide," by J. J. Polivka—published by Les Études des Composés Siliceux, Bruxelles, 1934.

The coefficient C_f is equal to 0.85 when the compression face is parallel with the neutral axis and must be modified for other positions of the compression face according to the varying distance between the points of the boundary in compression and the neutral axis.

Example 1.—Consider an eccentrically loaded column 6 in. by 6 in., with symmetrical reinforcement of four $\frac{3}{8}$-in. round bars, and an eccentricity of the concentrated load $e = 2.50$ in. (see Fig. 24(*b*)).[62] The radius of gyration of the cross-sectional area is given by $r^2 = \frac{t^2}{12} = 3$ in.^{2} and $r = 0.289\,t$; and the distance between the neutral axis and the centroidal axis is $x = \frac{r^2}{e} = 1.2$ in.

For $f_c' = 4.02$ kips per sq in. ("kips" equal "kilo-pounds"; that is, 1,000 lb), $f_s = 43$ kips per sq in. (at the yield point), and $C_f = 0.85$, the statical moment of compressive stresses with respect to the centroidal axis of the tensile bars (in kip-in.) is

$$\begin{aligned} 25.2 \times 0.85 \times 4.02 \times (2.1 + 0.8) &= 249.714 \\ 2 \times 0.11 \times 43 \times 4.0 &= \underline{37.840} \\ \text{Moment } M_c &= 287.554 \end{aligned}$$

The magnitude of the concentrated load (see Fig. 24(*b*)) is $P = \frac{M_c}{q} = \frac{287.554}{2.50 + 2.00} = 63.9$ kips. If the ultimate strength of the steel is used (62.5 kips per sq in.), the corresponding load P' is $P' = 68.6$ kips, which is very close to the ultimate load found by the test: $P' = 73.9$ kips, compared with $P = 53$ kips computed from Eq. 20 or $P = 57$ kips computed from Eq. 21.

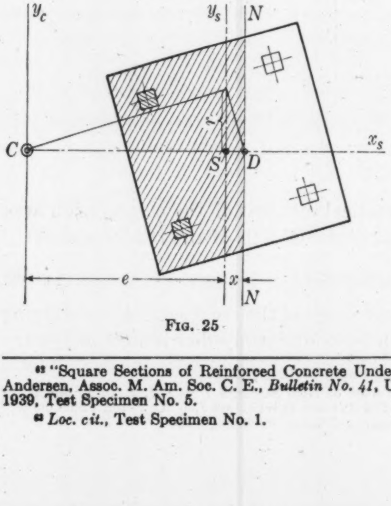

FIG. 25

Example 2.—Consider the same cross section as in Example 1, $e = 3.5$ in. along the diagonal of the square (see Fig. 24(*c*)).[63] In this case the constant C_f must be modified as previously stated. One method would consist in computing the stress volume for which the base is the area of compression, the stress remaining constant in planes perpendicular to the neutral axis and decreasing toward the corners. Then C_f becomes $\frac{2}{3} \times 0.85 = 0.567$.

---

[62] "Square Sections of Reinforced Concrete Under Thrust and Nonsymmetrical Bending," by Paul Andersen, Assoc. M. Am. Soc. C. E., *Bulletin No. 41*, Univ. of Minnesota, Minneapolis, Minn., Vol. XLII, 1939, Test Specimen No. 5.

[63] *Loc. cit.*, Test Specimen No. 1.

Considering the fact that f_s is decreasing toward the neutral axis, the statical moment of compressive forces with respect to the centroidal axis of the tensile reinforcement (in kip-in.) is:

(concrete) $0.567 \times 3.98\,(18 \times 4.242 + 6.979 \times 2.387) = 209.907$

(extreme bar) $0.11 \times 43 \times 5.656 = 26.753$

(two bars in the compression zone) $0.22 \times 43 \times \dfrac{0.867}{3.695} \times 2.828 = 6.278$

Moment $M_e = 242.938$

The intensity of the concentrated load is $P = \dfrac{242.938}{3.50 + 2.828} = 38.4$ kips.

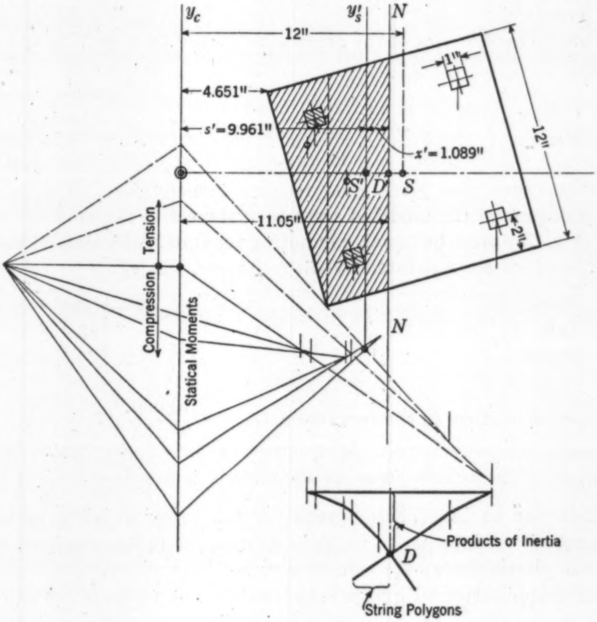

FIG. 26

If the ultimate strength of the steel is used, the corresponding load is $P' = 40.7$ kips. Both values are close to the ultimate load, 36.3 kips, of the test.

Example 3.—Comparison of the suggested method with the conventional analysis of eccentrically loaded concrete sections (Fig. 25) shows a square 12-in. by 12-in. section reinforced with four 1-in. square bars and subjected to a concentrated load $P = 10$ kips acting at a point C, which is 12 in. from the centroid S of the section; the plane of bending makes an angle of 15° with one of the principal axes.[64] The following definition of the neutral axis has been formulated by the writer, relating to the conventional elastic theory:

> The neutral axis N–N is a line parallel to a diameter of the ellipse of inertia that is conjugate to the plane of eccentric bending. It is determined by the condition that the products of inertia of the areas in compression and tension with respect to the neutral axis and to a parallel y_C through the point of application are equal. The products of inertia are determined by two string polygons (Fig. 26), applying the statical moments of cross-sectional areas with respect to the line y_C as forces acting parallel to y_C.

Both string polygons intercept at a point D, which locates the neutral axis N–N. The distance of the neutral axis N–N from the point of application C is found graphically: $s' + x' = 11.05$ in. (compared with 10.99 in. found by Mr. Andersen).[64]

The products of inertia of the areas with respect to axes N–N and y_C check very well:

Zone	Product of inertia
Compression	1,552 in.^{4}
Tension	1,551 in.^{4}

Another check also gives good results—namely, the condition that the statical moments of the modified areas with respect to the modified centroidal axis y_s' (Fig. 26) must be equal, computing separately the statical moments in both zones which are separated by the centroidal axis y_s':

Zone	Sum of statical moments
Left	125.455 in.^{3}
Right	125.454 in.^{3}

The compressive stress in the concrete is $f_c = -\dfrac{10{,}000}{98.193}\left(1 + \dfrac{5.31}{1.09}\right) = -598$ lb per sq in. The tensile stress in the steel is $f_s = \dfrac{10{,}000}{98.193}\left(1 - \dfrac{6.94}{1.09}\right) \times 10 = 5{,}472$ lb per sq in. These stresses would mean a safety factor of 7.9, assuming $f_c' = 4.7$ kips per sq in., $f_s = 43$ kips per sq in., and $n = 10$.

For the plastic theory the compression zone is confined by the antipolar of the point of application with respect to the ellipse of inertia of the homogeneous cross section. The radius of gyration is given by $r^2 = \dfrac{t^2}{12} = 12$ in.,^{2} and the distance of the antipolar from the centroid of the homogeneous cross section is $x = \dfrac{12}{12} = 1$ in. The coefficient C_f is computed in a manner similar to that of Example 2: $C_f = 0.335 \times 0.85 = 0.285$. Then the ultimate load of the column is $P = 51.6$ kips and, since the working load considered in the conventional theory was 10.0 kips, the safety factor is only 5.2.

---

[64] "A Graphical Method of Analyzing Eccentrically Loaded Concrete Sections," by Paul Andersen, *Civil Engineering*, January, 1940, p. 37.

Paul W. Abeles,[65] **Esq.** (by letter).—As explained by Mr. Whitney, the formulas of this paper do not take into account the excess strength that has been reported in beams and slabs with small percentages of steel. The reason for this neglect is that, in Mr. Whitney's opinion, the use of small percentages of steel is not likely to be as satisfactory in practical construction as in the laboratory; and, furthermore, it has not been demonstrated that the excess strength will remain after repeated loading. Against this statement it may be emphasized that small percentages of steel have become more and more common owing to the use of medium and high-grade steel. Before the use of new steel grades of unusually high yield point was permitted, many tests had to be made in various countries. In this connection (for example, on structures reinforced with twin twisted steel bars), tests with repeated loads were conducted which have proved that the behavior with such a loading is similar to that of structures reinforced with mild steel. It may be stated that a repeated loading in cases of higher percentages of steel also causes less favorable results than tests on beams, whose loading is gradually increased until failure.

The excess of strength in cases of small percentages of steel is especially great when high-grade materials are used. The excess of strength can be shown best by the theoretical lever arm of test specimens at failure c_t calculated for the breaking moment:

$$c_t = \frac{M}{A_s f_s} \qquad (59)$$

This value c_t may be compared with the value c according to Eq. 6

$$c = \left(1 - \frac{p\,m}{2}\right) d = \left(1 - \frac{p f_s}{2 \times 0.85 \times f_c'}\right) d = \left(1 - \frac{p}{1.7} k\right) d \qquad (60)$$

in which $k = \frac{f_s}{f_c'}$ represents the ratio of the steel yield point stress and the concrete cylinder strength. Although the ratios $\frac{c}{d}$ in Mr. Whitney's theory represent an improvement over the values j determined by usual designing method, they differ materially from the values $\frac{c_t}{d}$, calculated on the basis of test results, which may be shown in the following. In Table 1 only tests are dealt with whose percentages of steel are greater than 2%. Table 2 contains tests, conducted in 1912, of small percentages of steel. In this case, the ratio $\frac{c_t}{c}$ (which demonstrates the difference between real behavior and theory according to Mr. Whitney) varies between 1.006 and 1.188 for percentages of 0.49 and 0.98. As long as no greater differences are in question there would be no reason for any improvement; but newer tests, especially in cases of high-grade

materials, give much greater differences. This may be seen by reference to Table 13, which shows the relation between the ratio $\frac{c}{d}$ of beams or slabs and their reinforcement (between 0 and 2%). The values of $\frac{c_t}{d}$ calculated for several test results are tabulated. The ratio $\frac{c_t}{d} = 1$ represents a limit, the lever arm being identical with the distance of the reinforcement from the upper fiber, which case actually would be impossible should Eq. 59 be correct. This limit is materially surmounted, as shown in Table 13. The following test results have been taken into account: (1) Tests on slabs, conducted at Lehigh University,[19] Bethlehem, Pa.; (2) tests on rectangular and T-beams at Columbia University,[66] New York; (3) tests on rectangular beams by the writer[67] in Vienna, Austria; and (4) tests on tubular spun beams by Prof. C. Král[68] at Ljubljana, Yugoslavia.

Table 13(*a*) contains a selection of the Lehigh tests.[19] Two steel types were taken into account, one type with a yield point stress between 46,000 and 55,300 lb per sq in. (three different percentages of steel, two or three separate results for each percentage, respectively), and the other type between 93,000 and 95,000 lb per sq in. (two different percentages and only one test result each). Table 13(*b*) contains a selection of the Columbia University tests with two different steel types (yield point stresses 35,600 to 35,800 and 50,470 to 56,330 lb per sq in.), two different percentages in each case, no difference resulting between rectangular beams C_7 and C_{17} and T-beams D_3 and D_{13}. In Tables 13(*a*) and 13(*b*), also, the concrete cylinder strengths are given. The rectangular beams reported in Table 13(*c*), with a cross section 8 in. by 9 in., had a span of 8 ft and were loaded with two single loads in a distance of 3.3 ft; four different concrete mixes were tested, each with two different grades of steel (yield point stresses 37,100 to 37,600 and 87,000 to 95,200 lb per sq in.). From Table 13(*c*) (which contains average values of two specimens each), it can be seen that only concretes 1 and 4 have been taken into account, concrete 1 being of very low strength, much different from the high-grade concrete 4. For comparison the values $\frac{c}{d}$ have been computed on the assumption that $\frac{3}{4}$ of the cube strength given in the Table 13(*c*) (obtained from 8-in. cubes) is identical with the cylindrical concrete strength. The values j for $n = 15$ and ratios $\frac{c_t}{j}$ have been added in Table 13(*c*) for purposes of comparison. The tubular spun beams, according to Table 13(*d*), do not actually agree with this comparison, since they represent a combination of tubes and beams, which works very favorably, the automatic pre-stressing of the transverse reinforcement (owing to the centrifugal force during spinning) being of great advantage in regard to reduction of the principal stresses. Nevertheless, their results have been included to show the steel saving that is possible if consideration is given to the actual behavior of reinforced concrete structures with small reinforcement. In Table 13(*d*) only the results with the smallest breaking moments have been considered. In this case the percentages have been computed for the upper breadths of the tubular beams, and the ratios $\frac{c_t}{d}$ have been calculated with the assumption of an existing secondary reinforcement of one round bar (area = 0.22 in.) in either lower outside corner of the octagon, the values j_0 representing the ratios of the lever arms of T-beams $d - \frac{t}{2}$ and their depths d (t being the thickness of the slab). The tests were conducted on beams of 3.6-ft span and 7.4-ft span, subjected to two single loads in a distance of 1 ft and 1.5 ft, respectively.

[66] "The Modular Ratio," by K. Hajnal-Kónyi, *Concrete and Constructional Engineering*, Vol. 32, 1937, pp. 129, 189, 521.

[67] "Versuche mit Rechteckbalken, bewehrt mit besonders hochwertigem Stahl," by Paul Abeles, *Beton und Eisen*, Vol. 36, 1937, p. 295; also "Elastizität des Betons," by Paul Abeles, *Zement*, Vol. 26, 1937. p. 619.

[68] "Spun Tubular Beam," by P. Abeles, *Concrete and Constructional Engineering*, Vol. 35, 1940, p. 233.

From Table 13(*b*) it is seen that the results of tests made at Columbia University agree very well with those reported in Table 2. The ratios $\frac{c_t}{c}$ vary between 1.06 and 1.185; but the difference is much greater according to tests on slabs (Table 13(*a*)) and on rectangular beams (Table 13(*c*)). There is a discrepancy of 50% with a small percentage of medium-grade steel tests (Table 13(*a*)), whereas with a high-grade steel only a smaller excess of strength of 27.5% occurs. The Viennese tests, conducted by the writer, agree very well with those of Lehigh University, but in the first case slabs have been tested, and in the second case rectangular beams. Concrete 1, of very low strength, gives only an excess of strength with a small percentage by use of high-grade steel, whereas with a greater percentage no use can be made of the reinforcement, since the concrete strength is too low. In this case mild steel causes better results than high-grade steel similar to the test results (Table 13(*a*)). In neither case was the concrete strength very great. With concrete 4, of great strength, the excess of strength is greater when high-grade steel is used. (Similar results have been obtained with concretes 2 and 3.) The test results of spun tubular beams surpass those of rectangular beams and slabs materially. Attention is drawn to values $\frac{c_t}{j_0} = 2.13$ and 1.95 in the case of octagonal beams and of 3.07 (!) in case of beams with flat lower base, the concrete tensile zone being thus increased. Tests on these beams have proved that the concrete tensile zone, even at breaking stage, still resists to a large extent, in spite of the discontinuity caused by the cracks.

Even if the results of tests on tubular spun beams are eliminated, because of their different behavior, those of the tests in Tables 13(*a*) and 13(*c*) show an excess of strength of up to 50%, which fact is reason enough to study the matter more closely in order to make use of it in design. First, the fact itself may be investigated as to how these results can accord with the assumption that the yield point stress, or one connected with a definite elongation, is the reason for failure, the concrete tensile zone not cooperating due to cracks. The latter will be the case if the bond between concrete and steel is destroyed and the concrete strength is low. Actually, with increased concrete strength, the concrete area in the tensile zone cooperates to some extent, which causes the tensile stress of the reinforcement, between the cracks (especially in cases of small percentages), to be much lower than in the cracks. In the latter it ought to increase to a maximum stress calculated from the breaking moment, the tension in the concrete being neglected. Such a straining would cause the steel stresses between the cracks to increase gradually on both sides of the cracks, owing to the decreased bond, and thus obtain in the points of the cracks their greatest values. Such an irregular straining with maximum points at intervals seems to be unlikely to agree with the reality. It may be expected that a redistribution of stresses takes place and the greatest steel stresses are smaller than those computed for the crack points. This hypothesis was offered by the writer in 1936.[69] Besides, as long as the cracks are not too wide, it can be assumed that the actual steel stresses are materially greater than the yield point stress or its equivalent. Even if elongations of 5% and more are taken into account (the equivalent for yield point straining is only 0.2% and 0.4%, respectively, for permanent and total elongations), no great harm can be caused if the elongation extends only to a small length. The latter depends on concrete tensile and compressive strength, on the distribution of the reinforcement, its diameter and behavior (strain-stress diagram), etc., to avoid wide cracks and to insure a good bonding between the cracks. From this point of view, at failure, even stresses as high as the full strength may act in the steel at the cracks, as long as the latter have not surpassed a limit width. Besides, there is another possible explanation of the excess. The strain-stress diagrams of steel have been obtained on specimens of a certain length. It may be expected that the behavior of the material is quite different for a gage corresponding with the width of a crack, say, 0.2 in. From all these considerations it will be realized that further investigations would be of the greatest importance in finding the bases necessary for design. These particulars must be dependent on test results. K. Hajnal-Kónyi[70] has examined such a proposition which agreed very well with the tests reported in Table 13(*a*); but in this method only the compressive strength of the concrete is taken into account, and the results can therefore only correspond with the reality as long as a definite ratio exists between compressive and tensile strength, the respective bonding also being of importance. That method, for example, disagrees with the tests in Table 13(*c*). Concretes 2, 3, and 4, of different tensile and compressive strengths, differ little in their carrying capacities.

From this point of view it seems of greatest importance to make further investigations on beams and slabs reinforced with small percentages of steel to find the proper basis for an improvement in design, since small percentages become more and more common, owing to the use of high-grade material and of steel pre-stressing. For a definite concrete grade the basis can be found by a number of tests and can be applied to the design if definite equality of the concrete is guaranteed.

[70] Discussion by K. Hajnal-Kónyi of "A Study of Reinforcement in Concrete Slabs," by Inge Lyse and George R. Wernisch, *Journal*, Am. Concrete Inst., Vol. 33, 1937, p. 16–1.

O. G. JULIAN,[71] M. AM. SOC. C. E. (by letter).—In 1904 Arthur Newell Talbot, Past-President, Am. Soc. C. E., stated:[72]

> "The principles governing the strength and action of reinforced concrete construction have not been fully established and opinions and theories presented by engineers are somewhat conflicting."

That statement is as true today as it was 37 years ago. This is evinced by the discussion by sixteen authorities from eight different countries[3] regarding Prof. Rudolf Saliger's method published in 1937, by numerous articles regarding the effect of plastic flow published within the past fifteen years,[73] and by the discussion on The Joint Committee Report[74] published in 1940.

Concrete is not an elastic material but has characteristics not unlike those of a viscous fluid as defined by James Clerk Maxwell:[75]

> "If the stress when it is maintained constant causes a strain or a displacement in the body which increases continually with the time, the substance is said to be viscous. When this continuous alteration of form is only produced by stresses exceeding a certain value, the substance is called a solid, however soft it may be. When the very smallest stress if continued long enough will cause a constantly increasing change of form the body must be regarded as a viscous fluid, however hard it may be."

Messrs. W. H. Glanville and F. G. Thomas state:[76]

> "From the tests at the Building Research Station, it appears that if there is such a yield stress for concrete below which no inelastic deformation occurs as a result of loading, the value of this stress is so small as to be negligible."

General practice for reinforced concrete design is based on the Bernoulli-Eulerian theory that plane sections remain plane and that stresses follow Hooke's law. Experimental evidence indicates that, neglecting the effect of shearing detrusion, plane sections remain plane but that Hooke's law does not apply. If, as was the advocated practice prior to 1924, working stresses are limited to about one third of the ultimate unit strength of test cylinders, and if the variation of the equivalent modulus of elasticity with the duration of the loading is taken into account, the order of magnitude of the actual stresses and deflections may be computed on the basis that Hooke's law is valid. On account of the number of factors involved, the evaluation of the equivalent modulus of elasticity of concrete, even for low stresses, is highly speculative. As allowable stresses are raised, a point is reached where the action of the concrete is not even approximately elastic. At this point the application of Hooke's law and the use of the concept, equivalent modulus of elasticity, should be abandoned. It is at least questionable if this point has not been passed when working stresses equal $0.45\,f'_c$ for ordinary loads ($0.60\,f'_c$ with the effect of wind loads included) as is advocated at present. A proved method of design that does not involve the highly speculative quantity E_c should be accepted as a boon to the profession. Such a method, which is also simple, easily understood, and frankly recognizes concrete for what it is—a viscous or plastic material rather than an elastic material—is presented in the author's paper. For those cases in which static loads only are involved the method appears rational and amply proved empirically. The paper is comprehensive in as far as members subjected to unilateral flexure and such flexure combined with direct stress are concerned. However, it does not explicitly cover the important case of bilateral flexure and direct stress. Practically all columns of reinforced concrete frames and especially corner columns are subjected to such moments and direct stresses. It is hoped that the author will cover explicitly this important case in his closing discussion.

[76] "Studies in Reinforced Concrete, Further Investigations on the Creep or Flow of Concrete Under Load," by W. H. Glanville and F. G. Thomas, *Technical Paper No. 21*, Building Research Dept. of Scientific and Industrial Research, London, England, October, 1939.

It has been proved conclusively by independent tests[77,78] that, in the case of reinforced concrete columns subjected to axial forces only, the ultimate strength is independent of the elastic moduli, plastic flow, shrinkage, and temperature effects. For such columns, provided they are adequately reinforced laterally, the ultimate strength is a function of the yield point strength of the steel and the ultimate strength of the concrete only. In such a member the concrete, being viscous, gradually flows away from the load and in so doing transfers stress to the steel. When the load becomes equal to the yield strength of the steel, the latter becomes plastic, yields, and transfers stress to the concrete. Upon application of further increments of load the steel continues to carry load equal to its yield point strength, the remainder, of necessity, being carried by the concrete. When the concrete becomes stressed to its ultimate strength, it and the column fail. The ultimate load, P, for the column is given by the well-known formula,

$$P = R\,f'_c\,A_c + f_s\,A_s \ldots\ldots\ldots\ldots\ldots\ldots (61)$$

in which R is the ratio of the ultimate strength of the concrete in the column to f'_c of comparable concrete in test cylinders. For unreinforced columns

$$R = \frac{P/A}{f'_c} \ldots\ldots\ldots\ldots\ldots\ldots (62)$$

---

[77] "Fourth Progress Report on the Column Tests Made at the University of Illinois," by F. E. Richart and G. C. Staehle, *Journal*, Am. Concrete Inst., Vol. 28, 1932, p. 279 *et seq.*

[78] "Fourth Progress Report on Column Tests at Lehigh University," by Inge Lyse and C. L. Kreidler, *loc. cit.*, Vol. 3, 1931–1932, p. 317 *et seq.*

Tests[77] indicate variation in the value of R from 0.73 to 1.00 for members in air storage and from 0.46 to 0.80 for comparable members stored moist. It is somewhat questionable as to whether the value 0.85 used by the author is warranted, unless a high factor of safety is used.

It appears reasonable that much the same process, as described herein for an axially loaded column, takes place in a member subjected to flexure. Eq. 22, which is derived on the basis that there is sufficient compression steel to take all the compression without exceeding the yield point, implies that the concrete flows viscously and in time transfers all its load to the steel. By taking moments about the tension steel the yield point strength of the compression steel necessary to make Eq. 22 valid is found to be

$$A'_s f'_s = -P\left(\frac{2e + d'}{2d'}\right) \ldots\ldots\ldots\ldots\ldots\ldots (63)$$

in which the negative sign is used to signify compression. The sum of $A'_s f'_s$ and $A_s f_s$, of course, equals P. In this case the concrete contributes nothing toward resisting the load. A basic principle of the theory is that for loads of protracted duration the concrete in time relieves itself of all stress, provided the contiguous steel is not stressed beyond its yield point, and then, provided it is sufficiently strong, the concrete resists that part of the load that is not taken by the steel working at yield point stress. It should be emphasized that, in order to act in this manner, the concrete must have time to flow. This being the case, it appears that the theory may not be applicable to cases involving suddenly applied loads of transitory or cyclic nature such as impact or those resulting from the vibration of high-speed machines. It may be that the stress-strain relation for concrete subjected to very rapidly applied loads is practically linear up to the point of failure and that this point is materially different from that for static loads. Data on these points are not readily available.

The possible exclusion of the theory from the realm of impact loads leaves it a wide field of application, and there appears to be no good reason why it should not be widely used. It is interesting to note that Hardy Cross, M. Am. Soc. C. E., in 1931 stated:[79]

> "The method which we always use in America of computing the stresses in such [compressive] reinforcement on the basis of an assumed value of n is quite naive. * * * It may not be proper to go so far in this case as it is proposed to do in column design and depend upon the steel to carry load up to its yield point, but the tendency is evidently in that direction."

Since, as pointed out by the author, a balanced ultimate strength design requires several times the quantity of steel needed for a balanced design by the straight-line elastic theory, high yield point steel must be used in small beams if the design approaches balance for ultimate strength and the beams are not unduly crowded with steel.

---

[79] Discussion by Hardy Cross of "Flow of Concrete Under the Action of Sustained Loads," by Raymond E. Davis and Harmer E. Davis, *Journal*, Am. Concrete Inst., Vol. 3, 1931–1932, p. 265 *et seq.*

Differentiating M with respect to f'_c in the equation given in Fig. 7, the following is obtained,

$$\frac{\partial M}{\partial f'_c} = 0.456 \left[\frac{p}{p_0} - 0.256 \left(\frac{p}{p_0} \right)^2 \right] b\, d^2 \ldots\ldots\ldots\ldots\ldots (64)$$

This quantity is small and practically equal to $0.456 \frac{p}{p_0} b\, d^2$ when $\frac{p}{p_0}$ is small but approaches $\frac{1}{3} b\, d^2$ as $\frac{p}{p_0}$ approaches unity. For a beam of given cross section there is little increase in the resistance moment for a given increase in f'_c in case the steel ratio is small; but there is considerable increase when balanced design is approached. It appears, therefore, that there is little advantage in using high-strength concrete with a low steel ratio but that there is considerable advantage in using such concrete with balanced or nearly balanced design.

It is believed that the curved stress diagrams in Figs. 2 and 4 should indicate the maximum stress at the upper extremity of the beam. The diagrams as drawn imply that, in the process of loading the member, the laminæ near the upper edge of the beam were stressed to their ultimate strength and then, instead of failing, were relieved somehow of some stress while the load was still increasing. It is understood that, as the ultimate strength of the member is approached, the laminæ nearest the top of the beam transfer stress to those nearer the neutral plane, and that this process may continue until the stress for a substantial depth of the beam is practically constant—that is, rectangular stress distribution is approached. However, that laminæ stressed to their ultimate strength (in other words, broken) transfer a part of, but not all, the stress they were carrying to adjacent laminæ appears impossible. It is difficult to imagine the stress caused by a given strain being less than that caused by a lesser strain. These stress diagrams appear to require further justification. However, the point is largely academic and in no way invalidates the author's main argument. The exact shape of the stress diagram is of secondary interest. Other authorities have assumed the stress diagram to be represented by various curves, including parabolas up to the fifth degree.[80] These may all be replaced by the hypothetical rectangular diagram used by the author and others[80,81] as a mathematical tool. This concept, although it does not indicate the location of the neutral axis, is the simplest and hence the one best adapted for use in practical design work.

It is customary, in design, to refer the moment of the external loads to the centroidal axis of the member. However, in the equation immediately following Fig. 11 and in Eqs. 23 and 31 the quantity M is referred to the axis of the tension steel rather than to the axis customarily used. It would appear preferable to omit M from these equations, as it may lead to confusion.

Regarding factor of safety the author states (see heading "Flexure and Direct Load on Rectangular Sections"), "* * * it is customary to provide a greater factor of safety for axially loaded columns than for beams * * *." Factors of safety for columns, according to current codes,[82] vary from 4.5 for lightly reinforced tied columns to 2.75 for heavily reinforced spiral columns. The actual factor of safety of over-reinforced beams is not $\frac{f'_c}{f_c}$—which, according to current codes, is 2.22—but, as has been shown by the author (Table 7), 1.62 times that amount or 3.60. Furthermore, if full cognizance is taken of the eccentric loading to which practically all columns are subjected, and the author's method of design is used, there appears to be no good reason why comparable columns and beams should not be proportioned for identical safety factors. As stated by the author the first pronounced crack in a beam may occur at about 25% of the ultimate load; the corresponding percentage for a column increases as e decreases. If the appearance of the first pronounced crack is to be taken as a criterion, there appears to be considerable justification for using a higher factor of safety for members subjected to loadings with large eccentricities than for comparable members subjected to loadings with lesser eccentricities. This is the reverse of the author's statement as to customary practice. The writer cannot concur with the author's statement (see heading "Method of Design and Factor of Safety"),

[80] Discussion by Inge Lyse of "Design of Reinforced Concrete Members Under Flexure or Combined Flexure and Direct Compression," by Charles S. Whitney, *Journal*, Am. Concrete Inst., Vol. 8, 1936–1937, p. 498–21 *et seq.*

[81] "Plasticity," by A. Nadai, McGraw-Hill Book Co., Inc., New York, N. Y., 1931, Chap. 24, p. 168; and "Strength of Materials," by S. Timoshenko, D. Van Nostrand, 1930, Chap. 7, p. 237 (for materials with well-defined yield points).

> "Reasonably well-controlled concrete is such a reliable material at present that the use of any factor of safety to provide for sub-standard concrete can be eliminated by using f'_c as the minimum cylinder strength instead of the mean."

On jobs where considerably better than average supervision was exercised, the concrete strength was found to vary 30% either way from the mean. With sympathetic, omnipresent, and omnipotent supervision it has been found that the mean strength may be raised about 36% and the variation from this mean reduced to less than 10%. However, it is doubtful if such supervision will be available for all jobs. Miles N. Clair, Assoc. M. Am. Soc. C. E., reports[83] (under the heading "Variations of Compressive Strength of Concrete on Fourteen Projects Representing Approximately 100,000 Yards of Concrete") deviations from average 28-day compressive strength for any one project as follows:

	Plus (%)	Minus (%)
Maximum	63.0	65.6
Average	40.5	34.4
Minimum	18.5	10.1

These tests were made on concrete proportioned on the basis of 1 : 6 dry and loose by volume. The strongest cylinder for any job tested 4,980 lb per sq in., whereas the weakest tested 777 lb per sq in. The designer cannot know the minimum cylinder strength positively until 28 days after the last concrete is installed. Considering the possibility of loads being increased from the design loads, the variations that may occur in the available materials, and the difficulty of consistently obtaining proper supervision, a factor of safety of the order of 4.5 may not be excessive. This is in line with taking $f_c = 0.33\,f'_c$ in designing a beam according to the straight-line elastic theory and somewhat higher than that required by current codes. In case the loads are known definitely, satisfactory material is known to be available, and good supervision can be obtained, this factor may be reduced as found expedient.

CHARLES S. WHITNEY,[84] M. AM. SOC. C. E. (by letter).—The questions raised in the discussion have followed quite closely the pattern anticipated by the writer. They have for the most part been covered in the paper, but it is probable that additional consideration will help to clarify the subject.

The position that the present methods are best because they are familiar and have been used many years is not tenable unless they can be brought up to date and adjusted to new developments. Structural design methods have not advanced, in the twenty years since 1921, as much as the design of machinery and mechanical products, which have been practically revolutionized by the results of research. This has been due in part to the fact that the average structural designer is so circumscribed by codes that he thinks in terms of standard methods instead of underlying principles. A large proportion of structural research has been directed at the determination of factors involved in standard formulas without much examination of the meaning of the formulas themselves. The existence of the standard method has a tendency to direct the thinking of both the designer and the teacher and produce great inertia against the introduction of new ideas in practice. This inertia is of great value in so far as it protects against the adoption of unsound ideas, but it should not be permitted to discourage progress.

The plastic theory of reinforced concrete design has not been presented as a perfected standard but as a basis for research leading toward modernization of standard practice. It is the result of an attempt to build a practical design theory consistent with all pertinent facts that have been discovered regarding the nature of the materials, not with a few incomplete characteristics selected for convenience. There is some resistance to the conception of the rectangular stress block to represent the compressive stress in the concrete. Dean Grinter and Professor Caughey suggest that it is so contrary to physically observable phenomena that it is not sufficiently reasonable to be taught to students. The writer was interested in this reaction and has discussed it with a number of students and teachers who expressed themselves as being entirely satisfied with the use of the rectangle. It may well be that it would rouse the students' interest and stimulate them to pay more attention to the reasons for it, whereas the triangular distribution is so easily accepted that it leads to superficial consideration and a lack of understanding of the real conditions.

As a matter of fact, if the proper phenomena are observed, the rectangular block is truly consistent. There is no evidence that a better shape can be devised nor that any amount of research will ever lead to an accurate predetermination of the actual stress distribution under varying conditions.

---

[84] Cons. Engr., Milwaukee, Wis.

Fortunately, the determination of the actual stress distribution is unimportant if the total stress and its line of action are known. The stress-strain curves of Fig. 1 were given merely to indicate why the assumption of an equivalent rectangle is perfectly rational. Whether or not the maximum compressive stress at failure of the beam occurs at the face or in the interior is also unimportant.

The writer believes that there is a reduction in the stress toward the compressive face but that it may be small in amount and may occur very close to the ultimate load, especially in the case of high-strength concrete. He has observed the failure of concrete cylinders of strengths ranging up to 9,000 lb per sq in. and appreciates the reason for Mr. Hadley's skepticism regarding the descending portion of the stress-strain curve. With low-strength concrete, it is a simple matter to observe that beyond the maximum load the stress drops off gradually as the strain increases. With high-strength concrete, however, the failure appears to be sudden, and it is only at very slow testing speeds that a reduction in load just before failure can be noted. It should be realized that there is a sudden increase in strain that accompanies the sudden decrease in stress, due to the elasticity of the testing machine, and the stress-strain curve does not drop vertically.

In a beam, the concrete at the face is supported by the concrete in the interior, and compression failure does not occur until a sufficient area of the interior concrete is highly stressed. While the interior is being stressed, plastic flow effects a reduction of the stress at the face.

The writer does not feel that the stress-strain relation is sufficiently determinate to justify its direct application as suggested by Mr. Contini.

Since this paper was submitted for publication, the writer has received from Anton Brandtzaeg, M. Am. Soc. C. E., a copy of the report[85] on his tests to determine the strain and stress distribution in concrete members under bending or eccentric loading. The tests were made on heavily reinforced beams and struts about 6 in. deep, of concrete with cylinder strengths ranging from about 1,250 to 5,000 lb per sq in. Mr. Brandtzaeg assumed a stress distribution in the concrete as shown in Fig. 27.

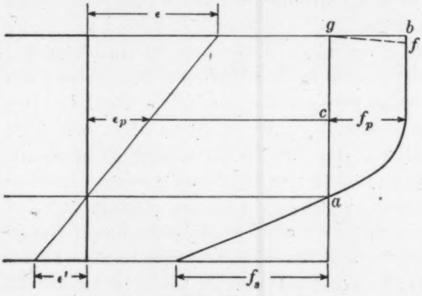

FIG. 27

The location of the neutral axis, a, is determined from the maximum strains in the concrete and steel, ϵ and ϵ', assuming the sections to remain plane. At c, where the strain is equal to the maximum strain given by prism tests, the stress is assumed to be equal to the prism strength, f_P, and the variation from a to c follows the stress-strain curve for the prism or an equivalent parabola.

---

[85] "Der Bruchspannungzustand und der Sicherheitsgrad von rechteckigen Eisenbetonquerschnitten unter Biegung oder aussermittigem Druck," by Anton Brandtzaeg, Norwegian Technical High School, Trondheim, 1935.

From c to g at the compression face, the stress is uniform and equal to the prism strength. Mr. Brandtzaeg suggests that there may be a falling off of the stress along such a line as $f\,g$ as the maximum load is approached but he does not consider it important. Rudolph Saliger reports[86] indications of a falling off similar to that in Fig. 4. Mr. Brandtzaeg reports that the loads and lever arms calculated according to Fig. 27 agreed satisfactorily with the actual measurements.

The value of $\frac{\epsilon}{\epsilon_P}$ for his strongest concrete (equivalent $f'_c = 5{,}000$ lb per sq in.) was 2.13, and for the weakest (equivalent $f'_c = 1{,}250$ lb per sq in.) it was 6.87. The value of prism strength f_P was 0.75 to 0.80 times the strength of 30-cm cubes. If the cube strength is assumed at 1.13 times the cylinder strength, this would be 85% to 90% of the cylinder strength, which agrees very well with the writer's theory. Mr. Brandtzaeg also suggests the use of an equivalent rectangle, but his solution involves the ratio $\frac{\epsilon}{\epsilon_P}$, which is rather erratic although it depends in a general way on the strength of the concrete.

TABLE 14.—COMPARISON OF ACTUAL AND THEORETICAL LOADS FOR THOMAS TESTS

SERIES II; f'_c (AVERAGE) = 1,960 LB PER SQ IN.		SERIES III; f'_c (AVERAGE) = 4,640 LB PER SQ IN.	
Item No.	Ratio[a]	Item No.	Ratio[a]
6	0.919	12	0.778
7[b]	0.993	13[c]	1.059
8	0.922	14[b]	0.787
9	1.007	15	0.845
10	0.827	16	0.875
11	0.905	17	0.754
....	....	18	0.860
....	....	19	0.860
Average	0.930	Average	0.853

[a] Actual load divided by computed load (see Col. 6, Table 10).

[b] Fixed ends.

[c] $f'_c = 5{,}400$ lb per sq in.

Although the writer believes with Professor Ernst that more tests are needed, he does not agree that the tests already made indicate that the equations are not correct for concrete strengths up to 5,000 lb per sq in. In his analysis of the Thomas tests, Professor Ernst used in the formulas the minimum concrete strength and the average steel strength for each series. Therefore, he did not get as true a check on the accuracy of the formula as he would have if correct values were used in each case. If the individual strengths are used for each case, the comparison of actual to computed strengths of the columns is given in Table 14 following the form of Professor Ernst's Table 10.

TABLE 15.—RELATIONS BETWEEN COLUMN AND CYLINDER STRENGTHS

Description	Air storage				Moist storage			
6-in. by 12-in. cylinder strength, in lb per sq in.	2,515	4,565	5,705	Average	2,685	4,445	6,510	Average
Column strength divided by cylinder strength	0.92	0.79	0.88	0.86	0.71	0.68	0.75	0.71

The writer believes that these results are probably caused by two conditions:

First, inadequate anchorage of the reinforcing steel caused slipping of the bars and splitting of the concrete ends. Contrary to Professor Ernst's statement, the writer believes this would affect the tests with large eccentricity, as well as the others, and Table 14 indicates no consistent trend. There is no doubt but that the efficiency of the specimens was reduced by the inadequate ends.

---

[86] "Versuche über Zielsichere Betonbildung und an druckbewerten Balken," by Rudolph Saliger, *Beton und Eisen*, Nos. 1 and 2, 1935.

Second, the control tests were made on 6-in. cubes and the tests on plain concrete columns made at the same time showed the following relations between column and cube strengths:

6-in. cube strength, in lb per sq in.	Column strength divided by cube strength
2,460	0.67
5,780	0.61

This reduction of the ratio of column-to-cube strength for the stronger concrete might be expected to account for a reduction in the strength of the reinforced columns. This may indicate that the standard 6-in. by 12-in. cylinder is a better control specimen than the 6-in. cube because the column tests made at the University of Illinois showed no such trend. The latter are reported in Table 15.[87]

Even more conclusive evidence that there is no reduction in the relative capacity of members of concrete with strengths up to at least 5,000 lb per sq in. is furnished by the high-strength specimens of the Slater and Lyse tests (Table 1) and the Brandtzaeg tests. In the range above 5,000 lb per sq in., evidence is lacking. There is no definite explanation for the lack of strength of the Richart and Olson specimens, but it is significant that those under axial load were also deficient.

The writer does not agree with Professor Abbett that the plastic theory is appropriate only for cases of sustained loading. The equations are based on tests made at ordinary testing speeds and should be suitable for general use. They are intended to indicate the strength of the member accurately so that the proper factor of safety can be provided. If they accomplish that, the calculation of theoretical working stresses is of no particular value. The writer believes that the theoretical stresses calculated by the straight-line formula are inaccurate and not satisfactorily indicative of the true factor of safety, especially for the higher percentages of steel. In that case, the straight-line formula indicates steel stresses lower and concrete stresses higher than the actual stresses to such a variable extent that proper interpretation of the results is difficult or impossible.

The significance of the comparison made by Mr. Stewart is questionable because there appears to be no justification for the assumption of a fixed value of $k\,d$. The sections do not have equal strengths, either actually or theoretically, and therefore are not comparable. Using the same bending moment (26,600 in-lb) and unit costs (steel at 5 cents per lb and concrete at $16 per cu yd), the writer has made a comparison of costs for different percentages of steel according to the plastic theory and for balanced reinforcement according to the straight-line formula. This comparison is shown in Table 16.

---

[87] "Fourth Progress Report on the Column Tests Made at the University of Illinois," by F. E. Richart and G. C. Staehle, *Journal*, Am. Concrete Inst., Vol. 28, 1932, p. 296.

This indicates very little difference in cost of beams of low percentages of reinforcement designed by the two methods. The plastic-theory formula requires a little less steel than the straight-line formula when p is less than 0.01 in. It also indicates a minimum cost at about 2% of steel for the conditions assumed, but several factors may operate to raise the most economical percentage above that value. They are the cost of forms, variation in dead load, and the fact that only a part of the beam requires maximum reinforcement. It may be cheaper to use a higher percentage of steel in that part than to increase the concrete section for the full length. This is especially true at the ends of continuous beams where haunches or deep stems may be avoided. The general use of the maximum percentage of steel will probably not be economical, but it will undoubtedly be desirable in special cases. Mr. Eremin may have had this in mind when he said the formulas require an excessive percentage of steel in deep girders, but the writer does not understand that there is any difference in their application to deep or shallow sections. The designer is left free to determine the most economical percentage of steel in any case, and need not use the maximum.

TABLE 16.—COMPARISON OF COST OF BEAMS

d (inches)	p	A_s, in sq in.	$\frac{c}{d}$	Cost per lin ft
PLASTIC THEORY (f'_c = 3,000 LB PER SQ IN.; f_s = 50,000 LB PER SQ IN.; FACTOR OF SAFETY = 2.5; AND b = 12 IN.)				
12.5	0.010	1.46	0.89	$0.964
10.6	0.0136	1.74	0.865	0.920
9.1	0.020	2.19	0.802	0.904
8.4	0.025	2.52	0.755	0.943
8.2	0.0274	2.70	0.731	0.959
STRAIGHT-LINE FORMULA (f_c = 1,350 LB PER SQ IN.; f_s = 20,000 LB PER SQ IN.; n = 10; AND b = 12 IN.)				
10.6	0.136	1.74	0.866	$0.920

A treatment of irregular cases such as is suggested by Mr. Polivka should be possible, but the writer believes it is a mistake to base calculations on the full section of the concrete. When the steel on one side is in tension, the concrete between the tensile steel and the outside of the concrete has no effect on the strength of the member and could not influence the location of the neutral axis nor the compression area.

Mr. Abeles is correct in his statement that further investigation is necessary to determine the proper basis of design with small percentages of high-strength steel. The apparent excess strength as compared with mild steel is no doubt due to the lack of a definite yield point. The writer has adopted what seems to be a conservative definition of yield point (the stress corresponding to a total unit strain of 0.004), and, if it can be proved that the actual useful strength is greater with high-strength steel than the equations indicate, an allowance might be made for it by changing the definition of the yield point, using a greater strain. There is not sufficient data to prove whether or not 0.004 is the best value.

Mr. Julian's discussion of the suggestion that "* * * any factor of safety to provide for sub-standard concrete can be eliminated by using f'_c as the minimum cylinder strength instead of the mean" indicates that the writer has not made his meaning clear. The writer wishes to propose that the value of f'_c be selected so as to provide in itself the proper factor of safety for substandard concrete, taking into account the job conditions. The concrete will then be designed for a strength higher than f'_c by an amount depending on the accuracy of the job control that is to be expected. This will have the effect of focusing attention on the concrete strength and simplifying the design by eliminating consideration of that factor from the design formulas. It will help to avoid the application of a standard factor of safety to jobs where it should not be used because of a variation in the concrete control methods.

DYNAMIC STRESS ANALYSIS OF RAILWAY BRIDGES

By R. K. Bernhard,[1] M. Am. Soc. C. E.

With Discussion by Messrs. R. S. Chew, and R. K. Bernhard.

Synopsis

Since it is a known fact that stresses due to dynamic impact often become an important factor in the design of a railway bridge, it is the purpose of this paper to indicate a simple method by which these stresses may be determined. In order that this method may be presented in the shortest manner, it will be restricted first to the main trusses or girders of single-track spans with known static loads. It is assumed that, as a steam locomotive crosses such a span at the "critical speed," the greatest vibrations are set up by the action of the free and unbalanced centrifugal forces of the moving parts. The various formulas deduced herein are set up in the form of nomographic charts. Seven of these are located side by side for ease of manipulation. If the damping capacity of any vibrating structure is known, the true value of the stresses due to impact can be read from the chart. One problem is worked through, showing the advantages, and also the limitations, of the method. Finally, a comparison is given with the impact percentage of standard specifications.

Introduction

One of the members of a steel railway bridge in Europe failed recently while a train of comparatively light weight was passing over it at a relatively low speed. The result has been a revival of the discussion of dynamic overloads. This question is often "sidetracked," particularly by practical field engineers, since purely mathematical methods[2–10] of developing the analysis may become extremely involved.

Note.—Published in January, 1941, *Proceedings*.

(footnotes continued on next page)

Most impact formulas of standard specifications, which make an allowance for the dynamic increment in the design of bridges, are derived more or less by experiment. Experimental methods for finding the impact value by field tests, using various types of measuring apparatus, are usually rather time-consuming. Even if the matter is approached from a strictly mathematical point of view, only approximate solutions can be obtained. For some time past many investigators have attempted to find a method of computing this impact value which would combine sufficient accuracy with ease of manipulation. One of the most comprehensive papers on this subject was published by J. B. Hunley in 1935.[5]

Following are nomographic charts which have been developed leading to an approximate solution of the dynamic problem by combining theoretical investigations with the results of numerous field tests that have been conducted both in the United States and in Europe.

There are various methods of including the impact factor in the design, but the simplest seems to be to make the computation in two steps: First, the structure should be designed for dead load and moving load in the usual static manner; and second, a supplementary computation must be made of the stresses caused by those locomotives which produce the maximum dynamic effect. This second computation is often the determining factor because, although the static investigation is based on the heaviest moving loads, larger dynamic stresses due to resonance effects may be set up by light or intermediate loads.

The computation as given herein does not provide a general solution for all possible cases. For the sake of simplicity, the method is made applicable only to such conditions as often occur in designs. Among these may be mentioned single-track, simple spans from 60 to 300 ft in length.

ASSUMPTIONS

The following assumptions are made:

(1) For main bridge girders the largest dynamic effect will occur at the critical speed. This critical speed is that at which the period of the unbalanced masses of the steam locomotive drivers, causing alternating forces of a sine form, coincides approximately with the natural frequency of the bridge. Hence, the fundamental consideration of dynamic design is based on this resonance case.

(2) Supplementary weights to equalize, partly, the reciprocating masses of steam locomotives passing at their highest allowable speed may cause centrifugal forces attaining, as a maximum, 15% of the vertical loads of drivers.[6]

[10] "Mathematical Studies of Vibrations of Girders in Particular Cases," by R. Desprets; publication of the International Railroad Assoc., 1930 (Madrid) and the International Bridge Assoc., 1930 (Luettich).

(3) The damping capacities of bridges are taken from experimental values of published tests.[11,12,13]

(4) Furthermore, experiments have shown that in the resonance case periodic forces may cause an amplifying factor of 16, with the loads acting in the middle of the span only. This decreases to 13, with the same loads moving.[9] The reduction factor becomes, therefore, 13 : 16 = 0.81. Hence, to simplify the design, the effect of the motion of the loads (the increasing influence in the center of the bridge and the decreasing influence at the ends) may be taken into consideration by this reduction factor.

(5) The main girders in the resonance case may oscillate in their fundamental vertical mode; for trusses, therefore, one impact value for all members is justified. Other periodic vibrations, such as horizontal or torsional vibrations, or even nonperiodic vibrations, are negligible in general. Theoretical derivations have proved that they do not exceed 7%, assuming the dynamic stresses due to the wheel effect at resonance to be 100%.[9] Old locomotives of British railways produced a strong "hammer-blow" effect.[7] The lifting of the driving wheels from the rails causes heavy shocks,[8] which, however, are of primary importance for the rails and track girders only. Hence, nonperiodic vibrations, excited by direct impact on the track girders (rail joints or flat spots on wheels), which in certain cases might increase the impact value for single members of the main girders (overtones), are neglected.

(6) The dynamic design is developed only for statically determinate main girders and trusses of railroad bridges, with span lengths from 60 ft to 300 ft. The wheel effect does not come into consideration for span lengths less than 60 ft, since the critical speed is usually higher than the highest allowable train speed. The nomographic charts herein take into consideration all possible maximum and minimum values of the dynamic properties of loaded and unloaded bridges within the aforementioned span range.

COMPUTATION

Determination of the Natural Frequency of the Bridge.—The natural frequency ω_n of the bridge in cycles per second may be computed by the formula:[13]

$$\omega_n = \frac{\pi}{2}\sqrt{\frac{5}{384}\frac{g}{y}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which (see Appendix) g = acceleration due to gravity in feet per second per second and y = deflection of the bridge in feet.

In order to produce the deflection for the equivalent load, two extreme values must be taken into consideration: The minimum, being the dead load alone, and the maximum, being the dead load combined with the load of all vehicles on the bridge. For the moving loads, a uniformly distributed load

may be assumed. In most cases, the natural period with dead plus moving load is critical.

Determination of Critical Speed, Caused by Wheel Effect on the Bridge.—The critical speed in miles per hour may be determined by the equation:

$$V_c = 0.68\,\pi\,D\,\omega_n \qquad (2)$$

in which D = diameter in feet of the drivers of the passing locomotive.

The maximum and minimum values of V_c are determined by assuming the largest and smallest diameters of the drivers of the passing locomotives. A special case is the critical speed for wheels with flat spots on heavy freight cars with small wheel diameters. It is obvious that if the critical speed is higher than the highest allowable train speed, no further dynamic investigation is necessary.

Determination of the Number of Vertical Impulses Caused by Unbalanced Masses of the Passing Steam Locomotives.—The number of impulses, N_i, alternating with a sine form caused by unbalanced masses of a single driving wheel, may be determined by the formula:

$$N_i = \frac{L}{\pi D} \qquad (3)$$

in which L = length of span in feet.

Determination of the Number of Vertical Impulses Necessary to Build up Oscillation.—The logarithmic damping decrement (θ) of bridges tested in recent years by the writer varies between 0.05 and 0.20.[11] It may be determined by recording power-input frequency diagrams (resonance curves) by means of mechanical oscillators. The width at the half point of the diagram, divided by the resonance frequency and multiplied by π, is equal to the damping decrement.[12] An average value of $\theta = 0.075$ may be suggested until more results are available. The nomographic charts, however, permit the use of maximum and minimum values.

The amplifying factor, F, for the resonance case (stable stage) and the number of periods, N_t, necessary to build up the oscillation (transient stage) may be determined with sufficient accuracy from the decrement, θ, by the following equations:[13]

$$F = \frac{\pi}{\theta} \qquad (4a)$$

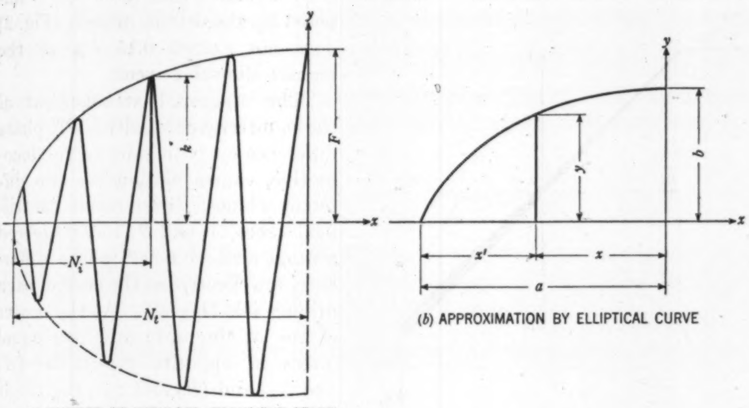
and

$$N_t = \frac{2.3}{\theta} \qquad (4b)$$

In other words, F is the multiplication factor for obtaining the maximum influence for the dynamic forces in the resonance case.

The time to build up the oscillation in the resonance case is determined by the number of cycles that are necessary to reach the maximum excursion (stable stage). To attain this stable equilibrium (that is, constant amplitudes) an infinite time is necessary; to reach a finite time value, however, it may be assumed that the equilibrium is reached as soon as the amplitudes have increased up to nine tenths of their final theoretical value.[12]

The computation is still accurate enough if, for the sake of simplicity, the amplitudes are assumed to increase from 0 to N_t cycles on an elliptic envelope (Fig. 1(*a*)). The following simple formula can be developed from Fig. 1(*b*):



(*a*) NUMBER OF IMPULSES (TRANSIENT STAGE)

(*b*) APPROXIMATION BY ELLIPTICAL CURVE

FIG. 1.—BUILDING UP VIBRATIONS

$$y = \frac{b}{a} \sqrt{a^2 - x^2} \qquad (5a)$$

or, for $x' = a - x$:

$$y = \frac{b}{a} \sqrt{2\,a\,x' - (x')^2} \qquad (5b)$$

Substitute $y = k$; $b = F$; $a = N_t$; and $x' = N_i$.

$$k = \frac{F}{N_t} \sqrt{2\,N_t\,N_i - N_i^2} \qquad (6)$$

The value k represents that part of the amplifying factor which, after N_t cycles, is still effective.

Substituting for F and N_t the values of Eq. 4,

$$k = 1.365 \sqrt{2\,N_t\,N_i - N_i^2} \qquad (7)$$

For most practical cases, the first part of the curve with small, and the last part with large, values of k do not occur; hence, the assumption of the elliptical envelope is accurate enough.

For further simplification, the increasing influence caused by the motion of the live loads near the center of the span, as well as the decreasing effect at the ends, may be taken into consideration by a reduction factor (experimental value) of 0.81:

$$k_w = 0.81 \times 1.365 \sqrt{2\,N_t\,N_i - N_i^2} = 1.11 \sqrt{2\,N_t\,N_i - N_i^2} \qquad (8)$$

Hence, k_w is equal to that part of the amplifying factor (F) caused by vertical forces of unbalanced locomotive drivers which is effective after N_i impulses. The symbol k_w may be called the amplifying number.

Determination of the Additional Vertical Forces.—The maximum value of the additional vertical forces can be determined by assuming that the load P_A imposed by the driving wheels (Fig. 2) does not exceed 0.15 P_A at the highest allowable speed.

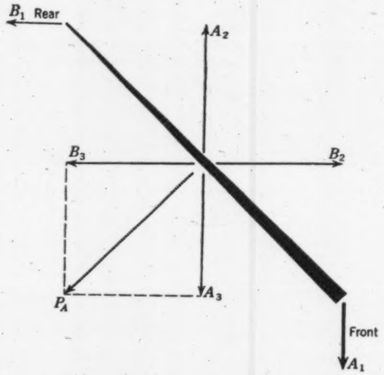


FIG. 2.—DISTRIBUTION OF UNBALANCED FORCES OF STEAM LOCOMOTIVE DRIVER AXLES

The staggered arrangement of the counterweights, with a 90° phase difference on both sides of the locomotive, causes motions in two different planes. Two equal centrifugal forces, A_1 and B_1, in a staggered arrangement of a 90° phase difference, are effective at the ends of each driving axle (Fig. 2). At the center of the driving axle add two equal forces in opposite directions—(A_2 and A_3) and (B_2 and B_3); the result is two staggered couples, composed of forces (A_1 and A_2) and (B_1 and B_2) with a 90° phase difference.

The remainder may be replaced by two staggered single forces, A_3 and B_3, with a 90° phase difference, and a resultant force $P_A = A\sqrt{2} = 1.4\,A$, assuming that $A_3 = B_3 = A$.

The first couple (forces A_1 and A_2) will excite the bridge to torsional vibrations; the second couple of forces (B_1 and B_2) will excite it to horizontal vibrations. Both couples may be neglected in the foregoing case. Only the vertical component $P_A = A\sqrt{2}$, alternating in a sine form and effective along the center line of the bridge, is to be considered. The numerical example has been computed, however, with the wheel load P_a, and not with $\frac{1}{2}$ times the vertical component P_A. This is to simplify any comparison with the static calculation, where often wheel loads of the theoretical train (standard specifications) are used. Finally, the free forces of the different driving wheels of one locomotive may be combined into one average force Z.

Knowing that the centrifugal forces increase with the square of the speed (angular velocity), the following equation is valid:

$$Z = 0.15 \times N_w \times P_A \left(\frac{V_c}{V_m}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which V_m = highest allowable speed of the locomotive, and N_w = number of driving wheels of one locomotive.

The assumption is made that the case of two or even more locomotives on the bridge, with their counterweights in phase at the same time, is a rare exception which need not be taken into consideration; furthermore, the damping influence of adjacent cars, especially on longer bridges, may be neglected.

The effective vertical additional forces to build up the vibration are:

$$Z_w = k_w \times Z \quad \text{(10)}$$

Hence, Z_w is the maximum dynamic load on the bridge in tons, which becomes effective during the passage of the locomotive. In other words, it is the load that builds up the maximum oscillation under most unfavorable dynamic conditions.

Determination of Dynamic Impact.—The total stress is a combination of a static pre-stress and a superimposed dynamic stress (Fig. 3). The maximum value of the static pre-stress may be taken from the routine static computation, but without impact, or from a design based upon the actual static loads of the previously chosen locomotive, whichever causes the most unfavorable conditions.

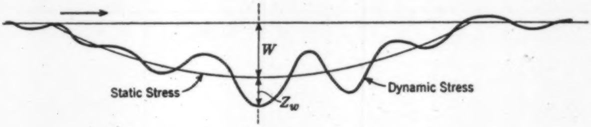

FIG. 3.—STATIC AND DYNAMIC STRESS DIAGRAM OF BRIDGE

This static load may be equal to W tons. The dynamic load has already been determined by Eq. 10 to be Z_w tons. Eq. 11 gives the final dynamic impact number:

$$\phi = \frac{W + Z_w}{W} \quad \text{(11)}$$

Hence, to obtain the maximum static and dynamic stresses (total stress) for a certain vehicle (locomotive), the static loads must be multiplied by ϕ. Thus, for special cases, ϕ may replace the impact value in standard specifications.

NOMOGRAPHIC CHARTS

The nomographic charts in Figs. 4 and 5 make it convenient to determine the dynamic effect for an existing bridge, as well as for a new bridge design. Normally, space permitting, these charts should all be on the same sheet. In many cases it is sufficiently accurate to determine the final value with seven adjacent nomographic charts and one double scale. Networks of curves have the advantage of being independent of the quality of the drawing paper (no changing scale through humidity); however, they may cause confusion among different curves.

A special advantage of the nomographic chart is the easy determination of maximum and minimum values simultaneously. All scales and indicators, corresponding to Eqs. 1 to 11, could be drawn in logarithmic scales.

The seven nomographic charts in Figs. 4 and 5 may be constructed as a simple mechanism. The connecting lines can be drawn on celluloid strips, mounted with flexible links on the scales. After having determined the fundamental values on the proper scales, the result will be indicated automatically.

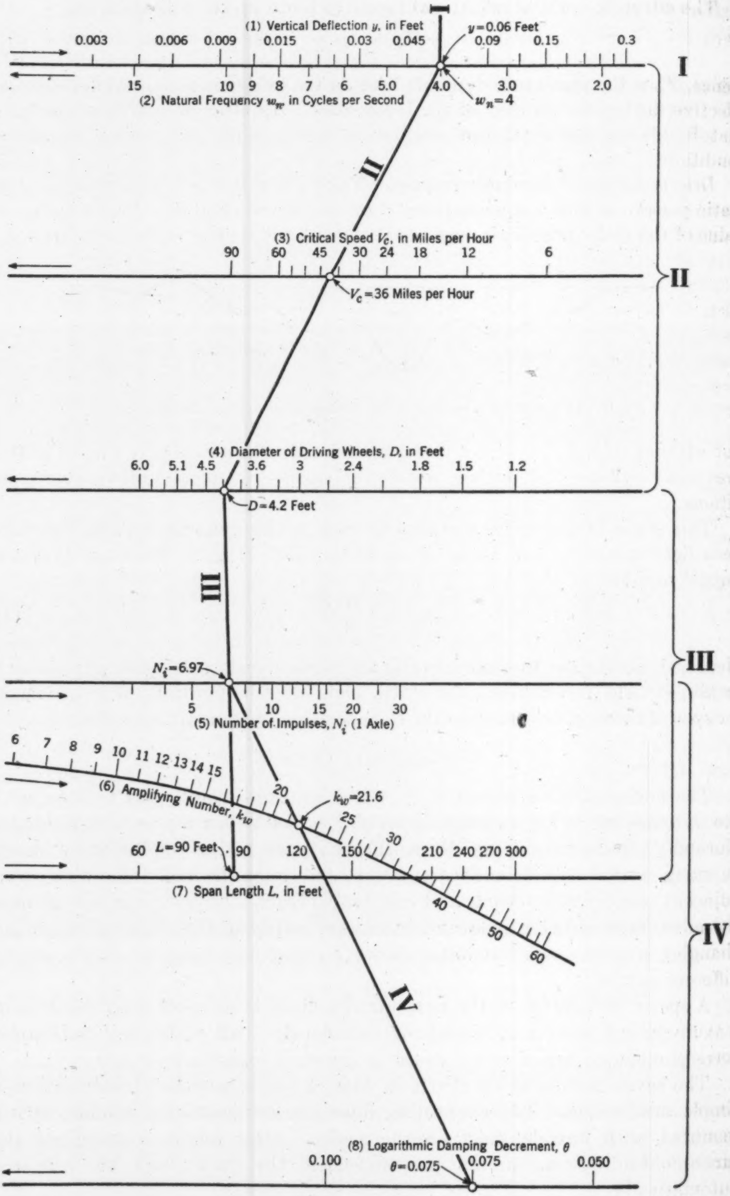

FIG. 4.—NOMOGRAPHS I TO IV

Certain cases may yield a dynamic impact number as great (for example) as $\phi = 3$, which is higher than that required by standard specifications. It must be borne in mind, however, that such a high dynamic impact number is not necessarily dangerous. Assume an allowable stress of 16,000 lb per sq in., an impact value, corresponding to the standard specification, of 1.4, and the same train loads as in the static design. The live load, including $I = 140\%$, may cause five eighths of the allowable stress ($\frac{5}{8} \times 16{,}000 = 10{,}000$ lb per sq in.). Hence, the combined stress of dead and live loads will be increased to $6{,}000 + 10{,}000 \times \frac{3}{1.4} = 27{,}400$ lb per sq in. This value is lower than the yield strength, but might be higher than the endurance limit of the steel (punched or

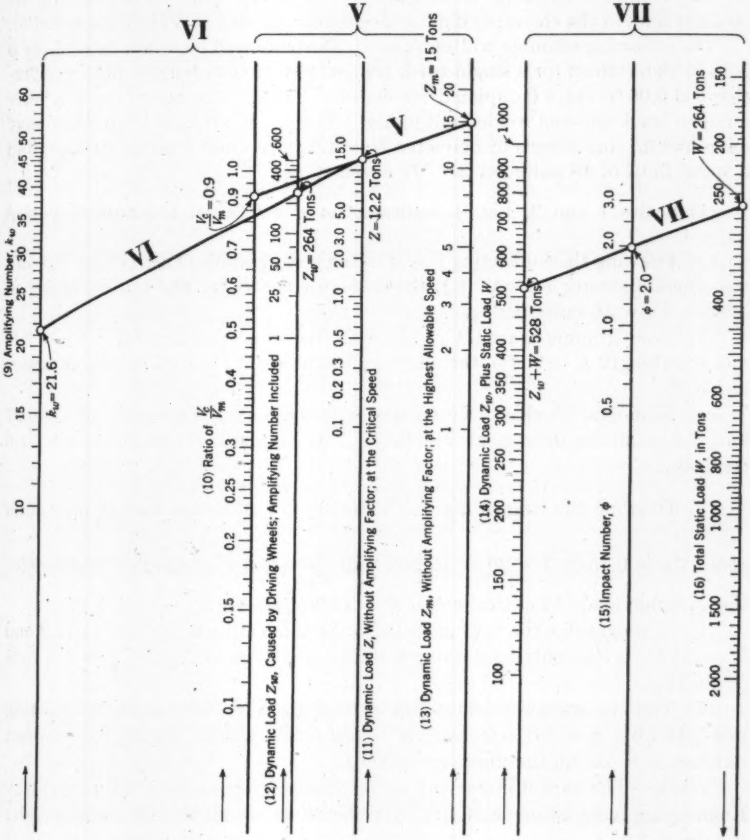

FIG. 5.—NOMOGRAPHS V TO VII

drilled structural steel). However, the bridge will stand the traffic for many years without failure, especially if the traffic is light (effect of repose).

NUMERICAL EXAMPLE

The complete dynamic investigation of a bridge consists in drawing six straight lines in the corresponding nomographic charts I to VII (Figs. 4 and 5).

The following example will serve as an illustration: The dynamic number ϕ is to be determined for a single-track bridge of 90-ft span length, with a deflection y of 0.06 ft, and a damping decrement θ of 0.075. The structure may have an open trackway and welded rail joints. The passing freight locomotive may have five driving wheels of diameter $D = 4.2$ ft, a wheel load of 20 tons, and a speed limit of 40 miles per hr. In seven steps:

(1) Scales 1 and 2, Fig. 4, indicate, for $y = 0.06$ ft, the natural period $\omega_n = 4$.

(2) Drawing the connecting line II in the nomographic chart II ($\omega_n = 4$ and the wheel diameter $D = 4.2$ ft), the indicator shows for the critical speed in scale 3: $V_c = 36$ miles per hr.

(3) Nomographic chart III yields, with the connecting line III ($D = 4.2$ ft and span length $L = 90$ ft), the number of impulses $N_i = 6.97$ on the indicator (scale 5).

(4) Nomographic chart IV indicates, with the connecting line IV ($N_i = 6.97$ and the damping decrement $\theta = 0.075$), an amplifying number: $k_w = 21.6$ (scale 6).

(5) Drawing the connecting line V in Fig. 5 $\left(\text{dynamic load at maximum speed } Z_m = 0.15 \times 5 \times 20 = 15 \text{ tons and } \frac{V_c}{V_m} = 0.9\right)$, the indicator shows for the dynamic load: At critical speed $Z = 12.2$ (scale 11).

(6) Nomographic chart VI gives, with the connecting line VI ($Z = 12.2$ and $k_w = 21.6$), the amplifying number included, the dynamic load: $Z_w = 264$ tons (scale 12).

(7) The final answer in chart VII is determined by drawing the connecting line VII ($W_{90\text{ ft}} = 264$ tons and $W + Z_w = 528$ tons), yielding the impact number: $\phi = 2.0$ on the indicator (scale 15).

Result.—The impact increment, corresponding to the old American Railway Engineering Association (A.R.E.A.) specifications, would be 1.79 and is smaller than $\phi = 2.0$.

The maximum stress caused by the live load, including $I = 179\%$, may be five eighths of the total stress $= \frac{5}{8} \times 16{,}000 = 10{,}000$ lb per sq in., or, taking ϕ into consideration, the stress is $10{,}000 \times \frac{2.0}{1.79} = 11{,}200$ lb per sq in. The stress caused by the dead load is three eighths of the total load; hence, $\frac{3}{8} \times 16{,}000 = 6{,}000$ lb per sq in., and the total stress, therefore, becomes, 17,200 lb per sq in.

The dynamic investigation proves in this case that the endurance limit for punched or drilled structural steel, which may be assumed as one fourth of the ultimate tensile strength ($0.25 \times 65{,}000 = 16{,}250$ lb per sq in.), is about 1,000 lb per sq in. smaller than the maximum dynamic stress.

CONCLUSIONS

The example presented herein can be supplemented to include span lengths from 60 ft to 300 ft and three different and comparatively light two-cylinder steam locomotives. The three locomotives are: One high-speed locomotive with three pairs of driving wheels of 6.9-ft diameter, 20-ton wheel load, and an allowable speed of 75 miles per hr; one medium-speed locomotive with three pairs of driving wheels of 5-ft diameter, 15-ton wheel load, and an allowable maximum speed of 55 miles per hr; and the aforementioned freight locomotive. The freight locomotive, with its five pairs of small drivers and relatively slow allowable speed, but comparatively large wheel loads, causes the highest dynamic impact.

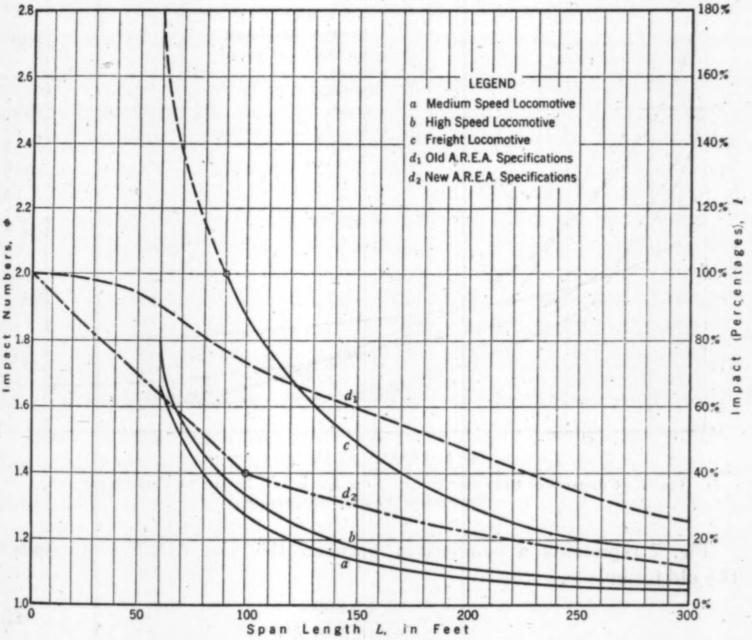

FIG. 6.—COMPARISON BETWEEN IMPACT NUMBERS ϕ OF THREE DIFFERENT TYPES OF LOCOMOTIVES AND A.R.E.A. SPECIFICATIONS

This result has often been verified in field tests.[5,7,9,13] It is not the two-cylinder high-speed and medium-speed steam locomotives, but nearly always two-cylinder freight engines with small driving wheels and relatively slow allowable speeds, which cause the greatest dynamic stresses. The numerous impulses on the bridge, and the centrifugal forces growing rapidly to their maximum value, are predominant.

For high-speed passenger service, steam locomotives with three or more cylinders, electric engines, or light-weight motor-driven engines may come more and more into favor. For freight traffic, the heavy two-cylinder locomotive with its high impact influence cannot be replaced so easily.

Fig. 6 shows clearly the increasing value of ϕ for bridges with shorter span lengths (60 ft to 120 ft). Similar results are reported by other investigators;[4,7] for relatively long bridges (more than 300 ft), as well as for short bridges (less than 90 ft), the dynamic influence caused by resonance between the unbalanced masses of steam locomotive parts and the natural frequency of the bridge decreases considerably. The tendency of the ϕ-curves, which decrease gradually with the span length (over 90 ft), is the same as in the impact curves of standard specification.

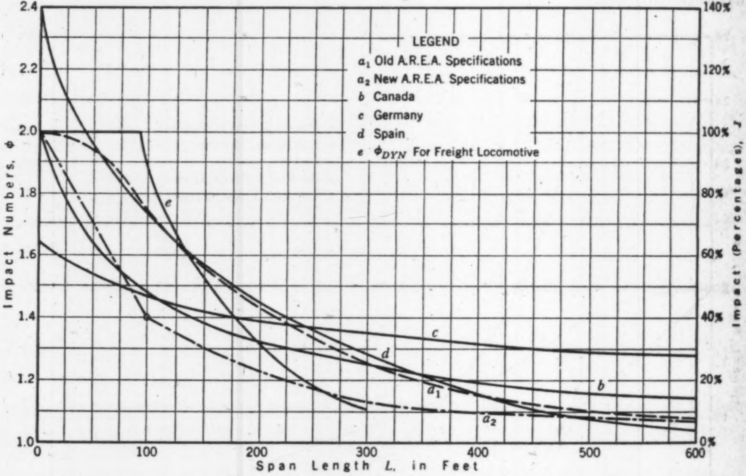

FIG. 7.—COMPARISON BETWEEN IMPACT NUMBERS ϕ AND IMPACT IN PERCENTAGE FOR BRIDGES IN VARIOUS COUNTRIES

Fig. 7 represents a comparison between the two A.R.E.A. formulas:[5] The old formula—

$$I = \frac{30{,}000}{30{,}000 + L^2} \qquad (12)$$

and the new formulas—

$$I = 100 - 0.60\,L\ (L \leq 100 \text{ ft}) \qquad (13a)$$

and

$$I = \frac{1{,}800}{L - 40} + 10\ (L \geq 100 \text{ ft}) \qquad (13b)$$

as well as the impact specifications of other countries.

It must be borne in mind, however, that, for span lengths less than approximately 90 ft, the dynamic influence will increase considerably for other reasons. The wheel effect is no longer important, because the critical speed becomes higher than the speed limit. On the other hand, the direct shocks are more effective since, for example, the distance from the exciting (nonperiodic) forces on the rail to the shorter girders, especially track girders, becomes smaller.

For span lengths between 200 ft and 300 ft, the impact number ϕ, as computed dynamically, follows the new A.R.E.A. specification, even under the most unfavorable dynamic conditions. In case of span lengths less than 200 ft, the values of ϕ may become higher than those of the new A.R.E.A. formula, although following rather closely the old A.R.E.A. specifications.

SUMMARY

(1) A dynamic stress analysis of railroad bridges becomes advisable in certain cases, especially if the impact value required by the standard specifications is smaller than the actual value.

(2) A simple and approximate dynamic analysis is possible for a considerable number of medium-size bridges by the use of nomographic charts which may avoid laborious computations.

(3) A dynamic analysis is possible only if certain dynamic qualities of the bridge are known. Furthermore, the dynamic properties of the different moving loads must be taken into consideration separately for each type of passing vehicle. The largest dynamic stresses are caused in many cases by relatively slow freight locomotives and not by high-speed or medium-speed engines.

(4) The method outlined in this paper should be verified further by tests on old and new bridges; that is, it should be clearly understood that the assumptions made in simplifying the dynamic computation require experimental checking. The dynamic properties of bridges, as well as of vehicles, both while standing and while moving, should be investigated—that is, their natural frequency, damping capacity, vibrating masses, deflection and stress diagrams, dynamic wheel-load diagrams, and the influence of the motion of the loads.

APPENDIX

NOTATION

The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering, and Testing Materials compiled by a Committee of the American Standards Association[14] with Society representation, and approved by the Association in 1932:

A = centrifugal force vector in Fig. 2;
a = major axis of ellipse;

---

[14] ASA–Z10a–1932.

B = centrifugal force vector in Fig. 2;
b = minor axis of ellipse;
D = diameter of driving wheels of locomotive;
F = amplifying factor for resonance case;
g = acceleration due to gravity;
I = impact, in percentage;
k = substitution constant (see Eq. 6):
    k_w = amplifying number (see Eq. 8);
L = length of span, in feet;
N = number:
    N_i = number of impulses;
    N_t = number of periods necessary to build up oscillation;
    N_w = number of driving wheels of one locomotive;
P = concentrated load:
    P_A = axle load = load imposed by locomotive drivers;
    P_a = wheel load;
V = velocity; speed in miles per hour:
    V_c = critical speed;
    V_m = highest allowable speed of locomotive;
W = total static load; weight;
x = abscissas;
y = ordinate = vertical deflection of bridge;
Z = dynamic load at critical speed:
    Z_m = maximum dynamic load without amplification factor;
    Z_w = maximum dynamic load including amplification factor;
θ = logarithmic damping decrement;
ϕ = impact number;
ω = frequency:
    ω_n = natural frequency.

DISCUSSION

R. S. Chew,[15] M. Am. Soc. C. E. (by letter).—The profession is keenly interested, at present, in the forced vibratory effect on structures due to wind and earthquake, so that Professor Bernhard's paper treating of the effect on bridges from moving train loads is timely. In his treatment, the locomotive unbalanced wheel load is presumed to build up a vibrational resonance that is more destructive than the dynamic impact that has heretofore been assumed.

In discussing the subject it is necessary to define the terms "dynamic impact" and "vibrational effect," as used by the writer:

(*a*) "Dynamic impact" indicates a blow that, if repeated, recurs at an interval that is widely removed from the natural period of the structure struck; and

(*b*) "Vibrational effect" is the result of a blow that recurs in an interval closely related to the natural period so that the initial effect is accumulative.

In the case of vibration, then, the effect is intimately connected with the period of the structure; but in any problem, including forced vibration, it will be found that the calculation of this period (except for the simplest type, such as a rod) is ambiguous, so that it becomes necessary to test the finished structure in order to obtain a period of any value.

To illustrate, the writer will set up the theoretical equation for the period of a bridge which is excited by the application of recurring movement at regular intervals of the load system shown.

Referring to Fig. 8, let: p_1 = train wheel load; p_2 = locomotive wheel load; w = uniform dead load per linear foot; y = deflection at the point of load from live load, in feet; and T_1 = the period of the bridge. Then,

$$T_1 = \frac{2\,\pi}{\sqrt{g}} \sqrt{\frac{\Sigma\,(w\,p\,y^2)}{\Sigma\,(w\,p\,y)} + \frac{\Sigma\,(p_1\,y^2)}{\Sigma\,(p_1\,y)} + \frac{\Sigma\,(p_2\,y^2)}{\Sigma\,(p_2\,y)}} \qquad (14)$$

Eq. 14 indicates:

(1) Certain values of y which include shear and flexure (if y_f = flexure deflection due to live load, and y_s = shear deflection due to live load,

$$y = y_f + y_s \qquad (15a)$$

In order to find deflection values from the elastic curve y_s must be in terms of y_f. If it is assumed that $y_s = R\,y_f$

$$y = y_f\,(1 + R) \qquad (15b)$$

in which values of y_f are determined from statics, with live loads in the position given);

(2) That this value of T_1 is true only for the loads acting in position on bridge as shown and any shifting of loads changes values of y and T_1;

(3) For forced vibration the same loading must recur in the same position during regular intervals; and

---

[15] Cons. Engr., San Francisco, Calif.

(4) The value of T_1 is the period imposed on an elastic structure of known value of $E\,I$ and dimensions, so that the calculated value must assume these characteristics together with R and is thus of little value.

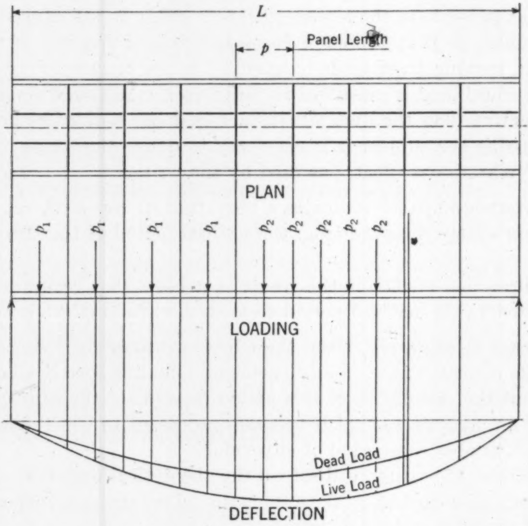

Fig. 8

Items 1 to 4 appear to indicate that a moving locomotive and train load will tend to produce a chaotic vibration, which will have an exciting but no accumulative effect.

When the locomotive has passed from the bridge, the structure becomes uniformly loaded and the action of this excited load will tend to produce forced vibration.

For this condition of uniform loading, a simple formula can be written, as follows:

$$\Delta = \frac{5}{384}\,\frac{w\,L^4}{E\,I} = \frac{5}{384}\,\frac{W\,L^3}{E\,I} = \frac{5}{8}\,W\left(\frac{L^3}{48\,E\,I}\right) \qquad (16)$$

in which W is acting through an average deflection of $\frac{5}{8}\,\Delta$. Therefore,

$$\frac{5}{8}\,W\,\Delta = \left(\frac{5}{8}\right)^2 \frac{4\,\pi^2\,\Delta^2}{g\,T^2_1}\,(1 + R)\,W \qquad (17)$$

from which the natural period of the bridge is found to be

$$T_1 = 2\,\pi\sqrt{\frac{5}{8}\,\frac{\Delta}{g}\,(1 + R)} \qquad (18)$$

in which Δ = maximum deflection due to live load. The natural frequency is:

$$f_n = \frac{1}{2\pi}\sqrt{\frac{8}{5}\frac{g}{\Delta\,(1+R)}} \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

If the uniform live load is moving with a speed such that the loads recur at panel points in regular intervals, forced vibration will occur due to an impulse created by the deflection of stringers.

For example, if: V_s = speed of the train, in miles per hour; p = panel length in feet; and T = time of recurrence = period of excitement,

$$T = \frac{0.68\,p}{V_s} \ldots\ldots (20)$$

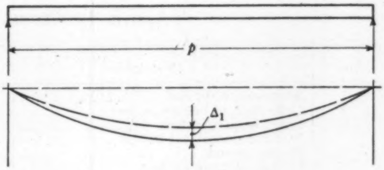

FIG. 9

which gives the period of excitement; and when $T = T_i$ resonance occurs.

In order to find the effect at this impulse (F), let Fig. 9 indicate a stringer carrying a uniform load of w pounds per linear foot moving with velocity of $v = \frac{p}{T}$. Then

$$F = \frac{5}{8}\,w\,p\,\frac{4\,\pi^2\,\Delta_1\,(1+R)}{g\,T^2} = \frac{0.8\,\Delta_1\,(1+R)}{T^2}\,w\,p \ldots\ldots\ldots (21)$$

in which Δ_1 = deflection due to live load. If N = number of impulses, U = length of train, in feet, p = panel length in feet, and L = length of bridge—

$$N = \frac{U - L}{p} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

Let V_c = the speed of a train in miles per hour such that $T_i = \frac{0.68}{V_c}$; then

$$T^2 = T^2{}_i\left(\frac{V_c}{V_s}\right)^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

which substituted in Eq. 21 gives the forced vibration at the panel in terms of the panel load:

$$F = \frac{0.8\,N\,\Delta_1\,(1+R)\,w\,p}{T^2{}_i}\left(\frac{V_s}{V_c}\right)^2 \ldots\ldots\ldots\ldots\ldots (24)$$

This value of F will be limited by frictional damping.

From the foregoing it can be seen that the writer is not in accord with the author in regard to the locomotive unbalanced wheel loads producing accumulative vibrational effect on the bridge as a whole. In reference to the value of z given in Eq. 9 and assuming that it holds, still its application for each impulse is πD removed, which means that it does not accumulate but rather acts as a dynamic force.

The writer approves of Fig. 3, if z is substituted for z_w.

It appears to the writer that the value z, plus the effects of the sudden application of load, is a measure of the dynamic impact to be used for girders and shear members. If Eq. 24 is adjusted to include the damping decrement K_w, as given by the author:

$$F_d = K_w \left[\frac{0.8\,\Delta_1\,(1 + R)\,(w\,p)}{T^2_i} \right] \frac{V^2_s}{V^2_c} \ldots\ldots\ldots\ldots\ldots \quad (25)$$

Two examples illustrating the application of Eq. 25 are given in Table 1, which is based on the premise that all values of $w\,p$ are identical, a condition that is very improbable. However, the formula does emphasize the fact that forced vibration is a factor of the ten items given in Table 1, so that, as in buildings subjected to earthquake, it is impracticable to establish a constant vibrational factor. After completion the bridge should be investigated for the items in Table 1 and from this the factor for the structure should be established.

TABLE 1.—APPLICATION OF EQ. 25

No.	Description	Symbols	Example 1	Example 2
1	Span length, in feet	L	90	200
2	Deflection of bridge, in feet	$\Delta\,(1 + R)$	0.06	0.20
3	Panel length, in feet	p	20	20
4	Stringer deflection, in feet	$\Delta_1\,(1 + R)$	0.01	0.01
5	Bridge period	T_i	0.214	0.395
6	Length of train, in feet	U	4,000	4,000
7	Critical speed, in miles per hour	V_c	63	35
8	F at a speed of V_c	F_d	6.5	1.65
9	Limiting speed, in miles per hour	V_s	31	27
10	F at a speed of V_s	F	1.0	1.0

It may be noted further that Eq. 25, with adjustments, will indicate the vibrational condition on the suspension bridge under wind. If, from any cause, a differential vertical deflection between cables recurs in time T_i, the formula will indicate the forced vibration, in which: $w\,p$ is the load on the suspender; and T_i is the natural period of the bridge.

Then F indicates approximately the condition that existed on the Tacoma-Narrows bridge in Seattle, Wash., when V_s has equaled V_c.

In conclusion the writer believes the author's paper to be of value and trusts that it will receive the attention it deserves.

R. K. BERNHARD,[16] M. AM. SOC. C. E. (by letter).—Mr. Chew's discussion certainly represents a welcome addition to the paper.

In order to simplify the setup of the nomographic charts, the writer tried deliberately to avoid more complicated formulas. The accumulative effect of unbalanced wheel loads of steam locomotives has been proved experimentally. Numerous stress-time diagrams as given, for example, by J. B. Hunley in 1935,[5] or as early as 1928 in the report of the Bridge Stress Committee,[7] give sufficient evidence.

It would be rather simple to change the nomographic charts slightly in order to adapt them for transverse torsional vibrations. This case corresponds to self-sustained vibration due to aerodynamic instability of suspension bridges excited by horizontal wind loads.[17]

It must be emphasized, however, that investigations on actual bridges to determine the damping values more accurately are essential.

CONCRETE IN SEA WATER: A REVISED VIEWPOINT NEEDED

By Homer M. Hadley,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Thomas E. Stanton, W. F. Way, Glenn S. Paxson, Lester C. Hammond, Ladis H. Csanyi, G. M. Williams, Harry E. Squire, J. W. B. Blackman, E. C. Jack, Alfred M. Freudenthal, T. B. Rights, and Homer M. Hadley.

Synopsis

Results of extended observations of concrete marine structures, along the Pacific Coast of the United States and Canada, are presented in this paper. No evidence is found of sea-water (sulfate of magnesium) attack on the concrete; where deterioration has occurred, it has been due to other causes. It is concluded from the uniform absence of sulfate attack in the wide range of concretes and cements involved in these structures that special precautions against sulfate attack are needless. It is concluded, however, that in sea-water concrete every care should be exercised to use sound materials, to obtain uniform density and impermeability of concrete, and to protect reinforcement from corrosion.

Introduction

The final criterion by which the behavior of anything in nature is to be judged is not the behavior of some similar thing; it is not the advance opinion of authority; and it is not the preliminary findings of laboratory investigation and research. The final criterion of behavior is no more or less than the actual behavior itself, and it is by their conformity and agreement with this actual behavior that the preliminary bases of judgment are to be appraised and assessed. If there is agreement, well and good. If there is disagreement, then it is the preliminary findings that must be adjusted and revised; it is not the actual behavior that must be denied.

This paper attempts to summarize the actual behavior of concrete marine structures along the Pacific Coast. How can that behavior be truly presented? When the mountain did not come to Mohammed, Mohammed went to the

---

Note.—Published in January, 1941, *Proceedings*.

[1] Regional Structural Engr., Portland Cement Assn., Seattle, Wash.

mountain. Nothing similar is possible here in the case of the average reader. The best that can be done is to submit representative views of structures taken in the very act of "behaving," in place, and to invite consideration of these views in combination with other stated facts, all of which evidence, of course, is subject to quite independent check and examination by those to whom access to the structure in question may be available.

The writer is quite aware that there is a large body of opinion at variance with the views set forth in this paper. He regards it desirable, therefore, to focus attention on the question at issue—the behavior of concrete marine structures in service and the existence, in any form, of deterioration in such structures, apart from the enumerated kinds, which is definitely and peculiarly attributable to the sulfate action of sea water upon the hydrated cement of the concrete. Otherwise stated, the question is: Does any form of deterioration occur in the concrete in sea water that would not develop if the exposure were changed to similarly agitated, similarly fluctuating, fresh water? In the considerable body of evidence that exists along the Pacific Coast, the writer is aware, with noted exceptions, of none whatever. It is also to be observed that it is with sea water in its normal range of concentrations—not with other sulfate waters—that the paper is concerned.

THE PREVAILING VIEWPOINT

> "Many engineers who are most experienced in marine construction are of the opinion that all concrete structures in salt water, and a considerable proportion of those near salt water in warm climates, deteriorate steadily and surely."[2]

These words express a widely accepted opinion that deterioration is inevitable. It is supposed to result from the combination of sulfates of magnesium in the sea water with free lime in the hydrated cement and from the consequent formation of calcium sulfate which either by dissolution or expansion disrupts the concrete and effects its destruction. Periodically, in the technical press, reference is made to the sulfates of magnesium in sea-water attack on concrete in the most casual, matter-of-fact manner, as if it were definitely proved—an established reality. Remedies are proposed for it.

Under these conditions it is, to say the least, extraordinary that nowhere along the Pacific Coast, from Canada to Mexico, has the writer been able to find any evidence in concrete marine structures that an attack of such a nature occurs. Deterioration of various kinds assuredly is to be found. There is much of it in certain localities. Sometimes it is very serious; sometimes it is minor and trivial. None of it, however, is of a character to satisfy the sulfate of magnesium-free lime explanation which Messrs. Atwood and Johnson state[3] was advanced by L. J. Vicat. They quote E. Candlot as follows:

> "According to Vicat, it is the action of this salt [sulfate of magnesia] to which must be attributed the rapid decomposition of lime and of certain cements by sea water; the sulphate of magnesia combines with the free lime of the mortar and is transformed into sulphate of lime; the magnesium is precipitated. If the current of the water which traverses the mortar be

---

[2] "The Disintegration of Cement in Sea Water," by William G. Atwood, M. Am. Soc. C. E., and Arthur A. Johnson, *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 205.

[3] *Loc. cit.*, p. 207.

> somewhat rapid, the sulphate of lime is carried out, a new quantity of lime enters into solution, is in turn transformed into sulphate, and the *gangue* thus decomposes continuously and finishes by forming only a sandy mass. When the current is weaker or is produced only at rather long intervals, the lime sulphate may crystallize and thus cause the expansion of the mortar. It is to this cause that we may attribute the phenomenon of expansion of mortars decomposed by sea water."

From the foregoing it appears that there should be either a progressive leaching out of the calcium sulfate with a correspondingly developed porosity and weakening of the concrete, or the concrete should become swollen, disrupted, and disintegrated by crystallization of the calcium sulfate. Furthermore, although there is no definite statement of the time rate at which these changes occur, it is to be assumed that they take place at a rate sufficiently rapid to show some indication of this deterioration after a reasonable period of time—say twelve or fifteen years. Certainly one should not be compelled to wait longer than that to find the first traces of it if it is a matter of any practical consequence.

With the understanding, then, that the characteristic form and manifestation of sulfate of magnesium attack on concrete is either a developed porosity or a swollen disruption of the mass and, after extensive inspections and examinations of many structures which uniformly fail to reveal deterioration of the requisite type, it is repeated that there is no evidence in concrete exposed to sea water along the Pacific Coast to substantiate the sulfate of magnesium-free lime theory. The confirmation is not to be found, however diligent the search. On the other hand, when a large amount of concrete (made with many different brands of portland cement) is seen that has been subjected to full sea-water action for fifteen, twenty, or more years and still has the original wood grain and form marks showing in its surfaces; still has clean, sharp corners and offers flinty, hard resistance to hammer blows; and is utterly lacking in deterioration, there is no avoiding the conclusion that the sulfate of magnesium-free lime deterioration theory is deficient in that indispensable necessity of all valid theories—proof. If, as is said, sea water attacks concrete, why does not all concrete deteriorate? Why, even in deteriorated structures, is most of the concrete free from deterioration in spite of having the same identical exposures as the deteriorated parts?

CONCRETE A GENERIC TERM

It would be well at the outset to consider what concrete is and to recognize that the term is a broad and generic one. Concrete is the name given to any hardened mixture of portland cement, water, and fine and coarse aggregate. If the coarse aggregate is lacking, the mixture is called mortar, but otherwise the name concrete is given, regardless of wide variations in the proportions of the several components of the mixture and regardless of the manner and method by which it is mixed and placed in its forms. Whatever it is, it is called concrete as long as its material components are as stated. The consequence of this convention is that the behavior of concrete under any particular set of conditions may vary widely, depending upon the particular concrete that is subjected to the exposure. Quite similar would be the variable behavior of rock which, if it were hard granite, would behave in a markedly different manner than rock which was a soft sandstone.

It is to be expected that a wide range of mixes has been used in concrete marine work, and such indeed is the case. Likewise variable have been the methods of placement. It is apparent in many structures that care has been exercised to place the concrete uniformly and without segregation. It is apparent in other structures that little or no concern was felt for the attainment of these objectives: The concrete was dumped into the forms in a carefree, happy-go-lucky fashion, contentment abiding in the knowledge that "sufficient unto the day is the evil thereof." In reinforced structures the thickness of the protective covering over the bars varies in different jobs as does the quality of concrete in the covering. Out of all these variables, manifestly, there are opportunities for diverse behavior of "concrete in sea water," and it is not surprising that deterioration of various kinds has developed.

The Sea-Water Exposure

The sea-water exposure itself varies widely. In the most sheltered and protected locations there is the rise and fall of tides with alternate wetting and drying of the concrete. Waves, swells, and the wash of ships frequently amplify the tidal wetting. Flotsam and drift are tossed about by the water and deliver mechanical blows. On the open ocean coast, storm waves themselves deliver tremendous thrusts and blows against the structure and may roll and grind loose boulders against it; moreover, along the Pacific Coast, from San Francisco (Calif.) north, the forest mantle of the country yields great quantities of drift which sometimes may be whole logs and trees that form heavy battering material. Additional to this along some coasts are the disruptive effects of ice and freezing. All in all it must be recognized that, quite as a marine exposure is a poor place for rock of a soft shale, indurated mud type, so, likewise, is it unsuited for lean, porous concrete of segregated, random structure.

Deterioration by Mechanical Attack

Indeed the most striking and characteristic forms of deterioration to be found in concrete exposed to sea water are those due to deficiencies in the quality and structure of the concrete itself: Weak concrete is abraded, honeycombed areas become full cavities, laitance seams become extended voids, construction joints and pour planes tend to chip and widen at their edges, and sharp corners and projections become broken and knocked off. The processes of attrition and erosion by which, in the long reaches of time, all things are reduced to fragments and to dust are in aggressive action on the ocean's shores, and that which is vulnerable to attack is speedily revealed. On the other hand, strong, sound concrete that is uniformly dense and impermeable shows but slight change in a quarter century or more and quite merits the term "permanent" in the time scale of human affairs.

Such contrasting aspects of concrete in sea water obviously result from variations in the concrete itself. They have nothing to do with sulfates of magnesium in the sea water, nor with the sulfate-resistant qualities of cement. Deterioration such as that described is due to physical and mechanical causes and could, and would, occur as well if the ocean were of fresh water instead of salt water. Unfortunately, a great deal of writing has indiscriminately lumped all forms of deterioration together as "sea-water attack," whence the conclusion is readily drawn that it is the sea water itself that exercises a peculiarly malign effect upon the concrete. For resistance to this, the commonest form of deterioration in concrete exposed to sea water, it is safe to say that making concrete which is fresh-water resistant or frost resistant elsewhere will furnish full and adequate protection.

Rusting of Reinforcement

In reinforced structures, the second most common form of deterioration is that due to rusting of reinforcement, disruption of the covering concrete, further corrosion of steel with loss of section, loss of bond, etc. It develops most frequently in members of small section—piles and the stems of beams and girders. Unprotected steel rusts. It rusts very slowly in a dry climate and more rapidly in a moist climate. It rusts most rapidly and heavily of all along the sea coasts where the air may carry minute drops of salt water in suspension, caught up from waves and surf. In such an atmosphere, rust will form quickly on reinforcing bars wherever the covering concrete is porous or absent. If possible it will develop progressively along the bar and with its inevitable expansion will split and disrupt concrete. The primary remedy is to provide dense, impermeable concrete and adequate cover. Around salt water is a poor place for scant cover over reinforcement, for misplaced reinforcement, or for lean concrete. However, it is to be noted that, although the rusting of reinforcement is indeed aggravated and accelerated by the salt-water exposure, it is wholly independent of the sulfate-resisting properties of the cement used in the concrete. Consequently, here again, primary importance attaches to density and impermeability and to the thickness of the protective concrete rather than to other things. Additional protective measures that may be accepted as thoroughly effective are the asphaltic impregnation of concrete piles, extensively used by the Los Angeles (Calif.) Harbor Board,[4] and the ingenious system of applying an asphaltic coating to the underside of a concrete deck, developed and used by the engineers of the San Francisco Harbor Board.[5] To the best of the writer's knowledge, these methods have been 100% effective in accomplishing their respective objectives.

Solvent Action

Occasionally there is evidence of a slight solvent action of sea water on concrete. The original surface film of cement has disappeared, or a honeycombed spot weakens and loosens some pieces of aggregate. In time, porous concrete may appear to become increasingly porous. Such changes are not peculiar to sea-water exposure, however. They can occur equally in fresh water. Long-time tests made in the testing laboratory of the City of Seattle, Wash., about 1925, by T. H. Carver, M. Am. Soc. C. E., clearly showed a minute but definite dissolution of concrete in flowing fresh water, which dissolution did not occur in still water. In Fig. 1(*a*), the cylinders on the left were stored in a tank through which a slow steady flow of Cedar River water was maintained. Those on the right (Fig. 1(*b*)) were stored in still water in sealed jars. The mixes were, left to right, 1–1–2, 1–2–4, and 1–3–6, respectively, in both Fig. 1(*a*) and Fig. 1(*b*). After five years the standard-cured 2-in. by 4-in. cylinders, in Fig. 1(*a*), all showed evidence of attack. The specimens of 1–3–6 mix had entirely lost their surface films of cement paste; the 1–1–2 specimens could have theirs removed easily by wire brushing. The companion specimens, in Fig. 1(*b*), stored in still water in sealed jars, were unaffected. The loss of strength, running-water storage compared with still-water storage, was markedly greater with the lean mixes than was the case with the richer mixes. The desirability of an impermeable concrete was clearly shown. In the case of sea water, there is a continual change of water with tides, currents, surf, etc. There is ample evidence from both laboratory and field investigations of the need for density and impermeability in concrete exposed to sea water, and also in concrete exposed to fresh water.

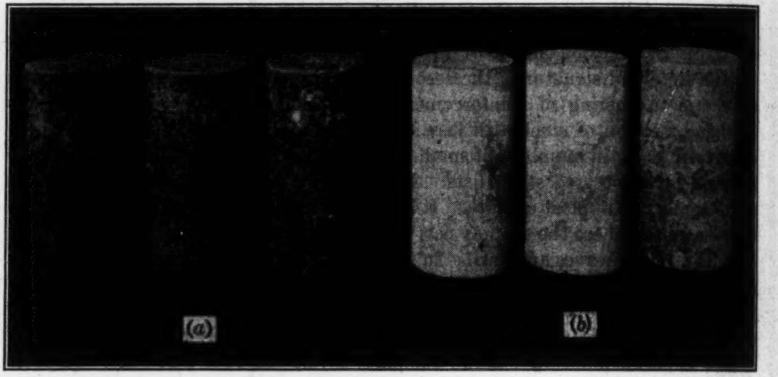

FIG. 1.—WIRE-BRUSHED, 2-IN. BY 4-IN. CYLINDERS AFTER FIVE YEARS IMMERSION IN FRESH WATER

FREEZING

Disruption of porous concrete by the freezing of absorbed water does not occur along the Pacific Coast of the United States, not because there is no porous concrete to be found, but because freezing seldom, if ever, occurs. Such disruption of porous concrete by freezing is quite independent of sea water, however. It occurs with both fresh and salt water.

EVAPORATION

Disruption may likewise develop with porous concrete in the tidal zone or above if evaporation produces seriously harmful concentrations of sea water in the pores. The late C. S. Pope,[6] M. Am. Soc. C. E., has presented a view of the top of a sea wall that shows scaling and deterioration which were undoubtedly due to concentrated saline solutions and crystallization produced by evaporation. This is a form of deterioration which is indeed peculiar to sea water and not to fresh water. In general, however, it is of limited occurrence, since the usual freedom of drainage appears to prevent it. The flat top of the sea wall cited by Mr. Pope acted to trap and hold a certain amount of spray thrown upon it, and with rather porous concrete and aggregate the consequences were as shown in Fig. 1.

---

[6] *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 511.

Unsound Materials

Still another type of deterioration—that due to the use of unsound materials in the manufacture of concrete—is to be found. This is characterized by a pronounced general expansion of the entire body of the concrete and much cracking. There are two distinct varieties of this classification. The common one is that in which the concrete remains hard and is entirely unaffected by the sea water. In the other variety the concrete softens into a mushy mass practically devoid of cohesion.

Concrete is composed of cement, water, fine aggregate, and coarse aggregate. The coarse aggregate is a highly unlikely cause of a general and all-pervasive expansion in a concrete structure free from local poppings and pittings and may be dismissed from consideration in all but exceptional cases. So, likewise, are differences in mixing waters, although, as the agent initiating the hydration of cement, mixing water may be regarded as a cause. Perhaps strongly alkaline waters under some conditions may be unfit for use, although sea water itself, notably in the case of the Florida East Coast Railway Extension to Key West, has been used as mixing water in a number of instances with no appreciable ill effects. There remain the cement and fine aggregate. The latter is almost always a natural sand produced by weathering and erosion of a great variety of rocks, and is transported, intermingled, and deposited by streams. Depending upon their origin, sands from the same pit may be of definitely uniform or of utterly diverse and random mineralogical characteristics. It is a common and usually valid assumption that natural sands are stable, sound, and chemically inert, but this assumption, easy though it is to make, is not necessarily true. It is cement and sand, individually or in combination, that must be considered as possible causes of the expansion referred to.

Improperly manufactured cement may indeed be the cause of the trouble. Nevertheless, the adoption of modern improvements in manufacturing and testing procedure should give the engineer increased confidence in the capability of portland cement to meet fully all reasonable construction requirements. More careful grinding and particularly blending of the raw materials insure more uniform and correct burning and therefore a more dependable product. New and more severe tests for soundness detect any tendency toward delayed unsoundness. However, the cases of deterioration in existing marine structures in which serious expansion has occurred are not numerous, and those in which this expansion is properly to be charged to the cement alone—that is, wherein the aggregate is not partly or completely responsible—have yet to come to the writer's attention.

Expansion of the type in which the structure cracks but the concrete remains hard and not observably affected by sea water is discussed and illustrated in a series of valuable papers by Thomas E. Stanton,[7] M. Am. Soc. C. E. The original paper, presented at the annual meeting of the Society in January, 1940, describes a typical case of such expansion in a sea wall in Ventura County,

---

[7] "Influence of Cement and Aggregate on Concrete Expansion," by Thomas E. Stanton, *Engineering News-Record*, February 1, 1940, Fig. 2, pp. 59–61; see also *Proceedings*, Am. Soc. C. E., December, 1940, p. 1781

California. In March, 1940, the writer discussed[8] the condition of this sea wall and others nearby. There appears to be no reasonable doubt that the nature and cause of deterioration of this kind have been definitely established by the notable work of Mr. Stanton and his associates. This form of expansion has developed in bridge piers and abutments in fresh-water streams—for example, the highway bridge across the Salinas River at King City, Calif.

A. A. M. Russell, Assoc. M. Soc. C. E., has made some tests which brought into definite and almost dramatic focus hitherto confused and obscure causes of trouble of the expansion-softening type. From a pit from which had come the sand used in a waterfront structure that developed very serious deterioration of this type in a few years' time, he obtained sand samples, and for comparison he used sand from another pit, several hundred miles distant from the first pit, and of known soundness. Petrographic examination of the questioned sand revealed a heavy percentage (more than 40%) of feldspar grains which proved to be of a highly unstable nature.

As an accelerated test, equal samples of both sands were put in beakers of sea water, which were then placed on an electric plate and held continuously at a temperature slightly below boiling. In four days about half of the questioned sand had broken down and changed completely to a mud, whereas the other sand sample showed only a thin film of mud across its top surface. Then, as a direct sea-water test, briquet specimens were made up of the questioned sand and of standard Ottawa sand. The latter, consisting entirely of particles passing No. 20 and retained on No. 30 sieves, suggested a similar grading for the other sand. Consequently, it was sieved into three gradings and three different mixes were prepared. In one mixture only particles passing the No. 10 and retained on No. 20 sieves were used; the second had only particles passing No. 20 and retained on No. 30 sieves—that is, the Ottawa sand grading; the third mixture had a grading with particles ranging uniformly from fine to coarse. After tension tests were made, the briquet fragments were placed in jars of sea water and were kept at room temperature, the sea water being renewed occasionally as evaporation took place. In less than a year the Ottawa sand specimens were wholly unaffected, having hard sharp edges and no trace of deterioration. The same was true of the specimens of the questioned sand that had the fine-to-coarse grading and were therefore of reasonably dense structure. The specimens made with the No. 10 to No. 20 mesh particles were beginning to soften slightly on their edges but were in fair shape. The No. 20 to No. 30 mesh samples, on the other hand, were in an advanced state of disintegration. They had swelled, cracked, were slimy on their surfaces, and their edges were soft and crumbly. These specimens, being directly comparable in every respect to the specimens made with Ottawa sand and with the same cement from the same sack (which Ottawa sand specimens were wholly unaffected), showed conclusively, in conjunction with the preceding accelerated test on the sand, that the unsoundness in this case was in the sand and not in the cement.

Inasmuch as the deterioration produced closely resembled that in the structure built with this sand, it appears to be established, at least in this case, that the sea-water attack was on the sand and not on the cement. It is scarcely conceivable that this trouble could have been avoided by special sulfate resistance or other special qualities in the cement. It is a fact that serious deterioration of this type appears to have developed in a section of the coast of rather marked geographical limits. It should be added that it is only in sea water that the writer knows of the occurrence of this form of deterioration, and indeed it may be that this feldspathic sand is particularly unstable in sea water. Its use for any concrete anywhere, however, appears to be questionable.

---

[8] *Engineering-News Record,* March 14, 1940, p. 45.

There are a few cases known to the writer where concrete in exposed locations appears to have developed expansion troubles somewhat intermediate between the two types—that is, there has been cracking of the type described in Mr. Stanton's papers with apparently a certain softening of the concrete. This has resulted in the complete destruction of parts of the structures. Extensive cracking of exterior surfaces due to expansion of the interior of the mass, of course, greatly weakens resistance to flexural stresses; similarly, such complete prevention of longitudinal expansion in certain sections as to lead to crushing at the ends would practically destroy their resistance to the pounding of waves at such points. Whatever the exact cause of the trouble in these cases, there is no uncertainty about abnormal expansion; it is to be avoided and eliminated. It is believed that the preceding covers all the main types of deterioration that are to be found in Pacific Coast concrete marine structures.

SUBJECTIVE DETERIORATION

Another trouble of concrete in sea water has nothing to do with the sea water. This trouble arises from hasty observation and incomplete reporting of conditions. In glowing zeal to establish either broad generalizations or the urgent need for the adoption of certain safeguards, only as much of the evidence is adduced as supports the contention. This frequently creates in readers' minds an entirely erroneous idea of conditions.

Fig. 2 shows a view of an old quay wall at the Puget Sound Navy Yard, Bremerton, Wash., built in 1901 and known as quay wall D. It extends from the stepped-off joint at the reentrant angle to the corner at the extreme left. At the right of this section and in the right foreground of the view is a portion of quay wall E, constructed in 1896. The deep cavities and extremely bad conditions at the base of wall D are clearly apparent. Likewise clearly apparent is the condition of the wall above the base portion which is extremely hard and today (1940) shows no trace of deterioration, the wood grain and form marks being discernible through the coating of fuel oil which now covers it. An official statement regarding this condition is the following:

> "The bottom part of the west wing wall from the stepped off joint to the south corner was poured in 1901 with a tremie up to a point where the water could be expelled from the open cofferdam, probably three feet higher than the water level in the photograph."

Regarding this same wall, the following is the complete report,[9] published in 1924 by the National Research Council:

> "Quay Wall D—This is a gravity type wall built in 1901–02. Local aggregates and condon [Condor] cement were used in the proportions of

---

[9] "Marine Piling Investigations," National Research Council, 1924, p. 403.

1 : 2½ : 5. This concrete was hand mixed and deposited below water level by tremie and above with wheel barrows.

"The inspection of Mar. 8, 1923, showed this wall to be badly deteriorated."

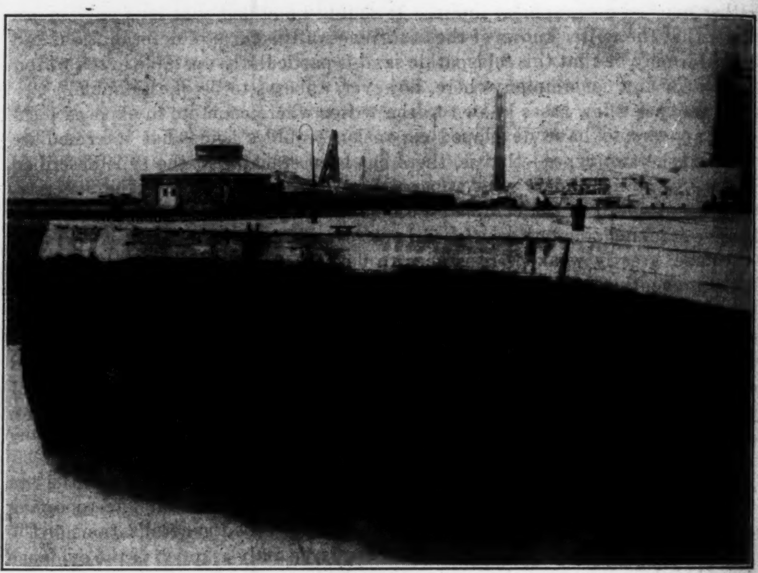

FIG. 2.—QUAY WALL D, PUGET SOUND NAVY YARD, BREMERTON, WASH.

Although this report is literally true, it nevertheless creates a wholly erroneous impression since no reader would know that the upper part of the wall, also in sea water, made with the same cement as the base, was practically free from deterioration on March 8, 1923. With the same construction methods, any and every cement regardless of type or composition that might have been used in this wall would have been similarly attacked or not attacked by the sulfates of magnesium in the sea water, depending on whether it was dumped through a tremie tube or deposited by wheel barrows. Many reports of sulfate-of-magnesium attack on concrete in sea water are of the foregoing character.

SUMMARY

The harm resulting from misunderstanding a natural phenomenon arises from the likelihood that measures adopted to effect changes and alterations in it will be misdirected. There is no particular reason for research and for grave alarm over the strong links of a chain so long as there are weak links that need strengthening. Not until the real hazards of sea-water use are definitely foreseen and are guarded against is there need for such extreme refinements as protecting against sulfates of magnesium—and no particular harm will result if this safeguarding is completely neglected.

FIG. 3.—TYPICAL VIEW OF SUBSTRUCTURE OF FERRY PIER, NORTH VANCOUVER, B. C., BUILT IN 1909

FIG. 4.—DETAIL OF OLD WATERFRONT WALL, SEATTLE, WASH., BUILT IN 1913

This paper is based upon visual observations of concrete structures in sea water along the Pacific Coast and is concerned with sea water only. It is intended that its statements and conclusions apply to sea water only—not to those sulfate waters and exposures elsewhere which assuredly require special measures and treatments. The dearth of supporting laboratory data may be regarded as somewhat unusual, but it is hoped that the references to the work of Messrs. Carver, Stanton, and Russell will supply this deficiency in some measure. After all, it really is not necessary to have laboratory confirmation of that which is spread obviously before one's eyes.

FIG. 5.—BROADWAY PIER, SAN DIEGO, CALIF., BUILT IN 1912

Probably no better ending could be made to this paper than to append a short list of some representative older concrete-in-sea-water structures, variously located, which exemplify the behavior of sound, impermeable concrete and which may be examined by any one. Several views are shown in Figs. 3 to 7. These structures are not without flaw or blemish. Some of them have bad spots such as patches of honeycomb dating from original construction, or have been worn by abrasion. However, they have had twenty or more years of sea-water exposure, and their concrete is substantially free from trace of sea-water attack. They were built at different times, with different brands of

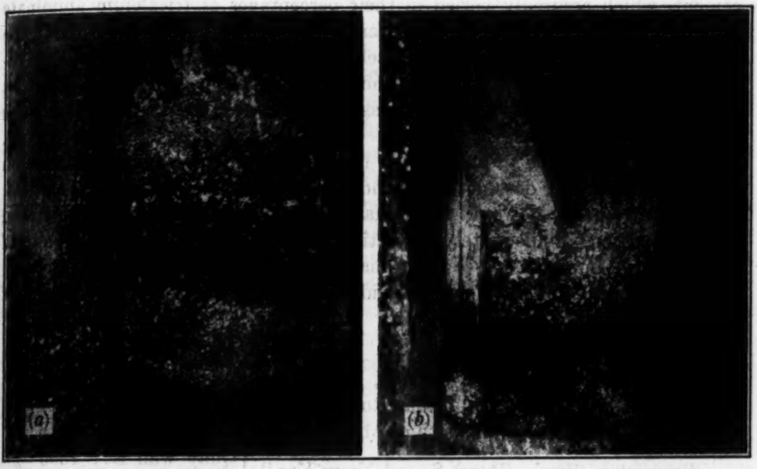

FIG. 6.—PIER ON SAN FRANCISCO WATERFRONT, BUILT IN 1909

FIG. 7.—DETAIL OF ABUTMENT OF EAST NEAPOLITAN BRIDGE IN NAPLES DISTRICT, LONG BEACH, CALIF. OFF ALAMITOS BAY, ERECTED IN 1913

cement, which assuredly varied in their percentages of tricalcium aluminate and other compounds, and with different construction methods. After the examination let the observer ask himself the question: Where is the sulfate-of-magnesium attack? Assuming that there is only one conclusion—namely, that he has not seen any—it is then fair to ask why it is not to be found. It is to be hoped that he will look for it elsewhere—not in books, but along the waterfront. This paper is intended to present the idea, definitely, that such an attack on concrete in sea water does not occur and therefore need not be guarded against. On the other hand, it would re-emphasize what many observers have stated before—the need of adequately protecting reinforcement from corrosion and of having dense, impermeable concrete made of sound and enduring materials.

Representative older structures evidencing no sulfate-of-magnesium attack upon their concrete are the following:

Location:		Built:
North Vancouver, B. C., Canada, Ferry Pier		1909
Victoria, B. C., Canada, Dallas Road sea wall		1911
Seattle Wash., sea wall south of Madison Street		1916
Bremerton, Wash. (Puget Sound Navy Yard)	Quay wall E.	1896
	Quay wall D.	1902
San Francisco, Calif.	Cylinder substructure, pier 38	1909
	Pre-cast pile substructure, pier 17	1912
Los Angeles, Calif.	Lighthouse base, San Pedro breakwater	1910
	Piers of Southern Pacific Railway bascule bridge at West Basin	1912
San Diego, Calif., Broadway Pier (see Fig. 5)		1912

Reports of 27-yr tests of concrete specimens, made with five different brands of cement immersed in sea water on the San Pedro breakwater at Los Angeles,[10] were published in 1932. These specimens were made in 1905 by the U. S. Engineer Department and were exposed in the tidal zone. No evidence of sulfate-of-magnesium attack was found in them nor any deterioration other than abrasion due to mechanical causes.

Fig. 4 is a view of an old sea wall in Seattle, Wash., built in 1913. Part of the wall shows what is commonly called "sea-water attack," whereas most of the wall shows no attack. The cause of the trouble is self-evident.

In Fig. 6(*a*), honeycombed concrete and sound concrete are shown side by side in the same cylinder, and both conditions occur at the water level. Fig. 6(*b*) shows another cylinder that is honeycombed at the high-tide line and also above that line.

CONCLUSIONS

Because of complete lack of evidence in concrete marine structures of sulfate-of-magnesium attack upon them, there appears to be no valid basis for believing that such attack occurs.

The vitally important matter for concrete used in marine work is to have dense, impermeable concrete made of sound materials with adequate cover over reinforcement.

---

[10] *Western Construction News*, June 25, 1932, p. 367.

DISCUSSION

Thomas E. Stanton,[11] M. Am. Soc. C. E. (by letter).—Mr. Hadley is to be complimented for his presentation of the results of his extended observations of concrete marine structures along the Pacific Coast of the United States and Canada and for his emphasis on density and uniformity. The writer is in accord with Mr. Hadley's conclusions that if, in concrete exposed to sea water, every care is exercised to use sound materials, to obtain uniform high density and impermeability of concrete, and to protect reinforcement from corrosion, there need be little fear of subsequent disintegration due to sea-water attack, at least in so far as cements similar to those under observation are concerned, which probably include all of the standard cements manufactured on the Pacific Coast. That this is true everywhere, however, can be ascertained only through similar observations conducted throughout the world and with all brands of cement. Certainly the literature on cement and concrete is replete with "alleged" instances of salt-water disintegration.

The writer checks Mr. Hadley's observation of numerous concrete structures, subject to sea-water attack along the Pacific Coast, which are at least 25 years old and apparently as sound today as when constructed. This observation, combined with confirmatory laboratory tests, was the basis for the writer's conclusions, published[12] in 1938, that density and uniformity are the first considerations for a durable concrete, assuming that sound ingredients are used.

It was definitely observed, however, based on laboratory tests, that porous mortars of unquestionably sound fine aggregates, but with a high C_3A portland cement, are non-durable[13] when subjected to attack by sea water of normal concentration, but that mortars using a low C_3A cement are highly resistant even in 1 : 3 ungraded Ottawa sand mortars.

The conclusion was reached, therefore, that, for insurance against disintegration due to sea-water attack in the case of porous concrete, at least a moderate sulfate-resistant (8% or less of C_3A) cement might well be specified, particularly if such a cement can be secured without paying a premium. It is freely conceded, however, that "The vitally important matter for concrete used in marine work is to have dense, impermeable concrete made of sound materials with adequate cover over reinforcement" and that, if these conditions are met, little concern need be felt relative to the cement component, provided the cement is sound in every respect and of the general composition of those manufactured by Pacific Coast mills. The exception to the foregoing conclusions, of course, is the condition described by the writer in the paper to which Mr. Hadley refers.[7]

W. F. Way,[14] M. Am. Soc. C. E. (by letter).—It is the writer's impression that Mr. Hadley's paper is timely. Too long it has been thought that all concrete, good or bad, deteriorates in sea-water structures, the deterioration being due to chemical reaction between the sea water and the various compounds in the hydrated cement of the concrete. The writer agrees quite heartily with the conclusions in the paper. In fact, one cannot come to any other conclusion when observing in the same structure both sound and unsound concrete in close proximity. Concrete that was placed, probably, from the same bucket or buggy—that is, concrete that has been under the same exposure—is found partly sound and partly unsound. Surely the difference is not due to chemical action. True it is that concrete structures in sea water do not enjoy a flawless record; but it is also true that the real causes of unsound concrete have not been explained by the allegations of sea-water attack.

[12] "Resistance of Cements to Attack by Sea Water and by Alkali Soils," by Thomas E. Stanton and Lester C. Meder, *Journal*, A. C. I., Vol. 9, March–April, 1938, pp. 433 *et seq.*

[13] *Loc. cit.*, supplement, September, 1938, p. 464–7.

[14] Project Mgr., Constr., Basic Magnesium, Inc., Las Vegas, Nev.

The writer once had occasion to repair the substructure of a reinforced concrete pier whose supports were cylinders 4 ft in diameter, belling out to bases of 13-ft diameters. In the original cylinder construction, a timber shell form was made that was placed over a pile cluster previously driven, and when in place the marine ooze was pumped out and the base was sealed with a tremie plug. The next step was to dewater the form and to place the reinforcing steel. The base and shaft were completed with a concrete supposedly placed "in the dry." For various reasons a good job was not obtained, and years later after the teredos had eaten away the wooden forms (which had all been left in place) the concrete began to ravel away. The repair contract required all work to be done in the dry, which necessitated the use of a pneumatic caisson. This caisson enclosed the cylinders successively, one at a time, from high water to the mud line—about 45 ft. Thereby an excellent opportunity was afforded to study this concrete after its fifteen years of service. The typical case showed lenses of mud through the base of tremie concrete, above which was a very lean concrete in the shaft capped off with a plug of solid laitance varying from 2 to 4 ft thick, or sections of lean concrete separated by bands of laitance 6 to 12 in. thick. Many local areas of good solid concrete were encountered. It can be appreciated that this "failure of concrete" was due solely to poor workmanship, although the impression gained by many was that an inherent weakness of concrete when exposed to sea water had something to do with this failure.

The design of marine structures is a most important factor in determining the amount of maintenance that later will be required. Generally, designers have the option of using concrete piles or concrete cylinders in supporting pier decks. With concrete piles it is almost certain to be specified that all cracked piles shall be pulled and replaced with sound piles. Considerable controversy may arise over this point and therefore a brief description of a project in which 3,500 piles were driven may be apropos.

The piles on this job were 16 in. by 16 in. for lengths as great as 60 ft, and 18 in. by 18 in. for 60-ft to 80-ft lengths. All piles were driven with a double acting hammer on a floating rig. These piles were carefully designed; the materials used were certainly of the highest quality; and the workmanship throughout, including curing, was in accordance with the very best practice (1933). When the piles were placed in the leads of the driver, no signs of cracks were visible. After they were driven each of the 3,500 piles was inspected by inspectors in diving suits, and it was found that practically every one had developed cracks during driving. Only at the inshore and in shallow water where the piles were shorter (about 40 ft), and the unsupported length during driving was 20 ft or less, were no cracks observed. Since it would have been beyond reason to expect the contractor to pull these piles and drive others, a distinction was made on this project between a "cracked" pile and a "broken pile," under which it was considered that only such piles as were incapable of acting as elastic members would be rated "broken." Of the total number driven, about 60 piles were definitely "broken" and had to be replaced.

In reaching this decision about "cracked" piles an investigation was made of the piles in an adjacent existing structure, built fifteen years previously. The marine growth was removed and the faces of the piles were inspected carefully in an effort to locate cracks similar to those developing on the present job. As expected they were found; the concrete was then chipped back along the cracks, and in all cases the cracks were found to be opposite the reinforcing ties binding the vertical bars. They were all tight, and no signs of corrosion of either the bands or the main steel were observed.

Since it was definite that these cracks, which occurred opposite the bands, had developed during the driving it was decided that the new piles should be watched during the actual driving process. Because the water was warm, a shallow-water helmet was used, being safer and permitting freer movements around the pile. Furthermore, the large face plate affords excellent vision. After a pile was in the leads, the inspector, in a shallow-water suit, climbed on the pile, keeping under the barge as much as possible to protect himself from falling spalls. After a few blows the cracks would be observed forming, and as driving proceeded the cracks would start to "spit" out the crushed material ground up by each blow. In many of the piles there would be a crack opposite each reinforcing band. The conclusion was that as long as the bond on the main vertical steel was practically unimpaired there would be sufficient ground-up material remaining in each crack to re-cement itself and to protect the steel, and that the pile was as good as could be obtained. It is the writer's opinion that it is impossible to drive a pre-cast reinforced concrete pile, as now being made, without developing these small fine cracks, especially when the length is around 35 to 40 ft from the mud line to the water surface. It is his further opinion that such fine cracks are not harmful if the concrete of the pile is of good quality, but that they are dangerous if the concrete is of poor quality. It all depends on "what kind" of concrete cracks.

Many instances of poor concrete have come to the writer's attention, occurring both in fresh and salt water substructures, and also many examples of good concrete have likewise been observed. One that might be mentioned is a small sea wall built along the beach of Elliott Bay at Seattle, Wash. This wall is 5 in. thick at the top and 7 in. at the base, and 5 ft high. The elevation of the top is at extreme high water. The wall is reinforced at the center with ⅜-in. round bars 15 in. on centers both ways. The concrete was made with the sand and gravel shoveled up from the beach, which at times contained a considerable quantity of sea water. The cement content was 6 sacks per cubic yard. The exposure is very severe and the wall has had to stand much pounding from both waves and drift. The wall is now (1941) thirteen years old and the only signs of distress are those due to erosion; no chemical deterioration can be observed.

GLENN S. PAXSON,[15] ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Hadley's excellent paper on the resistance of concrete to disintegration in sea water should find an appreciative audience among engineers who are working along the seacoasts. He should, indeed, be commended on this summary of his observations and its clear presentation.

It is noted that the list of representative structures given in the paper includes some in British Columbia, Washington, and California. The writer would add to this list the structures along the entire 400-mile length of the Oregon Coast Highway. Frequent inspections of all highway structures are made for maintenance purposes, and no example of disintegration due to chemical action of sea water has been found. These structures are not as old as those cited by Mr. Hadley—the oldest dating from 1920—but, if chemical action is taking place, some evidence should be apparent after 20 years of exposure.

Every indication points to abrasion rather than chemical action as the cause of any disintegration. It is noted that concrete members in deep water, where little or no sand is carried by wave action, retain the surface film of rich mortar and show the form marks. Piers and walls in shallow water or in the tidal range have this film worn away and show a granular texture. The concrete is hard and firm, and it can be assumed that this slight wear is due to the sand carried in the water rather than to any solvent or disruptive action of the sea water itself.

The enlargement of gravel pockets, laitance seams, and construction joints is the result of this same abrasive action. Examples of such structural defects that have not changed after 20 years of exposure to quiet sea water are common.

The excessive rusting of inadequately protected reinforcing steel in sea water with the concomitant spalling of the concrete incasement is often apparent. Adjoining bars with the same exposure, but with adequate protection, show no rusting. This disintegration is certainly not chargeable to any solvent or disruptive action in the concrete itself.

The writer is in complete accord with Mr. Hadley's conclusions that there is no evidence of any solvent or disruptive attack by sea water on properly made and placed concrete.

LESTER C. HAMMOND,[16] M. AM. SOC. C. E. (by letter).—In his "Conclusions" the author states that "The vitally important matter for concrete used in marine work is to have dense, impermeable concrete made of sound materials with adequate cover over reinforcement."

Although he agrees heartily with this statement, the writer cannot agree that the lack of evidence Mr. Hadley has observed, of sulfate attack in concrete marine structures, warrants him in assuming that sulfates in sea water do not reduce the life of the concrete. The writer observed concrete in sea water that was constructed in 1911, which in 1924, after 13 years of service, showed no signs of deterioration; yet the same concrete, when inspected in 1934, showed signs of surface disintegration.

[15] Bridge Engr., State Highway Comm., Salem, Ore.

[16] Chf. Engr., Borough of Manhattan, New York, N. Y.

The concrete viaducts of the East River Drive in New York City were built in sea water. The East River is a tidal estuary connecting the Long Island Sound and New York Bay. During construction, Ladis H. Csanyi, M. Am. Soc. C. E., made an extensive series of tests on twenty-nine concrete cylinders, of which all but nine were samples of the actual concrete used in the structures. These tests consisted of the complete submersion of the samples in a 43% solution of Epsom salts, which is equivalent to a 20% solution of anhydrous magnesium sulfate. This solution is estimated to be about fifty times as strong as the sulfate concentration in the waters of the East River. The test was limited to purely chemical action. The result of these tests proved that, within 92 days, imperfect concrete would show surface attack, and that even the best concrete would not withstand this chemical action after 189 days. Many of the tests extended over a period of 250 days. This proves to the writer that the sulfates in sea water have some chemical action on any concrete. The visible effects on good concrete are considerably less than on poor concrete. Since the tricalcium aluminate (C_3A) content of the cement has a bearing on the resistance of the concrete to sulfate action, it is advisable to use sulfate-resistant cement. The tests confirmed this view and it was noted that concrete having a computed C_3A percentage between 6% and 7% showed best results.

It is not proper to assume that because the deterioration of the concrete observed in Pacific Coast waters can be largely explained by the fact that the concrete was improperly constructed, that the sulfates in the sea water did not contribute to this deterioration. In 1917, Rudolph J. Wig and Lewis R. Ferguson,[17] Members, Am. Soc. C. E., demonstrated that chemical action was noted all along the Pacific Coast. Furthermore, the report of Thomas E. Stanton,[18] M. Am. Soc. C. E., in 1938, indicates that chemical action has been cause for concern along the California Coast.

The reasons for concrete failure in sea water, stated in their relative importance, are: Improper placing, and forms; improper grading of aggregates; insufficient cement; excess of water; improper character of aggregates; and too much C_3A in the cement.

The causes are: Scouring action, frost action, and the chemical action of the sulfates in the water.

With the foregoing possibilities of failure, it is reasonable to claim that the chemical action of the sea water is not the most important cause of its failure; but it seems unreasonable to believe that it is not a contributing factor.

LADIS H. CSANYI,[19] M. AM. SOC. C. E. (by letter).—During the spring of 1939, nineteen concrete structures situated in the harbor of New York City were examined, and all pertinent information concerning the design, mixing, and placing of the concrete was compiled and analyzed. The results of this study confirm the findings of Mr. Hadley, in that a dense, uniform concrete properly placed is essential wherever sea-water exposure is encountered. Only three of the structures inspected showed a resistance to disintegration for periods of twelve years. Of these three, two utilized cements, approaching a moderate sulfate-resistant cement, by containing a computed C_3A-value of 9%. The other, in service for thirty years, yielded no information concerning the source or composition of the cement.

[19] Engr. in Charge, Asphalt Plant, Dept. of Borough Works of Manhattan, New York, N. Y.

In an inspection such as this and the one conducted by Mr. Hadley, the area open to visual examination is wholly above dead low water, wherein the differentiation of physical and chemical reactions is extremely difficult, due to the violent effect of mechanical action. The part below this area, which is totally and continuously submerged, where mechanical and physical action is greatly reduced, and where chemical action is increased, cannot be examined without diving gear. Thus, no conclusive evidence could be obtained by this examination to support, satisfactorily, the contention that cement is not a factor in the resistance of concrete in sea water.

In order to obtain further information concerning the behavior of concrete in that part totally and continually submerged, a series of tests was undertaken by the writer.[20]

The test consisted of subjecting twenty-nine standard concrete cylinders to total continuous submersion in a solution of Epsom salts. During the test the concentration of the solution averaged 27.2° (Baumé), or a 43% solution, which is slightly below saturation. Magnesium sulfate was selected as the test medium because: (1) Its concentration and composition can be controlled easily; (2) it is the main corrosive agent found in sea water; and (3) it is used in checking the soundness of aggregates used in concrete. The concentration was set high primarily to accelerate the test, and secondarily because the soundness test for aggregates used a saturated solution. "What is sauce for the goose is sauce for the gander." The concrete used for the cylinders was obtained in all except eight instances directly from the chutes leading into the forms of the bulkhead walls being constructed for the East River Drive (New York City) in order to provide concrete actually used in the structure for the test. The cements used were all of the sulfate-resistant type, varying in computed C_3A-content from 4.1% to 6.6%. The mixes tested were 1 : 1.8 : 3.2 and 1 : 2.9 : 5.1. In order to check cements of higher C_3A-content, the remaining eight specimens were prepared in the laboratory, having a mix of 1 : 2.2 : 3.9 and using cements having computed C_3A-contents of 9% and 16%.

The results of the test are briefly as follows:

(*1*) *Effect of Sulfate Action on Compressive Strength.*—The compressive strength of the concrete under the test increased generally to 30% above the standard 28-day check test after extended immersion in spite of surface disintegration. The increase stopped and decrease started upon approximately 50% of surface disintegration when further increase in strength was offset by disintegration.

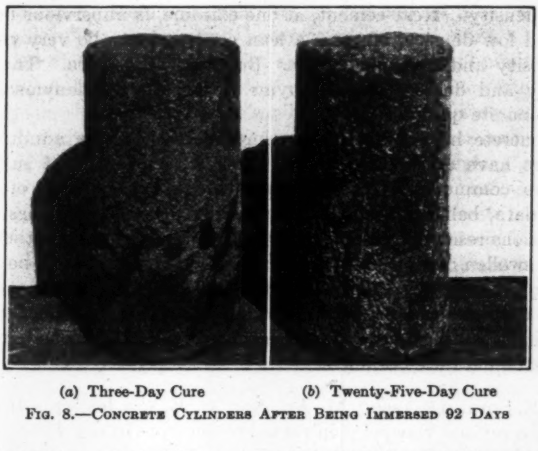
[20] "Resistance of Concrete to Magnesium Sulphate Solution," by Ladis H. Csanyi, with the cooperation of the Dept. of Borough Works of Manhattan, New York, N. Y., submitted to the Polytechnic Institute of Brooklyn, N. Y., in 1940, in partial fulfilment of the requirements for the degree of Master of Civil Engineering.

(*2*) *Effect of Curing on Rate of Disintegration.*—Samples cured for 3 days (1 day water, 2 days wet sand) showed a marked difference in the form of surface disintegration from those cured for 25 days (1 day water, 24 days wet sand). In the 3-day cure (Fig. 8(*a*)), the attack penetrated the grout or carbonate skin and progressed beneath it, flaking off large sections at a time, and thus rapidly exposing the aggregates of the concrete. In the 25-day cure (Fig. 8(*b*)), disintegration was isolated to the points of attack, giving the concrete a blotchy, pimply appearance. In this case exposure of the aggregates was limited and progress of disintegration materially curtailed.

(*3*) *Relation of Design of Concrete Mixture to Rate of Disintegration.*—In every case the richer mixes possessing the greater density showed better resistance for the same type of cement. Mixes of similar density with cement of 16% computed C_3A-content showed less resistance than one having a 9% computed C_3A-content.

(*4*) *The Influence of Cements Upon the Rate of Disintegration.*—The comparison based on the computed C_3A-content of the cement clearly showed that reduction of C_3A-content from 16% to 9% to 6% materially improved the resistance of the concrete. Reduction of C_3A-content below 6% to 4.5% and 4.1% showed material loss of resistance. Therefore, a range between 6% and 7% computed C_3A-content of the cement is indicated as yielding the maximum sulfate resistance to the concrete as far as the effect of the cement is concerned.



(*a*) Three-Day Cure (*b*) Twenty-Five-Day Cure

FIG. 8.—CONCRETE CYLINDERS AFTER BEING IMMERSED 92 DAYS

These studies, therefore, further confirm the essential need of good, dense, uniform concrete, carefully and properly placed and adequately cured, if good sea-water resistance is to be attained. They also refute Mr. Hadley's contention, and confirm the work and belief of others,[21,22,23] that cement is important in imparting some resistance to the concrete when subjected to sea water.

The writer's studies revealed two questions that concern engineers: "What is sea water?" and "What does it contain?" In harbors it may vary from brackish water to high concentrations of sewage frequently containing corrosive industrial wastes. Therefore, let the engineer study the sea water in which he must place his structure, and provide adequate protection and properly designed mixes placed with especial care when the sea water requires it.

G. M. Williams,[24] M. Am. Soc. C. E. (by letter).—The conclusion in Mr. Hadley's paper that there is no evidence of attack or disintegration due to sulfate action could be accepted more readily if chemical analyses of concretes were offered in support. Although developed porosity or disruption may not be apparent, this is not necessarily good evidence that deterioration due to sulfate action is not in progress. Rich concrete mixtures may fail by cracking without prior indication of surface swelling, spalling, or disruptions which are characteristic of failures of medium or lean concretes.

Chemical analyses of small samples taken at several points in a structure such as between low and high tide, parts exposed only to spray, and parts never in contact with sea water should indicate the extent of sulfate action, if any, as well as measure its rate of progress.

Concrete of low permeability is desirable for permanence and resistance to weathering or possible sulfate action, but such concrete is generally not one of greatest density. Neat cement, at one extreme, is impervious but has high porosity and low density, whereas a lean concrete may be very pervious but low in porosity and high in density. Both are absorptive. The terms impermeability and density are antonyms rather than synonyms as used to designate concrete qualities.

That concrete in sea water sometimes deteriorates is admitted. Other investigators have attributed this at times to the action of sulfates. The author, who comments upon the somewhat unusual dearth of supporting laboratory data, believes that no sulfate action has occurred, basing his conclusion upon the results of visual inspection and the absence of either developed porosity or swollen disruption of the mass which he assumes to be the characteristic form and manifestation of sulfate of magnesium attack. Since sulfate content of concrete can be determined so readily by chemical analyses of easily obtained samples, it would seem that valid conclusions can be drawn only after such data are obtained.

Harry E. Squire,[25] Assoc. M. Am. Soc. C. E. (by letter).—In purporting to advocate a revised viewpoint in regard to concrete in sea water, Mr. Hadley

[25] Asst. Chf. Engr., Board of State Harbor Commrs., San Francisco, Calif.

has actually presented a carefully prepared and plausible argument in favor of one of the oldest traditional viewpoints of this controversial subject—namely, that sea water does not attack "sound" concrete, or embedded steel that is adequately covered with "sound" concrete. The contrasting viewpoint is that sea water does attack portland cement concrete and embedded steel whenever it comes in intimate contact with the cement paste or embedded steel, and that the only difference in durability between "sound" and "unsound" concrete is the time factor and intensity of exposure.

Before little if any concrete had been subjected to the sea water of the Pacific Coast, European engineers with a background of more than fifty years experience in marine concrete construction had likewise divided along almost identical lines of opinion.[26] On the Pacific Coast, the forms had barely been stripped from the early concrete before the same cleavage developed among those charged with responsibility for waterfront structures. The extravagant claims of advocates of the newly introduced "permanent" construction faded under the searching forces of sea-water erosion which laid bare all manner of defects ignored under ordinary atmospheric exposure. Nevertheless, enough resistant concrete remained to encourage the proponents of "sound" concrete in their claim that all deterioration could be explained by the term "defective concrete." Improved understanding of concrete technology combined with improved methods of manipulation and manufacture have eliminated almost entirely the defects of the earlier structures; and these methods insure a service life of present-day concrete equivalent to the commercial life of most marine structures built. The controversy becomes more and more a question of academic rather than practical interest and, in the writer's opinion, might be automatically ended by setting up a definition of "sound" concrete in terms of sea-water exposure—material which would withstand for a stated time (say forty years) a certain type of exposure (say tidal or complete immersion) with a stated loss of calcium (say 5%) or, if preferred, an equivalent gain in magnesium. Every one acknowledges that such concrete has been, and is being, manufactured, and most authorities will agree that such concrete is satisfactory for 90% of the structures built. The energy and enthusiasm of those proponents who refuse to acknowledge the mortality of concrete in sea water could then be concentrated on extending the frontiers of durability to really debatable periods beyond fifty years.

In studying the behavior of "sound" concrete in sea water, the writer agrees that there is no better place to go than to the structures which have stood successfully for periods of from thirty to fifty years. However, the writer suggests that the next time the author emulates the prophet and "goes to the mountain," he take a core boring machine and a laboratory assistant with him. There have already been too many surface inspections of both sound and disintegrated structures and too much speculation as to what is going on under the outer skin of the concrete. This is well illustrated by one of the instances of "sound" concrete cited in the paper—namely, the breakwater test specimens exposed at San Pedro.[10] These experimental blocks are almost an exact replica of similar test specimens exposed by Russian engineers in the breakwater at Libau a decade earlier.[27] The Libau blocks were found to be sound under surface inspection but they were, nevertheless, blasted open and samples of concrete from the outside and interior were analyzed and tabulated to show variation from the original cement. Quoting the concluding sentence of the report:

---

[26] "Treatise on Dock Engineering," by Brysson Cunningham, 1904, Chapter 4, pp. 123–130.

> "One fact, nevertheless, was certain—that the process of deterioration had already commenced and that it progressed, slowly perhaps, but none the less surely in the case of the mortars considered."

The writer had the good fortune to make a visual inspection of the San Pedro specimens on the contractor's barge during coring operations. The concrete was sound but saturated even in the interior of the blocks. The cores were to be forwarded to the National Bureau of Standards for testing and analysis, but as yet (1941) no record of these tests comparable to the Russian tabulation has come to the writer's attention. The article referred to by the author[10] is merely a report of the surface inspection together with some photographs of the core specimens nicely crated for shipment—hardly sufficient information to warrant the author's rather positive statement that there was "no evidence of sulfate of magnesium attack." Physical and chemical tests of the core samples would give what the lawyers call "the best evidence" as to what attack, if any, has taken place and, if repeated on future cores, will give valuable data on the rate of attack.

The writer hopes that one of the organizations having funds available for research will find it advisable to make a systematic investigation of structures, successfully exposed to sea water, by means of core borings and laboratory analysis. The list of structures selected by Mr. Hadley would be satisfactory to begin with. No doubt, most waterfront engineers would like to add some pet structure to the list, in which case the writer would select the Ferry Building Foundation Wharf at San Francisco, Calif. This well-preserved structure, approaching its 50th anniversary and outliving its utility as a passenger terminal, is remarkable in that it violates some of the choicest taboos of sea-water concrete practice. For one thing, the immersed concrete was mixed approximately one to eight and can hardly be considered impermeable; for another, the Dykerhoff cement used was of a reasonably high alumina content (approximately 11%) in contrast to the special cements of low alumina content advocated for sulfate resistance.

Most of the analyses available have been made of concrete that was badly disintegrated. Investigators seem to take a ghoulish interest in these misfortunes but have little time for successful structures. Invariably, these analyses show a partial replacement of calcium by magnesium. This has lead to the hypothesis, questioned by the author, that the disintegration is the result of sulfate of magnesia reaction with the calcium hydrate of the set cement.

---

[27] *Proceedings*, International Assoc. for Testing Materials, 6th Cong., New York, N. Y., 1912, Second Section, XVII.

Analyses of disintegrated concrete taken from a recent and somewhat disconcerting failure of good concrete in sea water (that of the concrete piles of the Ford Motor Company Plant at Long Beach, Calif.) indicated not only the usual increase in magnesia content at the expense of the calcium, but in addition a marked increase in the alumina content. Search for the source of the alumina led to the discovery of variable percentages of soluble alumina and active silica in samples of fine aggregate taken directly from the gravel pit. Submitted to the state mineralogist, the samples were identified as mixtures of quartz particles with varying percentages of feldspar particles, the feldspar being partly kaolinized.

The disintegration was confined to that part of the pile below the line of immersion, and was spotted in a most irregular manner over the entire wharf structure. The conclusion was inescapable that it was due to chemical reactions caused by the sea water; the variation in the behavior of the piles could readily be attributed to variations in the percentage of deleterious feldspar in the aggregate. A marked characteristic of this disintegration was swelling in volume of the concrete affected. The formation of sulfo-aluminates (alums) with their great capacity for increase in volume by taking up water of crystallization has been suggested as the primary cause of this type of breakdown. No matter what the theory, whether due to replacement of calcium by magnesia, to the formation of sulfo-aluminates, or of complex silicates from the active silica of the sand, the fact remains that exactly the same phenomenon of disintegration was simulated in the laboratory by A. A. M. Russell, Assoc. M. Am. Soc. C. E., using the suspected sand mixed with local cement and immersion in San Francisco Bay water. The breakdown of the mortar was similar to what occurred in the Long Beach piles exposed to sea water.

The writer questions the author's opinion that disintegration is primarily the result of physical and mechanical forces rather than chemical, but he agrees that most breakdowns occurring in less than 25-yr exposure may be attributed to two kinds of defective concrete:

(*a*) The use of mixes having a deficiency of cement; and
(*b*) The placing of mixes in excessive water (not merely wet mixes but concrete drowned by leaky forms or by an accumulation of water in tight forms).

Both are probably phases of the same fundamental defect—concrete in which the water-cement ratio is so high that water voids or loose crystallization admits the sea water into ready contact with the cement paste.

After studying the breakdown occurring in the piles at Long Beach and also experiments made by Mr. Russell on a large number of puzzolan admixtures which showed that many substances containing active silica or alumina produce unsound briquets, the writer is convinced that a number of failures previously attributed to improperly proportioned or placed concrete have been accelerated, if not primarily caused, by aggregates which yield alumina and silica capable of reacting with the substances in the set cement paste and with the sea water; and that the superior behavior of some successful structures is due in large measure to the inert nature of the aggregate. In this type of failure, the expansion resulting from internal chemical activity seems, progressively, to open up the structure of even superior concrete to the sea-water salts.

In regard to the other ailment which afflicts concrete in sea water—the corrosion of embedded steel—experience has revealed one optimistic fact. Below the level of immersion, corrosion appears to be completely inhibited and the embedded steel appears to be quite as permanent as wood below the groundwater level. In tidal waters this immunity extends to about the mean high-tide line.

Above the high-tide line a very different condition prevails, and when the surface is subjected to intermittent splashing and drying out, superior concrete in thicknesses ordinarily specified in reinforced concrete practice will not protect against cracking and spalling from expansion of the corroded steel. Greater depths of cover may prevent this type of damage because there is a depth at which the shearing resistance of the concrete cover exceeds the pressure of the corroding materials; but the absence of cracking or spalling is no assurance that corrosion is not in process. Where small bars are used, they will frequently rust away entirely without showing surface indication. Furthermore, corrosion is sometimes localized, the same rod rusting entirely away at one point and having full section not more than a few feet away. The writer never has been able to satisfy himself that if the corrosion of a 1-in. rod cracks 1 in. of cover in from ten to fifteen years, it may not crack 2 in. to 3 in. in thirty to forty years or it may even rust off entirely. Here again is a place for field investigation to determine the relation between depth of cover, impermeability, and rate of corrosion. Perhaps the investigators will conclude, as the writer has, that it is easier to seal the concrete off from sea-water moisture than to obtain a convincing answer.

In the "Summary" Mr. Hadley makes a significant statement which rings responsively in the writer's mind:

> "The harm resulting from misunderstanding a natural phenomenon arises from the likelihood that measures adopted to effect changes and alterations in it will be misdirected."

There are few branches of engineering construction in which methods are more divergent and in which those engaged in the work more individually opinionated than in marine concrete work. Under the guise of producing resistant concrete, engineers resort frequently to the most extreme measures in proportioning, in the use of water, in surface treatments, in manipulation, and in the use of admixtures—measures which are frequently so onerous that they defeat their purpose by diverting attention from simple but necessary requirements. Much of this effort must be misdirected because the writer has rarely seen more than one or two of these extreme requirements applied simultaneously by any one engineering organization.

In addition, many practices are contradictory. Thus, in one case there is the exhibition of two groups of eminent engineers charged with the same problem of constructing bridge piers in harbor waters—the one group, adopting a special cement with a specially low alumina content, and the other prescribing a special puzzolan cement in which an activated alumina silicate is added to the normal alumina content; in another instance, the paradoxical practice of two large harbor organizations in which one protects the concrete under water to the extent of impregnating it under pressure with asphalt but ignores the surfaces above water, whereas the other carefully seals the above-water surfaces but exposes the under-water surfaces without protection to the ocean sea waters.

The best proof of the ability of ordinary, good concrete and standard portland cement to withstand the usual sea-water exposures is the fact that so many structures have given a good account of themselves in spite of extraordinary procedures resorted to in the name of producing resistant concrete. The writer agrees that it is highly desirable to clarify the concrete technologist's viewpoint and attitude when he comes down to the sea; but he believes that the way to do it is to probe into existing structures and discover what changes in structure and chemical content have occurred. Only by knowing what has happened in the first fifty years can one judge what may be impending in the next fifty or hundred.

J. W. B. BLACKMAN,[28] M. AM. SOC. C. E. (by letter).—Referring to Mr. Hadley's paper, it is noted that observations on marine structures are confined to the Pacific Coast. It is further noted that the paper deals only with disintegration of portland cement structures from the action of sulfate of magnesium. This very much limits the discussion.

It must be stated that there are very few portland cement concrete structures north of San Francisco. Since the seaports of the Pacific Northwest—in Washington, Oregon, British Columbia, etc.—are in a timber country, creosoted piling is used extensively for construction of their marine works. The San Francisco Bay area and the Los Angeles and San Diego harbors are where the greatest number of concrete structures exist.

Portland cement concrete, when exposed to sea water and sea air, is subjected to many causes of deterioration and disintegration other than the action of sulfate of magnesium (which is generally considered as secondary by engineers engaged on the construction of marine work). Mr. Hadley has mentioned the many other attacks of various kinds.

It may be well to summarize briefly some of the various causes of action that the writer has encountered. In driving pre-cast concrete piles, many hazards are met before the pile reaches its final position. Assume that the concrete mixture has been carefully designed, the mineral aggregates tested, the concrete compacted by careful vibration, a minimum quantity of water used, constant inspection by experienced men, and not less than 3 in. of cover for the steel. Then, with a perfectly impervious and well-protected pile cast ready for transportation, there are yet many hazards to guard against. It must be lifted and carefully handled at the point of driving. It must be placed in the pile-driver leads and driven with a hammer whose weight is proportioned to the size and weight of the pile. The amount of driving that the pile is to be subjected to is to be governed generally by the experience of the engineer and the type of soil it penetrates. Where piles are held entirely by friction, some engineers prefer to jet most of the way down, only driving the last few feet, whereas others prefer to drive the entire distance, if possible.

---

[28] Cons. Engr., Long Beach, Calif.

There is a difference of opinion between some engineers as to the amount of driving that a pile should receive. It is not necessary to elaborate in detail on Mr. Hadley's paper with regard to the many types of failure to which concrete is subjected, but briefly they appear to be as follows: Poor workmanship, faulty mineral aggregates, poorly designed mixtures, too much water, insufficient cover of reinforcement, cracks due to shrinkage, handling, and driving. Porosity is one of the greatest causes of failure. It allows the moisture to gain access to the steel reinforcement, causing ready oxidation and steel expansion which, in turn, spalls the concrete. Many writers have demonstrated that there are two distinct causes of failure—one due to mechanical action and the other due to chemical decomposition.

Porous concrete can be disintegrated by forces exerted by the crystallization of salts in its pores. This condition is accelerated by the constant wetting and drying of concrete exposed to the wave action of sea water. The continuation of this process creates surface cracks, which are caused by this building up of crystals and concentration of the salts, and will in time cause deterioration of the concrete both by mechanical and chemical action. It is apparent, therefore, that all concrete exposed to sea water and sea air must be as impermeable to water as it is possible to make it.

The writer was asked to inspect a wharf built some few years ago in Long Beach (Calif.) Harbor. A large number of the concrete piles were in a serious stage of disintegration. The concrete in which disintegration showed was swollen and disrupted, and this condition appeared to be more acute on the upper side of the batter piles. Repairs to the structure cost about $250,000. In the opinion of some engineers the disintegration was due to feldspar in the small aggregates. In the opinion of others the damage was due to other causes. It is interesting to note that a large number of the piles adjacent to those disintegrated showed no apparent decomposition. Is it to be assumed that the cause of the disintegration was due to faulty workmanship? For instance, some of the piles may have been compacted carelessly, there may have been too much water, and the porosity may have been much greater than that of the adjacent piles that were not injured. This raises a question that is difficult to answer.

The Portland Cement Association has, with wisdom, recommended[29] as follows: "For unusually severe exposures, as in sea water, etc., a clear cover of 3″ is recommended at least for the portion of the pile where such exposure is encountered." Some cement companies have placed on the market brands of cement such as "sulfate resisting cement," "high-silicate cement," etc. The chemists of cement companies have been endeavoring to find a remedy for attacks on cement concrete exposed to sea water and sea air.

---

[29] "Concrete Piles," Portland Cement Assn., November, 1939, p. 28.

Concrete in the soffits of slabs and beams is just as vulnerable as other parts of concrete structures to disintegration or deterioration from the various causes mentioned. Hence, various methods of protection have been tried, some of which have proved successful.

Reference is made by Mr. Hadley to the small ferry wharf at North Vancouver, B. C., Canada. The writer knows this structure well and has inspected it. He feels that where such examples are cited, for comparison, the following additional information should be supplied:

(1) The structure is built on columns (not piles). Had piles been used instead of columns, they would have been subjected to the stresses of handling and driving, which in many cases creates cracks. This in time readily admits sea air and salt water.

(2) The salinity of the Burrard Inlet (North Vancouver) is much less than that of the open sea because large bodies of fresh water are discharging all the year round from the creeks upstream and downstream from the ferry wharf.

Mr. Hadley's statement that the protective measures of asphalt impregnation of concrete piles, as used in Los Angeles Harbor, are thoroughly effective as to impermeability and density is interesting. A recent inspection of the same type of piles in Richmond Harbor, Calif., and San Diego Bay, shows that these piles are in excellent condition. Some of the piles in Los Angeles Harbor have been in use for twenty years.

Mr. Hadley should be thanked for bringing this interesting matter to the attention of engineers.

E. C. JACK,[30] ESQ. (by letter).—Any viewpoint of the subject of concrete in sea water should be somewhat philosophical, in that disintegration or deterioration may or may not be serious, depending upon the rate, and keeping in mind the anticipated life of the structure. So many of the construction people with whom the writer does business consider 10 or 20 years a long time, and anything that might happen after that they believe is immaterial. However, one needs only to look back over the centuries to realize that this matter of ships is a long-range, continuing one extending far into the future. The U. S. Navy is primarily interested in ships, and waterfront improvements to serve the ships should be provided with an eye to a life of at least 100 years. Thus, what to one person might be a negligible breaking up of the structure, to another would be a serious indication when a long life had been planned.

It has been noted that, in almost all cases where disintegration of one kind or another has taken place, there are contributing factors upon which the onus of the situation can be placed, thus clearing sulfate attack of the charge. Nevertheless, it is agreed with Mr. Hadley that the weakness of concrete toward sulfate attack has perhaps been over-stressed. Chemists have their catalytic agents and metallurgists their eutectics; and, in a similar manner, is it not probable that the weakness of concrete toward sulfate and acid attacks makes possible the disintegration by other means, such as wave and frost action, abrasion, and chemical action? In several places in Alaska, notably at

---

[30] Senior Civil Engr., Puget Sound Navy Yard, Bremerton, Wash.

Kodiak and at Dutch Harbor, concrete has met with progressive disintegration between tide lines, whereas the remainder of the structure has withstood weathering very well for 25 years. Surely these cases must be a combination of sea-water attack plus frost and wave action.

Cement is a wonderful material that has been improved remarkably through the years, and its comparatively low cost, together with the rather universal distribution of the mills throughout the United States, makes possible the building of many structures that would have been impracticable years ago. It is far from perfect, however, and it may be well to review the most well-known weaknesses of cement and concrete.

Aggregate.—The quality and usefulness of concrete, with present-day cements, demand that aggregate be sound, chemically neutral or basic, and free of oil and other deleterious substances, in addition to being well graded. Thus, in some localities, concrete is very costly because of the distance from which aggregate must be brought. On St. Paul Island, in Bering Sea, it was necessary, one time, to carry gravel by ship from San Francisco, Calif. If cement acted slightly different chemically, then a wider range of aggregate might be used.

Proportioning.—The mixture must be a proper one with sufficient cement, and this item of cement, too, is relative: Witness the amount of cement used per cubic yard today compared with the amount used 50 years ago.

Compounding.—The mixture must be put together in the right order, well worked, with one's weather eye open for numerous technical pitfalls.

Chemically Basic.—Cement and concrete in the green stage are strongly basic, and even when well hardened they are slightly basic. They are thus particularly vulnerable to all substances of an acid nature, such as humous, coffee, industrial wastes, sea water, etc. Just what goes on within the mass during hardening is still very much a mystery. A more thorough and complete chemical combination very probably would improve not only the chemical weakness but also reduce the troubles from erratic hardening, and actually reduce the shrinkage.

Porosity.—Concrete made in the best manner known is quite porous under some conditions, and is thus vulnerable to wave and frost action and penetration of salt water to embedded steel, causing spalling and other such deterioration.

Time of Set.—The time of set is not subject to very good control, which very much limits the use of concrete under some circumstances. In fact, this lack of control can be very embarrassing at times, being either too slow or too fast, and this also nearly prohibits its use for repair work between tides.

Rate of Hardening.—This property naturally varies greatly with different kinds of cement, but in all cases it is absolutely dependent upon the temperature—too much so for comfort in cold climates.

Heat of Crystallization.—This factor has been partly taken care of with the modified cements, but it is still difficult to disperse in spite of concrete being a relatively good conductor.

Workability.—In spite of great care taken to proportion cement and aggregate, the resulting mixtures are almost universally harsh; that is, the cement paste is not as smooth as one would like to have it.

Shrinkage With Hardening.—In practically all cases, concrete shrinks with hardening, thus causing troublesome construction joints.

Volume Change.—This phenomenon occurs, with addition or removal of moisture.

The foregoing résumé includes only the more obvious weaknesses. The items are interrelated in many cases. The first three will probably be present always as they are inherent in the universal use of any material of so cosmopolitan a character as cement. Modified cements and the use of admixtures are the result of trying to obviate some of these deficiencies. If a cement could be manufactured that would combine with all of the water ingredient, it would solve many of these problems.

In conclusion, the analysis of the many combinations of circumstances surrounding any one incident of deterioration is a complicated problem, and it has not been found possible in many cases to put one's finger definitely on any single underlying cause. Generally, it is a combination of poor circumstances, or a poor combination of circumstances, which made the deterioration possible. Therefore, sea-water attack by itself, it is believed, is seldom the cause of progressive disintegration, but in combination with other weaknesses it probably is a contributing factor.

Alfred M. Freudenthal,[31] Assoc. M. Am. Soc. C. E. (by letter).—In attempting to present the problem of resistance of concrete in marine work "in a nutshell," and in stressing the overwhelming importance of resistance against mechanical attack, Mr. Hadley is to be highly commended.

However, there are few engineering problems less suited to the dogmatic approach than that dealt with by the author, and if the question—"Does any form of deterioration occur in the concrete in sea water that would not develop if the exposure were changed to similarly agitated, similarly fluctuating, fresh water?"—is answered definitely in the negative, this appears to be overstating the point.

The deteriorating action of the sea is of two kinds: Mechanical and chemical. The lack of distinct evidence of chemical corrosion in concrete of adequate design and composition (on which evidence the author rests his conclusions) indicates that two "lines of resistance" may be assumed to exist, the "advance line" of the two being the resistance of the structure to mechanical attack. However, there is definite evidence of chemical attack of sea water on the cement and the conclusion that "* * * there appears to be no valid basis for believing that such attack occurs" (see heading "Conclusions") is in contradiction to the results of very extensive and very careful research in America as well as in different countries of Europe.[32]

It is not only the sulfate-of-lime attack that leads to disintegration of concrete; the tricalcium aluminate-hydrate is by far more injurious, although less frequent. Evidence of other corrosive effects of sea water, as well as of the interrelation between the specific cement qualities and the intensity and speed of deterioration, has remained inconclusive, and additional research is needed urgently.

[31] Res. Engr., Marine Trust, Tel. Aviv Port, Tel. Aviv, Palestine.

[32] "Resistance of Cements to Attack by Sea Water and by Alkali Soils," by Thomas E. Stanton and Lester C. Meder, *Journal*, A. C. I., Vol. 9, 1938, pp. 433–464; "Report of International Congress for Testing Materials," London, 1937 (see especially reports by H. Kuebl, F. Ferrai, and A. Steopoe; and "Deterioration of Structures of Timber, Metal and Concrete Exposed to the Action of Sea Water," Dept. of Scientific and Industrial Research, H. M. Stationery Office, London, 1935 (report by R. E. Stradling).

Questions of serious import are: "Is the effect of puzzolanic admixtures physical (that is, do they increase the density), or is it chemical?" The use of quick-setting cement in marine work creates an early mechanical resistance to external forces. "Do the mechanical advantages outweigh the chemical disadvantages?" The writer has observed conclusive evidence that aluminous cements are very resistant to the action of sulfur compounds in fresh ground water but has further observed that they are definitely weak in sea water. "Why then do they prove definitely weak in marine structure?" "Is this weakness due to physical or chemical action?" "Can pre-cast members be protected against corrosion by applying a bituminous coating to the surface?" Such investigations were begun at Tel-Aviv Port in 1939 in connection with the driving of concrete piles.

The foregoing questions are of considerable importance, and the opinion expressed by the author (see heading "Summary")—that "There is no particular reason for research * * *" is scarcely justified. If the metaphor used by Mr. Hadley were correct, the resistance against chemical corrosion might be considered a comparatively "strong link" in the "chain" of total resistance. This point is supported only by the author's testimony, since the structures referred to do not demonstrate more than the fact that, in all cases where sufficient resistance of the concrete against mechanical attack has been insured, the amount of chemical corrosion has appeared insignificant. The metaphor of the "chain" and its "links" is not a happy one, since the wearing down of both kinds of resistance—the mechanical and the chemical—is not simultaneous but rather consecutive. Considerable deterioration is always preceded and initiated by deficiencies in the mechanical resistance, and there is nothing to support the opinion that after the breakdown of this "first line" of mechanical resistance the subsequent deterioration is not considerably intensified and accelerated by the chemical attack.

Observation of marine structures shows that the main damage to the concrete occurs within the tidal range as well as on horizontal surfaces above sea level (such as flat tops of breakwaters and sea walls) subject to constant spray. It is due to the evaporation and consequent concentration of the attacking saline solution. The fact that the strongest mechanical action of the waves usually occurs near the mean sea level, and thus within the tidal range (wearing down the resistance of the concrete against mechanical attack more rapidly than elsewhere), makes this range particularly susceptible to the concentrated chemical attack beginning in the eroded cavities and voids. Since the corrosion of the permanently submerged parts of marine structures is almost nil, due to the formation of a siliceous gel film that protects the surface, it is not the actual saline concentration of the sea water that is relevant, but the high concentration of the saline solution caused by evaporation. The circumstance that the eroding effect of the initial concentration of the sea water might be regarded theoretically as rather weak thus has no bearing upon the actual intensity of the attack upon concrete marine structures.

It is evident that the density and the impermeability of the concrete, particularly near the surface, are the principal qualities constituting the mechanical resistance of the concrete against attack by the sea. Theoretically, these qualities may be obtained by adequate grading of the aggregates, rich mixes, and (if this is not thought sufficient) puzzolanic admixtures or the admixture of other dispersing agents. Practically, however, the placing of concrete and its early resistance to mechanical attack is of overwhelming importance in attaining the required density and impermeability, and the best mix will be entirely deprived of its merits if there is even slight neglect in the procedure of placing. The considerable hazards encountered in the construction of marine works are sufficiently known and may not always be forestalled. In spite of all precautions it often may not be feasible to secure practically perfect conditions of placing and to prevent local damage of the concrete surface. Thus its capacity to resist mechanical attack is affected. If no resistance against chemical attack is provided for, relatively rapid deterioration of the structure will start locally, and it will extend gradually over parts initially unaffected. Adequate capacity to resist chemical attack, however, will counteract the injurious effects of local erosion to a considerable degree.

Although the author's statement that "The vitally important matter for concrete used in marine work is to have dense, impermeable concrete made of sound materials with adequate cover over reinforcement" may be fully indorsed, his opinion that "* * * there appears to be no valid basis for believing that such attack occurs" is definitely contradicted by actual evidence (see heading "Conclusions"). The conclusion (see heading "Synopsis") "* * * special precautions against sulfate attack are needless" is not justified, and its application in practice would deprive concrete marine structures of a highly valuable "second line of resistance."

T. B. RIGHTS,[33] ASSOC. M. AM. SOC. C. E. (by letter).—Experience has led the writer to believe that concrete should never be used in sea water between high-tide and low-tide elevations. If there is disintegration in concrete in sea water, above the high-tide level, the factor of the brand of cement used in the construction should be investigated carefully.

In 1925, the engineers of an eastern railroad built a bridge across an estuary near New York, N. Y. At the eastern end of this bridge, two test piers were constructed. Pedestal piers that supported the steel work of the bridge protected these test piers, so that mechanical abrasion due to floating ice or logs was reduced to a minimum.

The test piers were identical except for the cement. The bottoms were about 2 ft below mean low water and the tops 2 ft above mean high water. No reinforcement was placed in either pier. Fresh water was used for mixing water. Both test piers were constructed "in the dry" with accurately measured water, and proper batching of aggregates. One test pier was built with the same brand of cement as the remainder of the bridge; the other was constructed with quick-setting high-strength cement.

---

[33] Roselle, N. J.

Within two years after construction, the test pier made of the quick-setting cement began to disintegrate and within five years had disintegrated so much that it could only be seen at low water.

Twelve years after construction, the test pier of regular cement was sound, and apparently unaffected by years of exposure to the tidal range of sea water. At that time, one would draw the conclusion that the failure of the one test pier was due only to the cement. At present (only sixteen years after construction), the regular cement test pier is beginning to disintegrate.

Engineers of this railroad company find that, as a general rule, concrete of the better grade will not show disintegration for at least twelve years. Consequently, on important bridge piers built in salt water, it is their general practice to face the piers between a plane about 2 ft below low water to a height of 2 ft above high water, with either granite or hard paving blocks. The railroad bridge cited herein, where the test piers are situated, has its many piers constructed in this manner, with a belt of granite blocks between extreme high and low water. There is no apparent disintegration in any piers thus protected. The concrete above the granite blocks seems (1941) to be in excellent condition. However, the mortar between the granite blocks, on the horizontal layers, is missing in a number of these piers. In fact, at some piers it seems as if only the bond at the backs of the granite blocks holds them in place. This railroad company has not experienced trouble with any of its concrete piers poured in fresh water. The only zone of attack and disintegration appears to be in sea water between the tidal range.

Figs. 2 and 4 apparently show disintegration at the base of the wall. If a belt of granite had been used, the structure might be in good condition today, as the remainder of both walls above high tide appears sound.

The writer does not know what caused this disintegration—whether it is sulfate-of-magnesium attack, freezing, or crystallization of the salt in the water—but he does know that if he were to construct piers in salt water, the concrete would be protected by a belt of granite at the tidal zone.

Homer M. Hadley,[34] Assoc. M. Am. Soc. C. E. (by letter).—It is the privilege of the writer to answer, or to attempt to answer, the objections that have been raised to his paper. On the moot subject of concrete in sea water there would probably have been a wider discussion and more objections raised if times were less troubled and more leisurely than now. However, a sufficient amount of skepticism has been presented, directly, indirectly, and by reference, to stimulate the writer to further and closing endeavors, as follows:

First be it said that the paper attempted to give a summarized but complete statement of facts and conditions as they exist; then an interpretation of those conditions. As to the statement that there are a large number of concrete structures of considerable age in sea water along the Pacific Coast, which are free from deterioration, no denials were entered. On the contrary Messrs. Stanton, Way, and Paxson confirm and indorse these statements, and Mr. Squire, although favoring the chemical attack theory, specifically declares that the substructure of the Ferry Building at San Francisco, "approaching its 50th anniversary," is free from deterioration. Therefore, the existence of the numerous old and unaffected structures, not having been challenged or denied, may be accepted as reality by every one. This may be done the more readily because beyond any one's assertion, pro or con, are the structures themselves, standing in place and giving their own testimony to whoever examines them. Mr. Squire appears to feel that conclusions based on a mere quarter century's performance are too hasty and precipitate and that good behavior for the first 25 years is no assurance as to what may happen in an ominous future; but apart from his warning no dissent on the widespread immunity from sea-water attack has been expressed. It is largely in the interpretation of the deterioration which has occurred that variance of opinion is most pronounced.

---

[34] Regional Structural Engr., Portland Cement Assn., Seattle, Wash.

Before coming to the other matters, however, the question of the significance of these old and unaffected structures may well be asked. If sea water attacks them why are they immune? If they are immune—and they are—what is the matter with the sea-water attack? Where is it? Why doesn't it attack? In short, where is the reality—in the structures or in the theory that they contradict and refute? Under these conditions the theory manifestly becomes untenable. There is no satisfaction in retaining and cherishing a theory that does not work, however plausible it may be. A prediction of future occurrences must be duly fulfilled if faith and credence are to be maintained in the prediction. Therefore, it appears advisable to the writer that the inevitable sea-water attack theory be abandoned because of altogether too much conflicting evidence. However, should any one be minded like Mr. Squire to retain it for another 10 or 20 years, let him feel wholly free to do so. Time is not an end. Nevertheless, he should bear in mind what was said of old: "Hope deferred maketh the heart sick."

Also deserving of fullest consideration are the partly deteriorated structures—those which combine disintegrated parts with perfectly sound and unaffected parts. Why do they do this? How can such things be? If the sulfates of magnesium, or what-have-you, attack the concrete in some places, why not in others? Attention is directed to Figs. 2, 4, and 6 as food for thought for every one, but particularly for those who yearn after the chemical and the obscure.

It is gratifying to find that there is general agreement on the need for proper mixtures, minimum water content, careful placement, etc. Since the importance of these matters is now widely recognized, it follows that concrete in sea water will have a far better record in the future than it has had in the past.

The dearth of supporting laboratory data in the paper receives adverse comment in two discussions. That the submittal of such data is most conventional is admitted. It is orthodox, regular, "almost always done." Yet is there need for it as an aid in permitting one to believe the existence of that with which he is confronted? Assuming that the observer stands before concrete that has been exposed to sea water for many years and that he not only sees that it is sound and unaffected but on striking it with a rock or a hammer he likewise feels that it is hard and unyielding and hears it ring to the blow as only hard, sound concrete does, then on this evidence of three of his five senses—all that are involved—it is submitted that without more ado and without waiting for core borings he may well believe that it is indeed unaffected by the sea water. Such may seem a daring, risky, hazardous thing to do on one's own initiative and "without benefit of clergy," so to speak, but inasmuch as there is a wealth of corroborative experience to be had, the act is recommended. If there were not the additional and supporting evidence, physical and chemical analyses would assuredly be most desirable. An extraordinary anomaly deserves the fullest investigation; but this is no rare thing, this unaffected concrete. It is everywhere, even constituting the major part of badly deteriorated structures. Relevant, therefore, appear the words of Lewis Mumford, who can see no need for research to prove that water is wet or that pepper tastes hot on the tongue. There is nothing particularly wrong with such research, of course, but why, laboriously and scientifically, demonstrate the obvious? What is needed far more than any laboratory research or cutting of cores is a comprehensive and detailed survey and report on conditions as they exist, supported with ample photographic evidence. Every one could then form his own conclusions from the photographs—and there would be little to argue about. In general, the cause of sea-water attack is no more than this: Too much water in too lean mixtures frequently assisted by careless placement. Change these conditions and the attack disappears. Retain these conditions and the attack follows. "Pay your money and take your choice."

Several advance the suggestion that where deterioration does occur the sea-water sulfates hasten and accelerate the destruction. Possibly this is true—possibly it isn't. What quantitative data exist to support the hypothesis? For many years the writer has looked at concrete—good, bad, and indifferent—not only in sea water but in fresh water as well, and he can only say that his impression is that the deterioration is substantially alike, allowance being made for the greater water movement and greater mechanical destruction along the seacoasts. Following Mr. Hammond's reference to them, the writer reread the articles[17] by Messrs. Wig and Ferguson published in 1917, and he looked at the illustrations of these articles. Then he looked through a dozen or so volumes of the *Proceedings* of the American Concrete Institute (A. C. I.), which have carried many a paper and report about durability of concrete, deterioration of concrete, frost-resistant concrete, etc., principally illustrated with examples in the Great Lakes region. For every Wig and Ferguson illustration of sea-water deterioration—reinforcement troubles excepted—he thought he found its counterpart illustration of structures around the Great Lakes, far from the sulfates of magnesium. To any one interested in seeing for himself, these several writings are commended.[35] Also, let every one who would make sea-water resistant concrete read a paper by R. B. Young,[36] published in 1940. It presents the recipe although not written with that thought in mind.

Captain Blackman and Mr. Freudenthal advance the view that the making of proper concrete for sea-water use is a matter of delicacy and extreme refinement. "A hair, perchance, divides the false from true." From which view the writer must dissent. Given reasonable proportions and control there is no cause for believing that a slight departure from the established quantities is

FIG. 10.—VARIATIONS OF C_3A-CONTENT; CEMENT SPECIMENS AFTER FOUR YEARS IN SEA WATER (STANDARD OTTAWA SAND; 1 : 3 MIX)

fraught with dire consequences. If water is kept to the minimum which placement will permit, and if the cement content is not less than 1.50 bbl per cu yd, considerable fluctuations can occur without ill effects. They are not recommended, of course, but neither should they be appalling to contemplate if they do occur.

Of all the evidence in support of the sea-water attack theory, the writer knows of nothing more convincing than tests described by Mr. Stanton[21] in 1938. He has seen these specimens with his own eyes and accepts the findings without hesitation. There is clearly demonstrated by immersion (not in some other alkaline water but by immersion in sea water itself) the fact that pronounced differences in these specimens develop between cements of high and low C_3A-content. Figs. 9 and 10 are views of certain of Mr. Stanton's typical specimens at the age of 4 years. There is no question as to the way in which the test specimens have behaved. However, Fig. 11 of pier 17 on the San Francisco waterfront, built in 1912, is highly relevant to the conclusions that are to be drawn from Mr. Stanton's investigations since it is built of that same brand of cement used in the tests which was found to have 17.2 C_3A-content and to have the poorest resistance to sea water of any of the cements tested. Despite this fact, the piles of pier 17 are unaffected by sea water and the little fins that formed at the joints in the forms still project from their surfaces. Inevitably the question arises: "So what?"

It is to be recognized by every one that the same name on a sack of cement does not mean the same identical cement from year to year unless raw materials and manufacturing processes remain unchanged. However, no change of major consequence has occurred with this particular brand of cement. It uses the same limestone and same clay and essentially the same manufacturing process today as it did in 1911 and 1912. Its raw materials are more carefully proportioned, more finely ground, and are better controlled; the burning is better controlled; the clinker is more finely ground. Beyond these changes, however, the manufacturing process is substantially unaltered. It can safely be assumed, therefore, that the cement of pier 17 is practically the same as that used in Mr. Stanton's tests. Other differences, therefore, must account for the extraordinary contrasts in behavior. These other differences are immediately apparent in the contrasting mixtures and contrasting specimen structure that results. In the one case a highly permeable porous structure was sought and obtained with mortars using sand of practically uniform particle size. In the case of pier 17 a concrete mixture with its aggregate particles grading from fine to coarse was used.

There are other differences also—those of shape, form, and size. A 2-in. by 4-in. cylinder, although a very convenient laboratory specimen, resembles nothing that is built in structures; on the contrary, it is quite unlike anything so built. How great these differences are is shown in Table 1, in which are to be noted particularly the curvature (Col. 4), and surface-to-volume (Col. 5) and edge-to-volume (Col. 6) ratios. The little cylinder is much more unfavorably shaped than is the corresponding round pile or square pile section. The square pile has more edge length—usually chamfered—but has flat plane surfaces.

There is not only pier 17 at San Francisco in conflict with Mr. Stanton's and others' findings regarding C_3A-percentages. Mr. Squire records the 11%

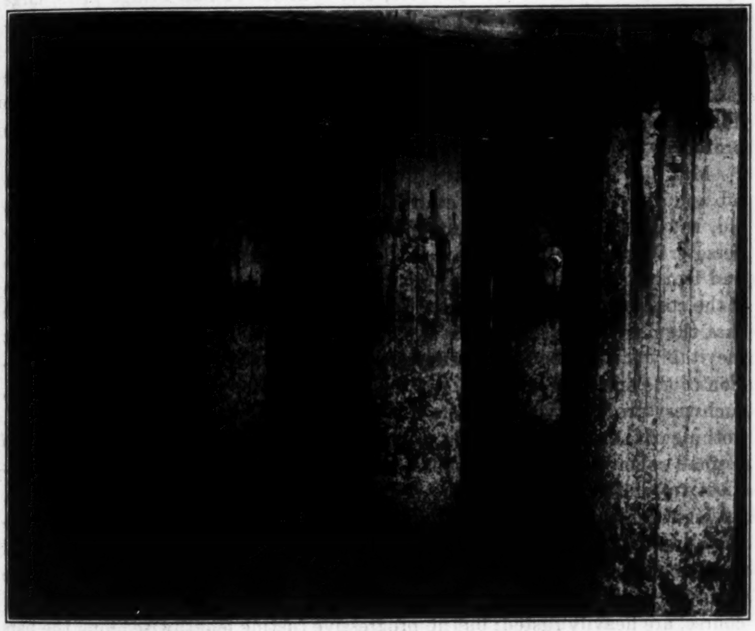

FIG. 11.—PRECAST CONCRETE PILE JACKETS; SAN FRANCISCO PIER BUILT IN 1912

C_3A of the unaffected San Francisco Ferry Building substructure, which has been nearly 50 years in sea water. The cylinder substructure of pier 38 at San Francisco built in 1909, the base of the lighthouse on the San Pedro breakwater at Los Angeles built in 1910, the cylinder shells of pier 8, Puget Sound Navy Yard at Bremerton, built in 1911 are all 30 or more years old, are all perfectly sound and unaffected by sea water, although the cylinders of pier 38 contain numerous honeycombed areas dating from their original construction. They were built of that brand of cement which in Mr. Stanton's tests was found to have 13.2% C_3A-content. Average analyses of bin samples of this cement for the years 1909 to 1913 ranged from a low of 14.5% to a high of 15.9% C_3A-content. Moreover Mr. Stanton advises that his specimens made with high C_3A cement but with the graded Russian River sand still showed no signs of attack after seven years of the same complete immersion in sea water that proved so disastrous to the specimens made with Ottawa sand. It is for these reasons that the writer is unable to attach more than minor significance to the C_3A-content of cement for sea-water use. It certainly is important in 2-in. by 4-in. cylinders made of Ottawa sand; but what further claims are (by evidence) warranted concerning it? The disparity between 2-in. by 4-in. cylinders and ordinary piles is great, but how much greater is the disparity between 2-in. by 4-in. cylinders and 4-ft cylinders, 8-ft cylinders, small bridge piers, large bridge piers! The differences may become of wholly different orders of magnitude. The matter of concern is the behavior of the structure and the prototype. Therefore distinctions which, by a process of magnification, are made manifest in a laboratory appear to the writer to have little significance unless they are also found in the prototype; and if they reveal no effect in the prototype, what practical importance attaches to them?

Mr. Way's detailed account of experiences with a large new concrete pile job and of what was found on examination of a near-by pile structure, 15 years old, is a valuable one, particularly in its bearing on the importance of transverse cracks in concrete piles. Frequently a great deal of alarm, agitation, and trouble to all concerned result from fine shrinkage cracks in piles which, if the concrete is of proper quality, cause no harm whatsoever. It is not true that the mere admission of sea water through fine cracks to the reinforcement inevitably brings about progressive rusting of that reinforcement and disruption of the enclosing concrete. If the concrete is (or was) of a lean, wet mix, such very probably will be the result; if the concrete was not lean and not wet, nothing of the sort will happen. A few miles west of Olympia, Wash., in 1920 a small concrete bridge was built across the head of Mud Bay, the southernmost tip of Puget Sound. The columns of the bents were poured in place. At high tide they are almost completely immersed in sea water. At low tide they are completely bare. At a number of places on the square, chamfered corners of these columns, drift logs have broken off the concrete, exposing the main vertical reinforcing bars for several inches. These exposed lengths, of course, are heavily rusted; but no progressive rusting lengthwise along the bars or splitting of the concrete has ever resulted. The rust formed to the edges of the concrete and stopped there. The writer makes this statement with the greater assurance because he broke off some of the abutting concrete, further exposing the reinforcement, and saw that the rust stopped at the edge of the original fracture. Why should this be, if the admission of sea water through the least fine shrinkage crack means doom and perdition? Well, it means no such thing.

An interesting case showing the effect of too much water is in the San Francisco district where considerable corner cracking over the main longitudinal bars occurred in a large pile job, necessitating rather difficult and extensive repairs. The piles, as is almost always the case, were cast in a horizontal position. Three of their sides were thus poured against forms; their top sides were troweled. When the cracks developed, in practically every instance they occurred on the troweled side of the pile—that is, on what had been the top side. "Water gain"—a fine film of water on the under side of the top longitudinal bars, which water film later left an equally fine void space wherein rust could form and progress—appears to be the explanation of this case. Bond tests by H. J. Gilkey, M. Am. Soc. C. E., S. J. Chamberlin, Assoc. M. Am. Soc. C. E., and R. W. Beal[37] and by Carl A. Menzel[38] show strikingly the effect of casting position—"orientation." It is also worth recording here that the very unfortunate and widely celebrated early experiences with concrete piles in the work of the Los Angeles Harbor Commission were had with piles of 1 : 2 : 4 mix, some of which at least (as photographs attest) were cured by a man sprinkling them with a hose; how continuously or how intermittently is not revealed by the photographs.

Mr. Paxson's comments on sea-water concrete along the Oregon coast are appreciated. His observation that concrete in deep water shows less deterioration than that on the shore where abrasive and scouring action occurs is highly significant and amusing as well: The more completely the sulfates of magnesium surround the concrete the freer it is from deterioration.

To Mr. Hammond the writer would refer his preceding discussion of Mr. Stanton's tests. He would question Mr. Hammond's statement that Messrs. Wig and Ferguson "demonstrated" that chemical action was noted all along the Pacific Coast. Their papers published in 1917 reveal that they found a considerable amount of deteriorated concrete. The interpretation they placed upon it was that the deterioration resulted from sulfate attack. Presumably they examined all of the old concrete structures shown or referred to by the writer since they state[39] that their examination had been made in the preceding 2 years and that they had made "personal examination of nearly every concrete [marine] structure * * * in the United States." Nevertheless, having reread their papers, the writer cannot see that they "demonstrated" sulfate attack. They attributed the deterioration to sulfate attack. It would be very interesting, however, to see how well their theory of immunity to sea-water attack achieved by the formation of lime carbonate near the outer surfaces of the concrete would be sustained by little 2-in. by 4-in. Ottawa sand specimens that were given proper initial curing followed by generous air curing, and what, under these circumstances, the effect of varying C_3A would be.

Mr. Csanyi's discussion, reporting the condition survey of nineteen structures in New York Harbor, is very interesting. Regarding the continuously submerged parts of concrete structures that cannot readily be examined, it is to be said that little or no question has ever been raised about them. It appears to be the general experience that this concrete does not deteriorate. When the piers of the Seaside Bridge of the Union Pacific Railroad were removed from Cerritos Channel, Los Angeles Harbor, in 1934, after 26 years of immersion, they were found to be wholly unaffected. They were built of a 1½ : 3 : 5 mix, not 1 : 3 : 5 as so frequently and so unfortunately has been done in the past. "Not a bad spot in them," declared the superintendent of Merritt-Chapman-Scott Corporation who took them out. The concrete fragments from the piers certainly confirmed this statement. When the old bridge at the site of the new Purdy Bridge, Pierce County, Washington,[40] was taken out, its foundations had been in sea water for 15 years. One of the piers had to be removed completely. Its concrete throughout was found to be in perfect condition and its reinforcement clean and without rust.

[37] "Bond Between Concrete and Steel," by H. J. Gilkey, S. J. Chamberlin, and R. W. Beal, *Bulletin No. 147*, Eng. Experiment Station, Iowa State College, Ames, Iowa, 1940.

[38] *Proceedings*, A. C. I., 1939, p. 517.

[39] *Engineering News-Record*, September 20, 1917, p. 532.

The rigor of Mr. Csanyi's refutation of the writer's contention is lessened and abated by the fact that his studies, experiments, and conclusions are based not on behavior of test specimens in sea water but on their behavior in a 43% solution of Epsom salts. It would appear to the writer that they are highly relevant to concrete that is to be given such exposure, but that the relationship of the 43% Epsom salts solution to sea water has not been established. Pending that determination the writer will continue "in the error of his ways," if such it be.

Professor Williams' brief discussion is charged with numerous doubts. Regarding chemical analyses, the subsequent discussion of two subjects referred to by Mr. Squire will be pertinent. As to Professor Williams' statement that "Rich concrete mixtures may fail by cracking without prior indication of surface swelling, spalling, or disruptions," the writer would inquire if he (Professor Williams) has ever seen this happen with rich concrete mixtures, not in other alkaline waters, but in sea water. If he has, it is to be hoped that full particulars may be reported, for assuredly it is a highly unusual, not to say unique, occurrence, the like of which has not come under the writer's observation. The terms dense and impermeable in the paper were not used academically but as they are commonly employed. The writer disclaims any responsibility for establishing the criteria by which the sulfate attack of sea water upon concrete is supposed to evidence itself. Messrs. Atwood and Johnson[2] quoted E. Candlot who attributes the sea-water sulfate attack theory and its supposed manifestations to L. J. Vicat. The writer merely assumed (see heading "The Prevailing Viewpoint") that if the theory were valid the evidences of the attack should be discoverable. The paper purports to be no more than an unequivocal statement that such evidence is not to be found along the Pacific Coast and a report of what deterioration is to be found. Also, it was stated at the outset: "* * * it is with sea water in its normal range of concentrations—not with other sulfate waters—that the paper is concerned" (see "Introduction"). It was not without knowledge of much to the contrary that has been published earlier that this paper was written. Despite that knowledge, it was written, quite deliberately.

Mr. Squire raises a number of points. One of these concerns the San Pedro breakwater specimens referred to in the paper, the cutting of cores from which, and the saturated condition of the interior concrete of which, on the basis of his "visual" and therefore, by his stern standards, very questionable inspection only, are attested to by Mr. Squire. What the result of the Bureau of Standards' tests and analyses might be was naturally an interesting question. The blocks gave every outward evidence of being all right but were they so in full reality? "Gilded tombs do worms enfold." One of Mr. Squire's fellow citizens in the Bay region who had read the magazine article cited[10] wrote to the U. S. Engineer office at Los Angeles and duly received a reply concerning the findings. When the writer made personal inquiry at that office, he was shown a copy of this letter, which was quite in accord with other information he had received. There was nothing about the findings to make them of a confidential nature, and there appears to be no good reason why they should not be summarized herein from notes made at the time.

---

[40] *Engineering News-Record*, March 3, 1938.

The Bureau of Standards felt that the tests were inconclusive, principally because the cores were of small diameter (3 in.). Tests were made of eleven cores—five of 1 : 2 : 4 mix and 6 of 1 : 3 : 6 mix. Six brands of cement had been used—three European and three American. The maximum size of aggregate was 2 in. The cores were sawed into cylinders, 3 in. high, which were first tested for strength and then analyzed chemically. Strengths varied widely. Values with the 1 : 2 : 4 mix ranged from 6,650 to 3,110 lb per sq in. Values with the 1 : 3 : 6 mix ranged from 7,560 to 1,630 lb per sq in. No signs of disintegration were noted in the broken cylinders. The report pointed out how the low strengths and erratic values were readily accounted for by the varying position and size of the coarse aggregate particles in the cores. It did not attempt to explain how, after 27 years in the tidal zone surrounded by seawater sulfates, the high values found could occur. Chemical tests were made with specimens of five of the six cements, two of which were in 1 : 2 : 4 mix cores, the other three being in 1 : 3 : 6 mix cores. There were six samples of the former and nine of the latter. The tests were to determine percentages of magnesia, sulfuric anhydride, and chlorine. Chemical analyses were stated to be inconclusive because of inability to secure representative samples from the small quantity of material in the cores. The samples of 1 : 2 : 4 concrete showed a 74% increase in magnesia content accompanied by a 19% decrease in SO_3-content, which decrease is not in good form chemically when concrete is disintegrating. The samples of 1 : 3 : 6 concrete showed a 358% increase in MgO accompanied by a 51% increase in SO_3. In considering the numerical magnitude of these percentages it must not be overlooked that they are percentages of original very small quantities. Regarding the samples of two of the three cements used in the 1 : 3 : 6 mix specimens the report stated: "While B-1 and B-4 would seem to indicate that some magnesia from sea water has replaced part of the original lime of the cement, this fact may be solely one due to the question of sampling. There apparently has been no increase in the SO_3 content, which is what should accompany this disintegration." The view was expressed (let borers of cores and takers of small samples give heed) that 2 to 3 cu ft of material were needed to make a satisfactory sample.

Inasmuch as there was no definite evidence of physical or chemical deterioration—which is entirely in accord with the many structures referred to—the writer feels quite warranted in stating that there was "no evidence of sulfate of magnesium attack." He feels further confidence in "what is going on under the outer skin of concrete" if this "outer skin" itself withstands scrutiny.

Mr. Squire introduces evidence of concrete in sea water in Europe by reference to Russian tests in the waters of the Baltic Sea at Libau, together with a choice quotation from the report[27] concerning them: "* * * slowly perhaps, but none the less surely" the processes of deterioration proceed, etc., presumably demonstrating that the San Pedro blocks were "an almost exact replica" of the Russian blocks. Thanks to the reference, the report on the tests was obtained and read. The highlights of, and additional quotations from, it are as follows:

Tests were made in June and July, 1905. Eight test blocks—four masonry and four concrete—were sunk in 1891 and 1892. The concrete blocks measured 6 ft by 6 ft by 10 ft. The concrete mix, by volume, measured separately, was: 1.0 Portland cement, 2.5 sand, 1.5 gravel, and 4.6 "rubble stone"—that is, 1 part of cement to 8.6 parts aggregate, measured separately. "Rubble stone" was stated to be granite "in pieces 10 to 14 cubic inches"—in other words 2⅛-in. to 2½-in. cubes. Quoting:

> "The greater part of the Portland cement came from Russian Works, foreign cement was also used, but no chemical analysis was made. * * * The sand was taken from the sea on the spot."

Concrete blocks Nos. 8, 9, and 10 were immersed with about 4½ ft of water above their tops. The fourth, No. 15, was set on the breakwater with its bottom at water surface. Incidentally, the Baltic is tideless, and the inflow of fresh water from numerous rivers exceeds evaporation:

> "* * * hence an enormous surplus must be got rid of by an outflowing current which is named the 'Baltic stream' * * *. The fresher Baltic water can be traced far into the North sea especially along the Norway coasts even as far as North Cape."[41]

On removal from the water the blocks were found to be "in good state of preservation" but with various defects: "White exudations," "liquefied mortar," "white liquid derived from deteriorated mortar" in seams and cavities, etc.

> "As a whole the three cements used, slag, Portland, and quartzose cements, were found practically equal in quality."
>
> "The physical tests having given but indifferent results in regard to the determination of the change which the mortar undergoes in the blocks, a chemical analysis of the various kinds of mortar was made.
>
> "The analysis made afforded bases for the following conclusions: If after the determination of the principal elements * * * of the mortar tested and after elimination of the elements proceeding from the Libau sand, the results be compared with the elements forming the cements used (Portland, slag, and quartzose cements) it is easy to ascertain the extent to which the elements forming the cements have undergone variation by action of the seawater.
>
> "* * * The transformation was characterized principally by the freeing of the lime * * * and by the absorption of the oxide of magnesia and of the sulphuric acid contained in the seawater" (refer to Le Chatelier, Michaelis, Feret *et al*).
>
> "The same tables show that the calculated proportion in weight of alumina and iron oxide exceeds in some instances the proportion of the same elements which were in the cements used in making these mortars. This is probably the case because the average composition of the Libau sand reckoned upon does not always compare completely with the composition of the sand actually used. The Libau sand has in fact but little

---

[41] *The Encyclopædia Britannica*, 14th Ed., 1929, p. 1016.

> homogeneity. The chemical analyses of five samples showed the amount in weight of Al_2O_3 and Fe_2O_3 to vary within very wide limits viz. from 0.10 to 0.70 percent. This is due to the presence of particles of earth and clay; these are found especially when the sand is taken in quarries on the downs and not at the sea shore.
>
> "It should be remarked also that although in the mortar made with quartzose cement the quantity of Portland cement was half that in the mortar made with Portland cement, the chemical analyses of the mortar made with quartzose cement was not inferior to that of the Portland cement one.
>
> "One fact, nevertheless, was certain—that the process of deterioration had already commenced and that it progressed, slowly perhaps, but none the less surely in the case of the mortars considered."

There appears to be little need for comment on the preceding testimony. The specimens were made 50 years ago, and the control conditions were not those regarded as necessary today; but as an instance of the highly extolled European practise and experience the reference has its interest. One further matter has its interest also. The English magazine "Port and Harbour Authority," for June, 1941, reprinted the present paper in its entirety with editorial comment. Some of this editorial comment was to the effect that here was surprising news: Concrete in sea water in America that had not deteriorated! True, it did not generally deteriorate in sea water in Britain, but practically all they had ever heard of sea-water concrete in America was that it deteriorated and "went to pot." Apparently while they were receiving such information from this side of the Atlantic, Americans in turn were hearing of the superior and long-established European practise that would not think of using Portland cement in sea water without treatment or process of some kind or other. What in current slang is called "the run-around" seems to have prevailed over a long term of years.

After so much disagreement with Mr. Squire, it is a pleasure to concur with him about the case of the Ford Motor Company Plant at Long Beach (except in minor detail) and to again express warm and sincere admiration for Mr. Russell's work in testing in connection with it. This is the case the writer referred to under the heading "Unsound Materials." It is undoubtedly the one Captain Blackman refers to in his discussion. It appears to be shown conclusively that the felspathic aggregate was the cause of the trouble. The concrete used in the piles deserves Mr. Squire's characterization as "good concrete" in every respect, except that all unwittingly the unsound aggregate was incorporated in it. Thereupon it ceased to be "good." As for Mr. Squire's "chemical reactions caused by the sea water," the writer would gladly subscribe to them while directing attention to Mr. Russell's demonstration, previously cited, of the "chemical reactions caused by the sea water" upon this aggregate all alone and without any cement present while the reactions were in progress. Since the aggregate alone is most unstable in the presence of sea water, it seems scarcely necessary to speculate upon the effects of the addition of cement. It is a not uninteresting fact that while this trouble was occurring at Long Beach the Ford plants at Richmond, Calif. (on San Francisco Bay), and at Seattle, Wash. (in the strongly saline waters at the mouth of the Duwamish

River), built at the same time as the Long Beach plant, were—and still are—free from any trouble in their concrete piles.

So far as the writer knows concrete piles are impregnated with asphalt primarily to protect the pile from low tide to its top, rather than to "protect the concrete under water." This latter protection is incidental to the manufacturing process. If this belief is correct, it is probably more fitting to so state.

With his friends, Captain Blackman and Mr. Squire, the writer has had some stirring arguments in the past. On this occasion may he differ with Captain Blackman regarding the number of Portland cement structures north of San Francisco by saying that, although most large structures are in the south, there is a wealth of lesser structures in the north—bridge piers, pile trestles, sea walls, culverts, outfall sewers, etc., together with a considerable number of larger works. It is not necessary to build a cathedral to have fine architecture reveal itself. Neither is it necessary to have a 1,000-ft long pier to determine the behavior of concrete in sea water.

The writer is made happy by Captain Blackman's statement that deterioration of concrete in sea water by the action of sulfate of magnesium is generally considered as secondary by engineers engaged in harbor work. It is hoped that Captain Blackman reads Mr. Way's discussion, particularly those parts dealing with the concrete pile jobs, cracks, etc. It is believed that the little bridge near Olympia, with certain parts of its reinforcing steel exposed, may also yield him cheer should the hazards to which unimpregnated concrete piles are subject weigh him down unduly.

He refers to the 3-in. cover over reinforcement recommended by the Portland Cement Association[29] and more recently by the 1940 Joint Committee Report.[42] Although this is needed cover with some kinds of concrete, it is not an unmixed blessing, as Captain Blackman knows full well, particularly as it affects the weight of a slender reinforced member subject to bending both in installation and in subsequent service. The writer is of the opinion that the suggestion of J. H. Wasson[43] advanced in 1929 that the tops of piles coming above low tide be made of a particularly good quality of concrete would warrant the omission of extra cover. As a matter of fact, it is doubtful in view of the performance of the 1918 ships and barges, with their limited cover over reinforcement, whether with richer mixes 3 in. of cover is not a wholly unnecessary precaution. Furthermore it would appear that the newly developed vacuum process might have very valuable application in the field of concrete piles in improving the density of the surface concrete and in permitting the reduction of cover over reinforcing bars to 1 or 1½ in.

Captain Blackman delicately refers to special sulfate resisting cements. He states that "The chemists of cement companies have been endeavoring to find a remedy for attacks on cement concrete exposed to sea water and sea air." Undoubtedly this is, or has been, true. Without knowing the exact basis of their action, the writer would assume it to result from the plethora of past writings about what is the best European practise, about sulfates of magnesium in sea water, and about all calamitous, inevitable things that befall concrete in sea water. Probably these special cements are highly efficacious in genuinely severe sulfate exposures.

---

[42] *Proceedings*, Am. Soc. C. E., June, 1940, Pt. 2.

[43] *Proceedings*, A. C. I., 1929, p. 760.

The writer gladly declares that the North Vancouver Ferry Pier is built upon columns, not piles. Fig. 3 is a view of part of its substructure. Considering the diagonal bracing shown in Fig. 3, it is very unlikely that any would think it was built on piles, but if they do, may this statement set them right. The beach beneath the pier is cemented hardpan, and piles could not have been driven.

Considering Captain Blackman's familiarity with the North Vancouver Ferry Pier, it was amazing to the writer to read his statements regarding Burrard Inlet, Vancouver's magnificent landlocked harbor which, with its north arm, covers an area of 31.6 sq miles. True, a number of small streams and creeks or little rivers flow into it from the mountains on the north side. The largest of these, the Capilano River, has its discharge greatly reduced by the use of its water in the water system of Vancouver. Sometimes these streams flood, sometimes they grow small; but at all times, compared with the mighty volume of sea water passing in and out of the harbor with every changing tide (the tides average 12 ft), the inflow of fresh water is insignificant indeed. The harbor authorities report a salinity of harbor water of 1,023 compared with 1,026 for ocean water and 1,000 for fresh water. Consequently "upstream and downstream from the ferry wharf," although a fanciful whimsy, seems more reminiscent of Captain Blackman's old home at New Westminster, British Columbia, on the Fraser River than applicable to Vancouver Harbor. The fact is that, unimpregnated though it be, the North Vancouver Ferry Pier is a very fine, very successful little sea-water structure now aged 32 years. Across the harbor on the city side, where no streams discharge, the Great Northern Pier built in 1913, the Ballantyne Pier[44] built in 1923, the Canadian Pacific Pier B–C,[45] and various other structures are free from deterioration and sulfate attack.

Regarding Mr. Jack's suggestion that sea water may "speed the parting guest," the earlier part of this closure presents the writer's opinion. Mr. Jack's résumé of the various deficiencies of cement is acknowledged as essentially correct, without the writer's having knowledge of how the deficiencies may be overcome. For many uses it would also be desirable to have cement and concrete of half their present weight. To have definite control over the time of set appears to the writer to be particularly desirable for sea-water concrete.

Certain of Mr. Freudenthal's points and objections have been answered previously. His stated experience with aluminous cements in sea water is not confirmed locally. The pier at the Puget Sound Navy Yard, in Bremerton, Wash.,[46] is now (1941) 15 years old, and its cylinders built with high alumina cement are, after 15 years in sea water, in absolutely perfect condition. On the other hand the writer heard of some bridge in Chesapeake Bay built about the same time with this same type of cement whose piers disintegrated very quickly. Probably this was not in any way due to the sea water but rather to inadequate provision for the dissipation of the large quantities of heat generated in this cement's setting process. Seattle has quite a number of street pavement patches made with high alumina cement. Some of the early ones crumbled and broke up. After it was learned that such patches had to be continuously sprinkled or ponded all trouble ended. It is obvious that sea water had nothing to do with these street pavement failures.

---

[44] *Engineering News-Record*, May 24, 1923, p. 908.

[45] *Loc. cit.*, December 16, 1926, p. 984.

[46] *Proceedings*, A. C. I., 1927, p. 79.

The effect of puzzolanics is speculated upon by Mr. Freudenthal. The south main pier of the Golden Gate Bridge at San Francisco was built with a high-silica puzzolanic cement, the north main pier with ordinary Portland cement. Perhaps some time in the future distinct differences will be observed between them, although, as Mr. Paxson notes, in deep water changes are much slower than at the shore. Bonneville Dam on the Columbia River was built with a puzzolanic cement. It was completed in 1937. The resistance of its concrete to abrasion and cavitation has not been wholly satisfactory, but it is believed that the number of shrinkage cracks in the dam are fewer than if it had been built with Portland cement, a very comforting thought.

Mr. Rights' discussion lacks sufficient detail to permit much comment on the failure of the railroad test piers he describes. The size and shape of these "piers," the cement content of their concrete, and the exact character of the change that is beginning to manifest itself in the remaining pier (described by the words "beginning to disintegrate") are either not stated or are indefinite. The year the test was initiated (1925) suggests the possibility that the "quick-setting high-strength cement" referred to by Mr. Rights may have been the same as that used in the Seattle street pavement patches previously mentioned. This is only conjectural on the writer's part, however. Under these conditions there does not appear to be much basis for comment on the failure referred to by Mr. Rights.

There is no question, however, that frost adds greatly to the severity of the sea-water exposure, and it may be that concrete of a quality that would perform satisfactorily in sea water where freezing conditions are absent would not be satisfactory where freezing conditions prevail. On the other hand, the writer sees no reason for believing that unfaced concrete of a quality adequate to resist the sea-water exposure under freezing conditions cannot be readily obtained.

In 1923 Meyer Hirschthal,[47] M. Am. Soc. C. E., reported sound 16-yr old concrete in a wall at Hoboken, N. J. The North River is not heavily saline, however. Nevertheless it is probably comparable to the estuary cited by Mr. Rights. It would be interesting to know the present condition of this unfaced wall. In his private files the writer has correspondence regarding two test prisms, 12 in. square and about 8 ft long, set in the tidal zone at Saint John, New Brunswick, Canada, in 1913. Freezing conditions prevail at Saint John and the specimens had four square corners, which do not help any toward resisting either abrasion or weathering. In 1933 one of these specimens (made of 1 : 3 : 5 mix, gravel aggregate, and "fairly wet mix") was reported to be entirely disintegrated. The mortar surface had disappeared and the specimen was in broken pieces. The other specimen, of 1 : 2 : 4 mix, crushed rock coarse aggregate, and of "about 2–3 slump," was reported to show "only slight wear just about high water."

---

[47] *Engineering News-Record*, January 17, 1924, p. 127.

It is to be hoped that a further report may sometime be made regarding the Aberthaw tests of unfaced concrete specimens placed in sea water in 1909 at the U. S. Navy Yard at Charlestown, Mass. The last published report was made in 1920. In 1940 the writer sought additional information regarding them, learned that twelve specimens of the original twenty-four still remained, and was unable to learn anything more. Since a very good record of the manufacture of these pile specimens exists, it is to be hoped that their condition can be reported. They are now (1941) over 30 years old and have a background of experience that will not be available to test specimens made today until thirty future years have passed.

Granite facings are both admirable and costly. So far as the walls shown in Figs. 2 and 4 are concerned, a solution to their troubles, simpler and less expensive than granite, would have been to have changed the careless construction practises plainly evident in them. There is plenty of unaffected concrete in the tidal zone in both of these views to demonstrate the nature and cause of the deterioration. The wall on the right side of Fig. 2, starting at the stepped-off joint at the reentrant angle is Quay Wall E, built in 1896, and still showing no need of granite facing. The only recent use of granite facing on the Pacific Coast that the writer knows of is the protective course in the tidal zone in the piers of the new Lions Gate Bridge at the entrance to Vancouver Harbor. There is no freezing or ice or unusual condition of abrasion to be concerned about at present, but if the glacial age ever returns these piers are foresightedly prepared to withstand it.

The Dallas Road sea wall at Victoria, listed in the paper as built in 1911, has a belt course of granite 2 or 3 ft high at the beach line, which has undoubtedly been helpful in protecting the concrete from abrasion. These are the only Pacific Coast uses of granite facing on concrete that the writer can think of, although there are quite numerous cases where concrete structures have had granite or other stone blocks dumped loosely around and against them. Granite of good quality, of course, is one of the finest and most resistant materials of construction that there is, and the writer would say nothing to impugn it. As a necessity for the preservation of concrete in the tidal zone, however, he entertains what he at least would call reasonable doubts concerning it. According to reports reaching him, a certain resin either interground with the cement, or introduced into the concrete as an admixture, gives most interesting promise of being a substitute for granite facings when the urge for special treatment in the tidal zone is strong upon one.

To sum up, the situation appears to be this: The sea water exposure is a very severe one. It has been sufficiently demonstrated that concrete can be made which will give a highly unsatisfactory performance in sea water. Undoubtedly bad concrete can be made with any brand of cement and with a wide variety of admixtures and treatments. The disintegrated concrete is, in general, characterized by a lean, porous, and frequently segregated structure. Too little cement, too much water, too little care in placement are the chief causes of trouble. Poor aggregate is sometimes a further contributing cause. On the other hand there are a large number of concrete structures of considerable age in sea water which are substantially free from deterioration or any evidence of sea-water attack. These have been made with many different cements, differing widely in composition and in percentage of tricalcium aluminate. This immunity occurs with, and is characterized by, concrete of dense, impermeable structure. There is no sea-water deterioration to be found, other than that due to rusting of reinforcement, that is distinctly different from fresh-water deterioration. There is no peculiar sulfate attack. For these reasons it appears to be highly important to use fairly rich mixtures, minimum mixing water consistent with good placement, care in placement, and all reasonable measures which result in density and impermeability. Special safeguards against sulfate attack can be reserved for use where they are needed—that is, elsewhere than in sea water.

To all who contributed discussions the writer would express his thanks and his hope that all differences of view are dispassionate and impersonal. Out of the reporting of various experiences comes increased knowledge and better understanding. It is to be hoped that such may be the outcome here with respect to concrete in sea water.

ANALYSIS OF STATICALLY INDETERMINATE TRUSSED STRUCTURES BY SUCCESSIVE APPROXIMATIONS

BY O. T. VOODHIGULA,[1] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. FRANCIS L. CASTLEMAN, JR., CHARLES A. ELLIS, DAVID J. PEERY, L. E. GRINTER, AND O. T. VOODHIGULA.

SYNOPSIS

In this paper the writer has attempted to simplify the classical method of analyzing statically indeterminate trussed structures, and to develop a physical concept whereby an analysis may be made rapidly by successive approximations.

INTRODUCTION

So far as the writer knows, there are two direct methods of successive approximation, applied to indeterminate trussed structures. Both methods were developed in England; the one by R. V. Southwell and the other by J. F. Baker, Assoc. M. Am. Soc. C. E., and A. J. Ockleston.[2] Due to the complicated nature of statically indeterminate trussed structures, the direct method of distributing stress becomes tedious. Professor Pippard states[3] that "It is clear that less labor was involved in determining the forces in the members of the framework * * * by strain energy methods than by either of the successive approximation methods * * *." The method of work still seems to be the best. The only objection lies in the solution of the simultaneous equations since the labor involved increases rapidly with the number of equations.

METHOD

The structure is made statically determinate by cutting the redundant bars and replacing each of them with a pair of equal and opposite forces, as shown in Fig. 1. When the loads are applied, there will be relative movements at different cuts due to the distortions of the bars; the ends of the cut bars will move away from or toward each other, depending on the nature of the distor-

[3] *Loc. cit.*, p. 108.

tions. The relative movement of the two ends can be found by the method of work. Let the relative movements due to the distortion of the statically determinate structure, of the two ends at a, b, and c, be δ_{a0}, δ_{b0}, δ_{c0}, respectively; thus

$$\delta_{a0} = \sum \frac{s\,u_a\,L}{A\,E} \tag{1a}$$

$$\delta_{b0} = \sum \frac{s\,u_b\,L}{A\,E} \tag{1b}$$

and

$$\delta_{c0} = \sum \frac{s\,u_c\,L}{A\,E} \tag{1c}$$

in which: s is the stress in each bar due to the applied load; u_a, u_b, and u_c are the stresses in each bar due to a unit resistance to movement at points a, b, and c, respectively; L = the length of the bar; A = the cross-sectional area of the bar; and E = the modulus of elasticity.

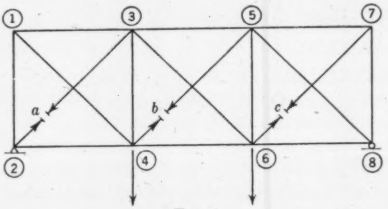

FIG. 1

The gaps must be closed by applying the forces X_a, X_b, X_c simultaneously. The relative movements at a, b, and c due to these three forces must be equal to the relative movements δ_{a0}, δ_{b0}, and δ_{c0} caused by the loads on the base structure; that is:

$$- \sum \frac{s\,u_a\,L}{A\,E} = X_a \sum \frac{u_a\,u_a\,L}{A\,E} + X_b \sum \frac{u_a\,u_b\,L}{A\,E} + X_c \sum \frac{u_a\,u_c\,L}{A\,E} + \cdots + X_n \sum \frac{u_a\,u_n\,L}{A\,E} \tag{2a}$$

$$- \sum \frac{s\,u_b\,L}{A\,E} = X_a \sum \frac{u_b\,u_a\,L}{A\,E} + X_b \sum \frac{u_b\,u_b\,L}{A\,E} + X_c \sum \frac{u_b\,u_c\,L}{A\,E} + \cdots + X_n \sum \frac{u_b\,u_n\,L}{A\,E} \tag{2b}$$

and

$$- \sum \frac{s\,u_c\,L}{A\,E} = X_a \sum \frac{u_c\,u_a\,L}{A\,E} + X_b \sum \frac{u_c\,u_b\,L}{A\,E} + X_c \sum \frac{u_c\,u_c\,L}{A\,E} + \cdots + X_n \sum \frac{u_c\,u_n\,L}{A\,E} \tag{2c}$$

or they may be written in the following forms:

$$- \delta_{a0} = X_a\,\delta_{aa} + X_b\,\delta_{ab} + X_c\,\delta_{ac} + \cdots + X_n\,\delta_{an} \tag{3a}$$

$$- \delta_{b0} = X_a\,\delta_{ba} + X_b\,\delta_{bb} + X_c\,\delta_{bc} + \cdots + X_n\,\delta_{bn} \tag{3b}$$

and

$$- \delta_{c0} = X_a\,\delta_{ca} + X_b\,\delta_{cb} + X_c\,\delta_{cc} + \cdots + X_n\,\delta_{cn} \tag{3c}$$

In Eqs. 3 all the terms except X_a, X_b, and X_c are known or can be computed; δ_{a0}, δ_{b0}, and δ_{c0} are dependent on the loads, their positions, and the given structure; and δ_{aa}, δ_{ab}, δ_{cc}, δ_{bb}, etc., are dependent on the given structure only and can be considered as the constants. This knowledge at once suggests that the equations can be solved by means of successive approximations. In Eq. 3*a* assume X_b and X_c equal to zero to obtain the approximate value of X_a. With X_a known and assuming $X_c = 0$, X_b can be computed from Eq. 3*b*. The approximate value of X_c can be solved from Eq. 3*c*. By repeating the foregoing process, successive values of X_a, X_b, and X_c will be obtained and these will approach the solution of Eqs. 3, if there is convergence. This is the solution of simultaneous equations by iteration.

In this problem a technique is needed in order to simplify the process of approximation to reveal the physical significance. Rearrange Eqs. 3 in the following forms:

$$X_a = -\frac{\delta_{a0}}{\delta_{aa}} - X_b\frac{\delta_{ab}}{\delta_{aa}} - X_c\frac{\delta_{ac}}{\delta_{aa}} \cdots \text{(etc.)} \ldots\ldots\ldots\ldots (4a)$$

$$X_b = -\frac{\delta_{b0}}{\delta_{bb}} - X_a\frac{\delta_{ba}}{\delta_{bb}} - X_c\frac{\delta_{bc}}{\delta_{bb}} \cdots \text{(etc.)} \ldots\ldots\ldots\ldots (4b)$$

and

$$X_c = -\frac{\delta_{c0}}{\delta_{cc}} - X_a\frac{\delta_{ca}}{\delta_{cc}} - X_b\frac{\delta_{cb}}{\delta_{cc}} \cdots \text{(etc.)} \ldots\ldots\ldots\ldots (4c)$$

They can be still further simplified as follows:

$$X_a = -s_a' - X_b K_{ab} - X_c K_{ac} \cdots \text{(etc.)} \ldots\ldots\ldots\ldots (5a)$$

$$X_b = -s_b' - X_a K_{ba} - X_c K_{bc} \cdots \text{(etc.)} \ldots\ldots\ldots\ldots (5b)$$

and

$$X_c = -s_c' - X_a K_{ca} - X_c K_{cb} \cdots \text{(etc.)} \ldots\ldots\ldots\ldots (5c)$$

The new notations may be defined as follows:

$s_a' = \frac{\delta_{a0}}{\delta_{aa}}$ = single redundant stress; that is, the stress in the redundant *a* when all the other redundants are not acting; and

$K_{ab} = \frac{\delta_{ab}}{\delta_{aa}}$ = stress in bar *a* due to a unit axial load in bar *b*; it may be called a carry-over factor of stress of *a* due to a unit axial load acting in the redundant *b*.

Eqs. 5 are easier to follow than the previous equations, and the physical significance of every term is clear and enables one to visualize the stress distribution in the structure. It may be stated that the stress in any redundant is equal to the single redundant stress of the bar plus the carried over stresses from the other redundants. One may begin with the single redundant stresses, like fixed-end moments in the moment-distribution method,[4] and then carry over the stresses from the other single redundants according to their carry-over factors. After the first approximation is complete, use the new values of the redundants and make the second approximation and so on. The convergence is very rapid as will be seen in the examples. This process of approximation is continued until the successive values of X become constant. In practical problems the approximations do not have to be extended so far; it is up to the designers to decide when to stop, depending on what degree of precision is required. This method is general and can also be extended to the external redundants.

---

[4] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

The single redundant stresses s' can be computed readily by the method of work and so can the carry-over factors K. The computation of K is not tedious. Maxwell's law of reciprocal deflection is helpful for this purpose, and by inspection one can see what bars contribute to the deflection; and thus much unnecessary work can be avoided. After the constants K and s' are determined and tabulated, the computation is simple. The method can be best illustrated by examples.

A single redundant stress in the redundant a is expressed by

$$s_a' = \frac{\delta_{a0}}{\delta_{aa}} = \frac{\sum \frac{s\, u_a\, L}{A\, E}}{\sum \frac{u_a\, u_a\, L}{A\, E}} \quad \text{......................} (6)$$

in which: δ_{a0} and δ_{aa} are the relative movements of the cut a due, respectively, to the distortion of the statically determinate structure and an axial load of unity applied at the cut. The first subscript defines the position of movement or stress, and the second defines the position of the applied load. Note that Eq. 6 is dependent on the loads and the given structure.

The carry-over factor of the redundant a from redundant b is expressed as

$$K_{ab} = \frac{\delta_{ab}}{\delta_{aa}} = \frac{\sum \frac{u_a\, u_b\, L}{A\, E}}{\sum \frac{u_a\, u_a\, L}{A\, E}} \quad \text{......................} (7)$$

Unlike Eq. 6, this formula is independent of the loads.

FIG. 3.—SOLUTION OF EQS. 8 BY SUCCESSIVE APPROXIMATIONS

Note that, in the determination of K_{ab} and K_{ba}, only bar 6–7 enters. The sign of all the single redundant stresses and of the carry-over factors must be changed, because every term on the right-hand side of Eqs. 5 has a negative sign; thus

$$X_a = -\ s_a' - X_b\ K_{ab} \qquad (8a)$$

and

$$X_b = -\ s_b' - X_a\ K_{ba} \qquad (8b)$$

The solution of Eqs. 8 is shown in Fig. 3, the correct values[5] being $X_a = +0.254$; and $X_b = -0.248$.

Moving Loads.—In applying the method of successive approximations, it is obvious that determining the carry-over factors and the single redundants requires most of the labor; the process of approximations requires little effort. The carry-over factors, once found, can be used for any loadings. The single redundants change with changes in loads.

EXAMPLE 3.—EXTENSION OF MÜLLER-BRESLAU'S PRINCIPLE TO BAR STRESS

The Müller-Breslau principle is probably the best means of plotting influence lines; the principle can also be extended to a bar stress. When the influence line of any bar is required, introduce a pair of axial forces at the two ends of the bar so that a unit distortion is produced. The deflected load line of the structure is the influence line for the stress of that bar.

Suppose the influence line of the stress in the bar 2–4, Fig. 5, is required. Introduce a unit negative distortion in bar 2–4; in this case the distortion of the bar does not affect the stress in the other bars. The angle change $\Delta\theta = \frac{1}{1} = 1$; the moment curve of the imaginary beam is the deflected load line and it is the influence line for the stress in the

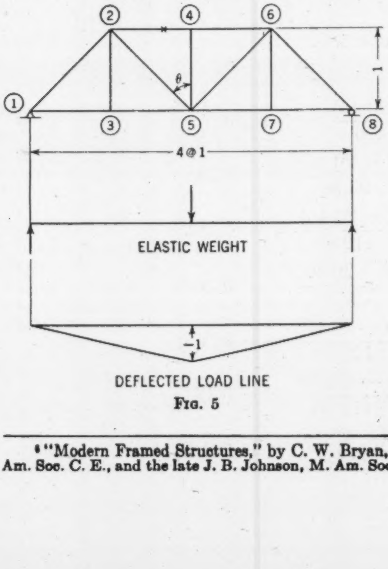

FIG. 5

---

[8] "Modern Framed Structures," by C. W. Bryan, Jr., M. Am. Soc. C. E., F. E. Turneaure, Hon. M. Am. Soc. C. E., and the late J. B. Johnson, M. Am. Soc. C. E., Pt. II, 10th Ed. (1929), p. 310.

bar 2–4. This can be verified readily by statics.

The following conventions must be observed: A negative angle change is an elastic load acting downward. The positive moment curve must be drawn below the reference line, because positive moment causes the beam to deflect downward. It does not matter whether negative distortion or positive distortion is applied to the bar, the sign of stress caused by a load can be determined easily by inspection. Suppose the load is applied at point 7 of the equivalent beam; it is obvious that the beam will deflect down farther and it means that the assumed compression stress is correct. If positive distortion is applied in the bar 2–4, the deflected load line is above the reference line. In this case, when the load is applied at point 7, the load tends to decrease the deflection which means that the sign is opposite to what it was assumed to be.

EXAMPLE 4.—DETERMINATION OF THE INFLUENCE LINE OF THE SINGLE REDUNDANT STRESS s_d' OF THE TRUSS IN EXAMPLE 2

When a distortion is applied to a single redundant, the problem is not as simple as in the previous case, because stresses will be set up in some other bars. However, it can be solved conveniently by the method of elastic weight. The constants for substitution in Eq. 5 are determined by setting up a computation form similar to Table 2, Panel 1, from which $s_d' = \dfrac{s\,u_d\,L}{A} = \dfrac{-83.68}{123.68} = 0.677$.

Stresses.—The force required to shorten bar 8–9, Fig. 6(*a*), 1 in. is $X = \dfrac{1.00}{0.677} \times \dfrac{12 \times 30{,}000{,}000}{40 \times 12} = 1{,}107{,}000$ lb.

Angle Changes.—Formulas for the angle changes (see Fig. 6(*d*)) are:

$$\Delta\gamma = \frac{1}{E}\left[(f_c - f_b)\cot\alpha + (f_c - f_a)\cot\beta\right]\ldots\ldots\ldots\ldots(9a)$$

$$\Delta\beta = \frac{1}{E}\left[(f_b - f_c)\cot\alpha + (f_b - f_a)\cot\gamma\right]\ldots\ldots\ldots\ldots(9b)$$

and

$$\Delta\alpha = \frac{1}{E}\left[(f_a - f_c)\cot\beta + (f_a - f_b)\cot\gamma\right]\ldots\ldots\ldots\ldots(9c)$$

The solution of Eqs. 9, applied to Fig. 6(*e*), is as follows:

Joint 8—

$$\Delta\theta_1 = \qquad\qquad 0$$

$$\Delta\theta_2 = \frac{1}{E}\left[(+29{,}800 + 23{,}800)\frac{32}{24} + (+\,29{,}800 + 3{,}710)\frac{24}{32}\right]$$

$$= \frac{1}{E}[+\,71{,}500 + 25{,}100] \qquad = \frac{+\,96{,}600}{E}$$

Total angle change at joint 8, Fig. 6(*e*) $= \dfrac{+\,96{,}600}{E}$

Joint 10—

$$\Delta\theta_3 = \frac{1}{E}\left[(-\,23{,}800 - 29{,}800)\frac{32}{24} + (-\,23{,}800 + 3{,}710)\,0\right] \qquad = \frac{-\,71{,}500}{E}$$

$$\Delta\theta_4 = \frac{1}{E}\left[(-\,3{,}710 + 23{,}800)\,0 + (-\,3{,}710 + 29{,}800)\frac{24}{32}\right] \qquad = \frac{-\,25{,}100}{E}$$

$$\Delta\theta_5 = \frac{1}{E}(0 + 23{,}800)\frac{32}{24} \qquad = \frac{+\,31{,}700}{E}$$

Total angle change at joint 10 $= \dfrac{-\,64{,}900}{E}$

Joint 12—

$$\Delta\theta_6 = \frac{1}{E}(-\,23{,}800 - 0)\frac{32}{24} \qquad = \frac{-\,31{,}700}{E}$$

Total angle change at joint 12 $= \dfrac{-\,31{,}700}{E}$

Influence ordinates are then computed, thus (see Fig. 7): For a unit load at joint 8, $s_d' = \dfrac{+16{,}100 \times 3 \times 24 \times 12}{30{,}000{,}000} \times 0.677 = +0.314$; for a unit load at joint 10, $s_d' = \dfrac{(+16{,}100 \times 4 - 96{,}600 \times 1)\,24 \times 12 \times 0.677}{30{,}000{,}000} = -0.210$; and, for a unit load at joint 12, $s_d' = \dfrac{-16{,}100 \times 3 \times 24 \times 12}{30{,}000{,}000} \times 0.677 = -0.314$. To check these results assume a load of 8 units at joint 14, Fig. 7: By computation, $s_d' = -1.675$; and from the influence line, $s_d' = -0.314 \times \frac{2}{3} \times 8 = -1.675$, which checks. Note that the deflection of the imaginary beam, which is equal to the moment of the beam at that point, is equal to the relative movement of the joints 8 and 9. The actual stress set up in the bar 8–9 is only 0.677 of the force applied.

EXTERNAL REDUNDANTS

The same principle can be applied to external redundants. Single redundants and carry-over factors must be found for the process of approximations. In the case of external redundant structure shown in Fig. 8, it is advantageous to draw the influence lines for the single redundants, because the carry-over factors can be taken directly from the influence lines.

For example (see Eqs. 5):

From Fig. 8(*c*)—

$$K_{ab} = \frac{\delta_{ab}}{\delta_{aa}} = \frac{\delta_{ab}}{1} \qquad \text{(10a)}$$

and

$$K_{ac} = \frac{\delta_{ac}}{\delta_{aa}} = \frac{\delta_{ac}}{1} \qquad \text{(10b)}$$

from Fig. 8(*d*)—

$$K_{ba} = \frac{\delta_{ba}}{\delta_{bb}} = \frac{\delta_{ba}}{1} \qquad \text{(10c)}$$

and

$$K_{bc} = \frac{\delta_{bc}}{\delta_{bb}} = \frac{\delta_{bc}}{1} \qquad \text{(10d)}$$

and from Fig. 8(*e*)—

$$K_{ca} = \frac{\delta_{ca}}{\delta_{cc}} = \frac{\delta_{ca}}{1} \qquad \text{(10e)}$$

and

$$K_{cb} = \frac{\delta_{cb}}{\delta_{cc}} = \frac{\delta_{cb}}{1} \qquad \text{(10f)}$$

CONCLUSION

The method of successive approximations, as presented herein, should be useful to structural analysts in effecting a saving of time and a better understanding of the structure. For practical purposes the slide-rule may be used without the fear of accumulating errors as in the solution of simultaneous equations.

ACKNOWLEDGMENT

The writer expresses his appreciation to Albert Haertlein, M. Am. Soc. C E., for guidance in the preparation of this paper.

DISCUSSION

FRANCIS L. CASTLEMAN, JR.,[7] ASSOC. M. AM. SOC. C. E. (by letter).—The term "classical method" is a misnomer when used to describe the general method to effect a solution for the internal redundants of frames, such as are shown in Figs. 1, 2, and 4. Classical methods, in such cases, are modern methods, since basically for problems of this type, a solution must always be effected by the method of deflections. Whether recourse is had in the detail of solution to least work, dummy unit loading, virtual work, etc., is a matter of individual choice; all lead to the same end. All analytical methods are based on the elastic energy of the system and can be derived from the general principles laid down for such methods.

Eqs. 3 express the gist of the matter. Once these equations are properly set up and their constants correctly determined the engineering is done. They have been known for a long time; they are still mandatory for the solution of many problems, and hence are modern in the sense that they are indispensable. Thus the writer questions if Mr. Voodhigula has simplified, in any way, the so-called classical method of analyzing the statically indeterminate structures in question. What he has really done, in the writer's opinion, and very ably, is to devise an extremely ingenious method for the detail of the solution of Eqs. 3.

After trying this method on several "pet problems" it was found to be quite helpful in some respects, but no faster than the ordinary method of iteration without the graphical interpretation such as given in Fig. 3. It is more compact and offers a visual interpretation of what is believed to happen. However, in all fairness, it must be said that perhaps complete facility was not acquired in its use. The implied visual interpretation of stress distribution is really a "second sight" as the true physical and visual interpretation is implied in Eqs. 3 and their proper development.

Errors of analogy are often introduced in an analysis when operations performed are remindful of those executed in a like manner in a previous but non-similar situation. In moment distribution there is an entirely different situation and one operation in the solution of this situation involves an action the end result of which is termed "carry-over." In the situation under consideration, which by no stretch of the imagination is similar to moment distribution, a name for an operation is literally "carried over" from a non-similar situation. On reflection the writer believes the term "stress factor" would be more appropriate. Certainly, if such were the case, excuse could never be offered (by analogy) for dividing the carry-over factor by 2 (or any other value).

Mr. Voodhigula dismisses the problem of external redundants with far from the proportionate space devoted to internal redundants; yet the former is generally the problem confronted, as structures of the latter type are few (at least in American practice) as compared with the former. This would seem the most fruitful field for the method under discussion. However, a more than cursory examination of such structures leads to some very interesting observations as regards the accuracy of solution by any method. Sometimes it is quite advantageous to choose a member or members of such a structure as the redundants rather than the reactions. For example, in Fig. 8 the reactions "*a*," "*b*," and "*c*" are treated as redundants. This presupposes for the statically determinate base system the full span acting as a simple truss under the appropriate loadings. Equations can be set up similar to Eqs. 3 and reduced with proper manipulation and interpretation such that, by their use, influence lines can be constructed for each of the external redundants, and subsequently those for the individual members in the truss. The latter step can be achieved by cutting the lower chord at "*a*" and the upper chord over "*b*" and "*c*" and treating the cut members as redundants. The statically determinate base system then becomes three simple-span trusses. Comparable errors will be greatly reduced, therefore, with consequent reduction in the errors of the required redundant values. American textbooks have paid too little attention to this fact. By way of illustration, consider:

---

[7] Head, Dept. of Civ. Eng., Univ. of Connecticut, Storrs, Conn.

$$X = \frac{\begin{vmatrix} \delta_m' & \delta_{mn} \\ \delta_n' & \delta_{nn} \end{vmatrix}}{\begin{vmatrix} \delta_{mm} & \delta_{mn} \\ \delta_{nm} & \delta_{nn} \end{vmatrix}} = \frac{\delta_n' \, \delta_{nn} - \delta_n' \, \delta_{mn}}{\delta_{mm} \, \delta_{nn} - \delta_{mn}^2} \qquad \text{(11)}$$

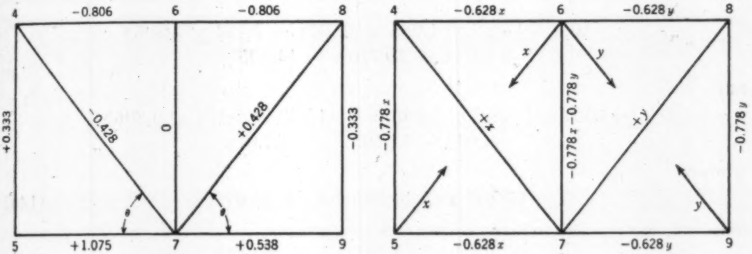
and with the following numerical values inserted, $X = \dfrac{50 \times 100 - 90 \times 60}{40 \times 100 - (60)^2}$ $= -1$. If the errors of determining the δ-values vary by $\pm 2\%$ then, in the extreme, $X = \dfrac{51 \times 102 - 88.2 \times 58.8}{40.8 \times 102 - (58.8)^2} = 0.225$. Thus a tremendous error has been introduced from small, possibly unavoidable errors in the basic quantities. Through use of a properly chosen statically determinate base system such errors can generally be held to a minimum. Exact solutions, computing machines, methods of iteration, and even Divine Providence cannot eliminate such errors once they are present in the fundamentally basic quantities.

In the interest of rigor it would seem logical to emphasize that the theoretically correct values indicated by Eqs. 3 have some properties that can be profitably studied before Eqs. 3 are thrown into the form of Eqs. 5 for use in the method of iteration. For a solution, Eqs. 3 must conform to the following: There must be as many equations as unknowns; the equations must be independent of each other; and possible conditions must be represented. Solving Eqs. 3 in determinant form and representing expressions for numerator and denominator by N and D, respectively, $x_a = \dfrac{N_a}{D}$, etc. If $D = 0$, the left-hand side of the equations are functionally related. If $N = 0$ also, the right-hand sides are related functionally in the same manner. Under the aforementioned conditions the equations are dependent on each other and by themselves will not lead to a solution. If $D = 0$, $N \neq 0$ the equations do not represent possible conditions.

In using the method of iteration once a definite trend has been established, by plotting known values against cycles the range can be extended graphically. If this is carefully done and good judgment is exercised the method of iteration itself will be considerably shortened.

Charles A. Ellis,[8] M. Am. Soc. C. E. (by letter).—There are three principles by which a statically indeterminate structure may be analyzed: (1) Principle of work; (2) principle of least work; and (3) principle of deflections.

The first two are essentially mathematical abstractions of horse-and-buggy days. They do not permit physical conception or space perception, so helpful in the comprehension of stress analysis. The principle of deflections is far superior, and analysis may be made by at least three methods: (*a*) Area-moments; (*b*) expression of moments in terms of angular rotations of joints and members (generally known as the "slope-deflection method"); and (*c*) moment distribution. The two latter methods are most easily derived by the area-moment method which the writer considers the closest to fundamentals.



(*a*) (*b*)

Fig. 9

The principles of work and least work were the only ones available for an algebraic solution of statically indeterminate trusses until the "Williot Strain Equations"[9] were discovered by the writer, when computing the tower stresses in the Golden Gate Suspension Bridge. These equations will now be used in solving the author's Example 1.

The stresses in the necessary members (redundant members removed) are shown in Fig. 9(*a*); and the stresses due to stresses x and y, respectively, in the redundant members are shown in Fig. 9(*b*). The combined stresses for each member are given in Table 4, in which s represents the stress and Δ the strain. Hence,

$$E\,\Delta = \frac{s\,l}{A} \quad \ldots\ldots (12)$$

TABLE 4.—Combined Stresses for Members in Fig. 9

[9] "Simplified Analysis of Indeterminate Frames," by Charles A. Ellis, *Engineering News-Record*, April 26, 1934, p. 534; also "Williot Equations for Statically Indeterminate Structures," by Charles A. Ellis, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 580.

plus the sum of the strains in the verticals, or

$$(\Delta_{47} + \Delta_{56}) \operatorname{cosec} \theta = (\Delta_{57} + \Delta_{46}) \cot \theta + \Delta_{45} + \Delta_{67} \ldots\ldots (13a)$$

and

$$(\Delta_{69} + \Delta_{78}) \operatorname{cosec} \theta = (\Delta_{79} + \Delta_{68}) \cot \theta + \Delta_{67} + \Delta_{89} \ldots\ldots (13b)$$

Substituting from Table 4,

$$(-10.315+48.2\,x)\,1.285 = (2.074 - 7.134\,x)\,0.8065 + 6.044 - 28.716\,x - 14{,}595\,y$$

and

$$(+10.315 + 48.2\,y)\,1.285 = (-1.132 - 7.134\,y)\,0.8065 - 6.044 - 14.595\,x - 28.716\,y$$

whence

$$96.407\,x + 14.595\,y = +\,20.972 \ldots\ldots (14a)$$

and

$$96.407\,y + 14.595\,x = -\,20.212 \ldots\ldots (14b)$$

or $x = +\,0.2551$; and $y = -\,0.2483$. Eqs. 13 may be written in the form

$$x = +\,0.2175 - 0.1514\,y \ldots\ldots (15a)$$

and

$$y = -\,0.2097 - 0.1514\,x \ldots\ldots (15b)$$

Any one with leisure time may solve for x and y by successive approximations, as follows: Assume $y = 0$ in Eq. 15a and $x = 0$ in Eq. 15b; then: $x = +\,0.2175$; and $y = -\,0.2097$. Substitute $y = -\,0.2097$ in Eq. 15a and $x = +\,0.2175$ in Eq. 15b; whence: $x = +\,0.2492$; and $y = -\,0.2426$. Repeat this process three times and the following successive values appear:

x	y
+0.2175	−0.2097
+0.2492	−0.2426
+0.2542	−0.2474
+0.2550	−0.2482
+0.2551	−0.2483

These same numerical values appear in Fig. 3.

Comment on solutions by successive approximations seems relevant. This process has received much attention since Professor Cross published his moment-distribution method[4] and used successive approximations as a tool; and it is an exceedingly efficient tool, especially when the unknowns are numerous. Moment distribution has no monopoly, however. Slope-deflection equations invariably have the same peculiarity that renders them susceptible to the same rapidity of convergence when solved by successive approximations, as when moment distribution is used.

Consider any problem in which rotation of joints, but no rotation of members, is assumed and solve by moment distribution. Then solve by slope deflection using successive approximations in the solution of the equations and note that identical numerical values appear in both methods.

When the unknowns are numerous, the method of successive approximations is an exceedingly efficient tool; but for many writers it has become a toy to be used whenever and wherever possible. For example: In a box culvert having large fillets with increasing moments of inertia at the ends of the members, wherein the carry-over factor is as large as three fourths, resulting in relatively slow convergence, the simultaneous solution of four slope-deflection equations is the method to be preferred.

Perhaps the most risible example is the so-called rigid frame—the two-hinged rectangular reinforced concrete arch. One and only one elastic equation[10] is required for finding the corner moment for each condition of loading, whether dead or live. The solution of such a problem, containing but one unknown quantity by any method where successive approximations may or can be used, is something fancy, and, if one reveres mathematical accuracy, the elastic equations can take into account the curvature of the deck axis, whereas the slope deflection and moment distribution are impotent to do so.

Finally the writer expresses doubt in the author's conclusion that the principle of work combined with successive approximations is useful in a better understanding of the structure.

David J. Peery,[11] **Jun. Am. Soc. C. E.** (by letter).—A method of analyzing statically indeterminate trussed structures is presented in this paper that is similar to modern methods of analyzing continuous beams and rigid-frame structures. The author points out that for trussed structures it seems better to solve simultaneous equations set up by classical strain-energy methods than to use direct methods of successive approximation in distributing stresses. The simultaneous equations are set up by customary methods, therefore, and a method of successive approximations is applied to their solution.

The method of solving the simultaneous equations is essentially the method of iteration, or successive substitutions. It has been in use for some time by structural engineers for the solution of similar types of equations obtained by the use of three-moment equations, slope-deflection equations, or moment distribution.[12,13] For equations in which the convergence of the proposed method is rather slow, the method proposed by George H. Dell,[14] Assoc. M. Am. Soc. C. E., in which a series summation is used after the first few cycles of substitution, will materially reduce the labor involved.

[14] "Solution of Equations in Structural Analysis by Converging Increments," by George H. Dell, *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 1543.

The examples chosen by the author yield systems of simultaneous linear equations in which the coefficients belonging to the principal diagonal of the matrix are much greater than the other coefficients. The solution of such equations by successive approximation converges rapidly. Most problems in indeterminate analysis are of this type, or can be made so by a proper selection of the redundants. In Example 2, for instance, the redundants are such that the equations are much simpler than for the general structure with eight redundants. If the expressions of Eqs. 3 are expanded, they yield, for the general case of a structure with eight redundants:

$$\left.\begin{aligned}
-\delta_{a0}&=X_a\delta_{aa}+X_b\delta_{ab}+X_c\delta_{ac}+X_d\delta_{ad}+X_e\delta_{ae}+X_f\delta_{af}+X_g\delta_{ag}+X_h\delta_{ah}\\

\end{array}\right\}(17)$$

It should be noticed that 42 of the 64 coefficients of the unknowns are zero, resulting in an enormous simplification of the solution.

The solution of Eqs. 17 is quite easy by the common methods of elimination or determinants, whereas, if none of the coefficients of Eqs. 16 were zero, the solution would be quite laborious by successive approximations, and practically impossible by elimination or determinants. It seems obvious, therefore, that it is more important to select the redundants in such a manner as to simplify Eqs. 3 than it is to simplify the actual solution of the equations.

If the redundants are selected so that all the coefficients δ_{mn} having unlike subscripts are zero, Eqs. 3 will have the following solutions:

$$X_a = -\frac{\delta_{a0}}{\delta_{aa}}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(18a)$$

$$X_b = -\frac{\delta_{b0}}{\delta_{bb}}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(18b)$$

and

$$X_c = -\frac{\delta_{c0}}{\delta_{cc}}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(18c)$$

This simplification eliminates the necessity for solving simultaneous equations, and makes it possible to obtain the influence lines for the redundants directly as simple deflection curves. The influence lines shown in Figs. 7 and 8 are not for the redundants X_a, X_b, and X_c, but give only the terms S_d', δ_{aa}, and δ_{ab} to substitute in the simultaneous equations, which must then be solved for the redundants.

It is possible to select the redundants for any statically indeterminate structure in such a manner that Eqs. 3 are satisfied.[15] Although this procedure is often used for the analysis of fixed arches, many engineers do not realize that it may be used for the analysis of statically indeterminate trussed structures. The influence lines for the redundant forces may be found directly by the method of elastic weights, without solving simultaneous equations.

FIG. 10.—CONTINUOUS TIED-ARCH BRIDGE

The continuous tied arch shown in Fig. 10 will be used to illustrate the method of analysis. This is a threefold statically indeterminate structure symmetrical about the center line of the main span. The statically determinate base system is formed by cutting the structure at the center line of the arch. If the redundant forces X_a, X_b, and X_c are applied at the ends of rigid brackets, as shown in Fig. 10(*c*), the conditions,

---

[15] "Simplified Calculation of Statically Indeterminate Bridges," by G. G. Krivoshein, Prague, 1930.

$$\delta_{ab} = \sum \frac{u_a\, u_b\, L}{A\, E} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19a)$$

and

$$\delta_{bc} = \sum \frac{u_b\, u_c\, L}{A\, E} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19b)$$

are evidently satisfied. The stresses u_a and u_c, resulting from $X_a = 1$ and $X_c = 1$, respectively, are symmetrical with respect to the center of the structure. The stresses u_b, resulting from $X_b = 1$, are antisymmetrical. The summations of Eqs. 19*a* and 19*b*, therefore, will have the same absolute values for the left half of the structure as for the right half, but will have different signs.

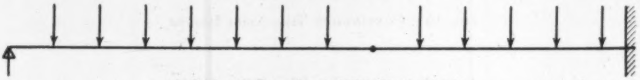
(*c*) $X_c = 1$ (Values of u_c)



(*d*) Conjugate Beam Loaded With Elastic Weights

FIG. 11.—STRESSES

The distance *e* may be computed from the equation,

$$\delta_{ac} = \sum \frac{u_a\, u_c\, L}{A\, E} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19c)$$

Substituting the numerical values of the stresses u_a (Fig. 11*a*) and u_c (Fig. 11*c*), in terms of *e*, into the summation of Eq. 19*c*, the following values are obtained: $\sum \frac{u_a\, u_c\, L}{A} = 46.570\, e - 75.942 = 0$; or, $e = 1.6307$ panels.

Since Eqs. 19 are now satisfied, the value of the couple X_a for a load $P = 1$ at any point *q* on the structure may be found as follows:

$$X_a = -\frac{\delta_{aq}}{\delta_{aa}} = -\frac{\sum \frac{u_a\, u_a\, L}{A\, E}}{\sum \frac{u_a{}^2\, L}{A\, E}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (20a)$$

The numerator of Eq. 20*a* represents the deflection of any point *q*, resulting from a couple $X_a = 1$. This numerator is evaluated for all positions of the load *P* by the method of elastic weights. The elastic weights, or angle changes, for the load $X_a = 1$ panel unit are computed as shown in Table 5(*a*), Col. 1. The shears and bending moments in the conjugate beam of Table 5(*a*), Cols. 2 and 3, represent the slopes and deflections of the actual structure when it is loaded with the couple X_a. The terms used in Eq. 20*a* may be in any units as long as the same units are used in the numerator and in the denominator. In this discussion the moment arms are used in panel units, in order that the moments in the beam of elastic weights (Table 5(*a*), Col. 1) may be obtained by a summation of the shears. The numerator and denominator of Eq. 20*a* both may be multiplied by *E*.

The denominator of Eq. 20*a* represents the rotation of the cut ends of the structure relative to each other, resulting from the couple $X_a = 1$. This term may be evaluated from the shear in the conjugate beam loaded with the elastic weights for $X_a = 1$. Thus, from Table 5(*a*), Col. 2: $\delta_{aa} = 2 \times 97.054 = 194.108$.

Therefore, the influence line for X_a is found by dividing the bending moments in the beam of elastic weights (Table 5(*a*), Col. 1) by 194.108, as shown in Table 5(*a*), Col. 4. This influence line is symmetrical with respect to the center line of the structure. The influence-line ordinates are shown in panel units, or they represent the value of X_a in panel-kips for a load of one kip. The moments may be converted to foot-kips by multiplying by 24, since the panel length is 24 ft.

The value of X_b for a unit load at any point *q* is found from the equation:

$$X_b = -\frac{\delta_{bq}}{\delta_{bb}} = -\frac{\sum \frac{u_b\, u_q\, L}{A\, E}}{\sum \frac{u_b{}^2\, L}{A\, E}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (20b)$$

The numerator of this equation represents the deflection of point *q* resulting from a unit value of X_b, and is evaluated for all positions of *q* by the method of elastic weights. These computations are shown in Table 5(*b*), Col. 1. The denominator of Eq. 20*b* is found as the deflection in the direction of X_b, for a load of $X_b = 1$; or as twice the bending moment in the conjugate beam at the center line of the structure. The influence-line ordinates for X_b are given in

[a] Elastic weights for X_a, X_b, or $X_c = 1$. [b] Values of δ_{aq}, δ_{bq}, or δ_{cq}. [c] Values of $-\frac{\delta_{aq}}{\delta_{aa}}$, $-\frac{\delta_{bq}}{\delta_{bb}}$, or $-\frac{\delta_{cq}}{\delta_{cc}}$. [d] Hinged. [e] Center cross. [f] Slope of the influence line at this point $= \theta = \tan\theta = 0.5$.

Table 5(*b*), Col. 4, for half the structure. They are antisymmetrical with respect to the center line.

The value of X_c for a unit load at any point q of the structure is found from the equation:

$$X_c = -\frac{\delta_{cq}}{\delta_{cc}} = -\frac{\sum \frac{u_c\, u_q\, L}{A\, E}}{\sum \frac{u_c^2\, L}{A\, E}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (20c)$$

The numerator of Eq. 20*c* may be evaluated by the method of elastic weights, as in the computation of the influence lines for X_a and X_b. The denominator, however, represents the horizontal deflection of the point of application of the redundants, and must be evaluated by summation. Substituting the values of u_c from Fig. 11(*c*), and the lengths and areas from Fig. 10, in this summation:

$$\sum \frac{u_c^2\, L}{A\, E} = \frac{126.34}{E}\left(\frac{\text{panels}}{\text{kip}}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

If the values shown in Table 5(*c*), Col. 3, are divided by 126.34, the ordinates of the influence line for X_c are obtained. This influence line is symmetrical with respect to the center line of the structure, and is shown for half the structure in Table 5(*c*), Col. 4.

The stresses in all the members of the structure may be found from the influence lines of Cols. 4, Table 5, by simple statics. Obviously, it is not necessary to solve simultaneous equations at any point in the analysis of this structure. G. G. Krivoshein[15] shows that all statically indeterminate structures may be analyzed without the solution of simultaneous equations for the redundants. Although the symmetrical continuous tied arch is readily analyzed in this manner, there are some types of structures in which it may be as laborious to select the redundants so that they satisfy Eqs. 18 as it is to solve the simultaneous equations. The redundants for the structure in Example 2, for instance, may be chosen by inspection so that 42 of the coefficients vanish, and it probably would not be desirable to compute the redundants so that 56 of the coefficients vanish in order to satisfy Eqs. 18.

Acknowledgment.—The continuous tied-arch bridge analyzed in this discussion is probably the first structure of its type in America. This bridge was constructed in 1940 over the Meramec River near St. Louis, Mo., by the Missouri State Highway Department. The data on this structure were furnished through the courtesy of Howard Mullins, designer of the bridge, and N. R. Sack, bridge engineer of the Missouri State Highway Department.

L. E. Grinter,[16] M. Am. Soc. C. E. (by letter).—This is the first paper on the analysis of trussed structures by successive approximations that has appealed to the writer as both interesting and practical. As mentioned by the author, several methods of successive approximations have been presented that complicated analysis instead of simplifying it. Actually, of course, the possibility of an important simplification does not exist for trussed structures because the usual procedure involving Maxwell's equations is not very complicated itself. There is a great difference between the difficulty involved in applying methods of deflection or work to a truss and to a rigid frame. In the first place, the truss is composed of members that are straight and are assumed to resist only direct stress. The application of virtual work for the computation of a deflection involves merely a simple summation of terms, and the calculations are readily tabulated. For a frame, integrations are always necessary and these may be complicated by variation of moment of inertia within each span, by distributed loadings, and even by a curved axis for one or more members. The other simplification that applies to trussed structures is that there are seldom more than three redundants to be considered, and, therefore, no more than three simultaneous equations need to be solved. The case of six or eight redundants in an indeterminate truss is almost limited to the case analyzed by the author as Example 2.

---

[16] Vice-Pres. and Dean, Graduate School, Illinois Inst. of Technology, Chicago, Ill.

The derivation of basic relationships in the paper is made dependent upon Maxwell's Eqs. 3. Actually, one might write out Eqs. 5 directly as a statement of a self-evident fact. That is, the final stress in any redundant member a must be equal to the stress existing in that member when the other redundants are eliminated, plus the changes in stress that occur when these other redundants come into play in sequence.

Hence, one may write at once without reference to sign, $X_a = s_a' + X_b K_{ab} + X_c K_{ac} \cdots$ (etc.); but it must not be overlooked that the terms s_a', K_{ab}, and K_{ac} demand the same deflection computations by virtual work required for the writing of Maxwell's equations.

The paper has been shortened to the point where certain fundamental considerations are not completely clarified. The computation of the deflection δ_{aa} is obtained by virtual work $\left(\sum \frac{S\,u\,L}{A\,E} \right)$ for six members only—those encompassed by a single panel. This is true because the virtual forces are unit

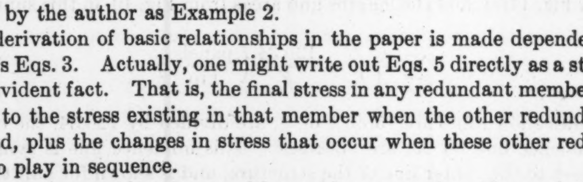

FIG. 12.—ACTION OF VIRTUAL FORCES

stresses in the cut diagonal member, which are represented by a pair of equal and opposite forces having the same line of action as shown in Fig. 12(a). Since two such forces are in equilibrium, the end reactions of the truss are zero, and there are no stresses in other panels.

The deflection δ_{ab} is computed even more simply than δ_{aa}. In Fig. 12(b), there are shown two adjacent panels of a truss with virtual forces (1 lb) acting in the redundant diagonals. The only member that receives stress from each of these virtual pairs of forces is the central vertical post *C D*. Since its stresses s and u are each -0.8 and its length is 32.0, the deflection δ_{ab} is computed as $0.8 \times 0.8 \times 32 \div A\,E$.

Many readers undoubtedly will question how the author simplified Eqs. 5 when they are applied to Example 2 in which there are eight redundants. One would assume that each of the eight equations should contain all such factors as K_{ab}, K_{ac}, K_{ad}, K_{ae}, K_{af}, K_{ag}, and K_{ah}, representing the interaction of the panel a with all other panels of the truss. Actually, all of these factors except K_{ab} are zero. The reason again may be found by reference to Fig. 12. For example, $K_{ac} = \delta_{ac} \div \delta_{aa}$. The deflection δ_{ac} would have to be computed by virtual work with virtual forces applied in the redundant diagonals of the panels a and c. In neither case would these redundant forces stress the same members and, therefore, the term $\frac{S\,u\,L}{A\,E}$ would be zero for each member. It is unfortunate when such matters as these are not explained in a technical paper since they save the reader much wasted time.

The writer has been greatly interested in the influence of errors in carry-over factors upon final results in any process of successive corrections. In Example 2, the carry-over factors are about 0.25 toward the end panels and roughly 0.20 in all other cases. In the latter instance, the actual variation of carry-over factors is from 0.165 to 0.218. In Table 6 the successive corrections of Table 3 are solved by use of the approximate carry-over factors 0.25 and 0.20. It is interesting that the maximum error for a redundant stress is 9% although the maximum error in the approximate carry-over factors was 18%. It is evident, therefore, that, whereas a small error in the solution of simultaneous equations is often very serious, small errors in the process of successive corrections tend to reduce themselves. One is often able to estimate carry-over factors with sufficient accuracy for preliminary studies. It must not be forgotten that the design of an indeterminate truss requires at least a preliminary analysis followed by a final analysis after the corrected areas have been chosen.

TABLE 6.—USE OF APPROXIMATE CARRY-OVER FACTORS FOR EXAMPLE 2

Description	Panel 1	Panel 2	Panel 3	Panel 4	Panel 5	Panel 6	Panel 7	Panel 8
1st $X = s'$	−1.75	−1.81	−1.71	−1.67	−1.67	+0.10	+5.42	+4.21
$K_{ab}\,X_b$, etc.	+0.45	+0.34	+0.33	+0.33	−0.02	−1.09	−0.84	
$K_{ba}\,X_a$, etc.		+0.26	+0.24	+0.23	+0.22	+0.30	+0.14	−1.18
2d X	−1.30	−1.21	−1.14	−1.11	−1.47	−0.69	+4.72	+3.03
$K_{ab}\,X_b$, etc.	+0.30	+0.23	+0.22	+0.29	+0.14	−0.94	−0.61	
$K_{ba}\,X_a$, etc.		+0.29	+0.26	+0.25	+0.23	+0.26	+0.12	−1.23
3d X	−1.45	−1.29	−1.23	−1.13	−1.30	−0.58	+4.93	+2.98
Correct X	−1.44	−1.21	−1.25	−1.23	−1.37	−0.53	+4.86	+2.93

The method presented by the author is interesting and also useful if there are many redundants. The usual procedure by the direct solution of Maxwell's equations is so simple in itself that the use of successive corrections could offer little advantage for two or three redundants. Nevertheless, the author is to be complimented for presenting the most usable device yet described for analyzing indeterminate trusses by successive corrections.

O. T. VOODHIGULA,[17] JUN. AM. SOC. C. E. (by letter).—Professor Castleman points out the advantage of choosing members as redundants in the case of a continuous truss. It is obvious that much work can be saved in computing the carry-over factors and the single redundants, whereas in the case of the reaction redundants every member must be included in every computation.

The writer has no objection to Professor Ellis' preference for "Williot Strain Equations." All the methods used in analyzing statically indeterminate structures are fundamentally the method of distortions or deflections.

Mr. Peery's discussion is very interesting. The writer fully agrees with his statement that "It * * * is more important to select the redundants in such a manner as to simplify Eqs. 3 than it is to simplify the actual solution of the equations." In the example chosen by him, it is possible to obtain a direct solution, because the redundants act at the elastic center, where a redundant has no effect on the others; in other words, the carry-over factors are zero.

Dean Grinter's comments are very pleasing.

CAVITATION IN OUTLET CONDUITS OF HIGH DAMS

By Harold A. Thomas,[1] M. Am. Soc. C. E., and Emil P. Schuleen,[2] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Jerome Fee, V. E. Leman, P. S. O'Shaughnessy and E. S. Randolph, Carroll F. Merriam, Hunter Rouse, G. H. Hickox, J. M. Mousson, J. H. Douma, and Harold A. Thomas and Emil P. Schuleen.

Synopsis

Occurrence of severe cavitation damage to the concrete surfaces of the outlet conduits of the Madden Dam, in the Panama Canal Zone, supplied the incentive to carry on extensive studies by means of laboratory models to investigate the cavitation potentialities, if any, in the conduits of the Tygart River Dam, near Grafton, W. Va., and to develop methods of eliminating or minimizing future damage in the conduits of the Madden Dam. Similar studies, on a less elaborate scale, were conducted in connection with the design of the Bluestone Dam in West Virginia, Hiwassee Dam in North Carolina, and Redbank Creek Dam in Pennsylvania.

The development of cavitation-testing facilities of two types, known respectively as the "enclosed-tank apparatus" and the "diverging-tube apparatus," is described, and the hydraulic theory pertinent to the making of cavitation tests in these facilities is presented. A description is given of cavitation studies conducted on models of the conduit entrances of the Madden Dam.

Introduction

In the late summer of 1935 the pouring of concrete in the lower portions of Tygart River Dam was in progress under the direction of the district engineer, U. S. Engineer Office, Pittsburgh, Pa., when word was received from the Panama Canal authorities that the concrete in the entrance portions of the conduits in Madden Dam had been seriously damaged by cavitation. Since the conduits to be placed in Tygart River Dam were identical in cross section to those in Madden Dam, and differed only slightly in entrance curvature,

[2] Senior Engr., U. S. Engr. Office, Pittsburgh, Pa.

concern was naturally felt regarding the possibility of cavitation also occurring in the Tygart River Dam conduits. To test the design for such a possibility, and to provide means for analyzing possible alterations in design to eliminate cavitation, should such be found to exist, arrangements were made with the Hydraulic Laboratory of the Carnegie Institute of Technology, in Pittsburgh, to construct and test a model of the Tygart conduit entrance.

The tests to be undertaken under this arrangement were of an unusual nature for which there was little precedent, since a search of records of cavitation tests disclosed none of models of existing or proposed conduits designed for high velocities. It was necessary, therefore, to design a complete testing apparatus in order that correct scale reproductions of the absolute pressures operating in the prototype could be developed in the model. The pioneering nature of these tests led to some uncertainty regarding the ability to secure an accurate reproduction in the model of cavitation effects which might appear in the prototype if the entrance were improperly designed. As a means of verifying the accuracy with which prototype phenomena were reproduced, a model of the conduit entrance in Madden Dam was constructed and tested, and the results compared with data on cavitation and damage in the prototype as reported by the Panama Canal authorities.

As the tests progressed, the Governor of the Panama Canal Zone took an increasing interest in the work and in the early spring of 1936 officially requested that tests be conducted to develop a feasible means of eliminating or alleviating the cavitation action and resulting damage in the conduits of Madden Dam. By this time, tests of the conduits designed for Tygart River Dam had been substantially completed, so that the testing apparatus could then be made available almost exclusively for tests of models of the conduits in Madden Dam. Various designs of entrance curves for conduits were tested in developing a design that might be readily installed in the prototype at a minimum cost. A suitable design was evolved and a report was in the final stages of preparation when the Governor of the Panama Canal Zone requested a series of additional tests. These additional tests involved: (*a*) A check of the previously developed design to determine its adequacy at somewhat higher heads as well as its adequacy when the two conduits of a pair were operated together (previous tests had disregarded the effect of an adjacent conduit in operation); (*b*) further study of a bellmouth entrance designed by the engineers at the Panama Canal; (*c*) studies of the degree of gate opening that could be permitted without destructive cavitation occurring in the conduit entrance; (*d*) various schemes for increasing the pressure in the critical area by constrictions within the conduit or at its discharge end; and (*e*) various studies involving fillers for stop-log slots, venting of the conduits, etc. The second series of tests was completed during the winter of 1937–1938 and a report was made the following summer.

During and subsequent to the tests at Madden Dam, the availability of the cavitation apparatus at the Hydraulic Laboratory of the Carnegie Institute of Technology permitted the testing of conduit entrances for several other dams, among which may be mentioned the Bluestone, Hiwassee, and Redbank Creek dams.

A description of the details of the numerous tests on the Madden models, and of cavitation studies on models of the outlet conduits of the Tygart, Bluestone, Redbank Creek, and Hiwassee dams, is included in the original manuscript from which this paper is condensed, the original being on file in Engineering Societies Library.[3]

CAVITATION EFFECT IN MADDEN DAM CONDUITS AS ORIGINALLY DESIGNED AND CONSTRUCTED

The Madden Dam,[4] a concrete gravity structure comprising part of the Panama Canal Project, is pierced by six rectangular conduits, located as shown subsequently in Fig. 12. These conduits are grouped in pairs and are controlled by service and emergency slide gates. Each is 5 ft 8 in. wide and operates under a maximum head of 168.3 ft. The upstream or intake ends of the conduits, which are the points of particular interest in this paper, were flared in the original construction on a radius of 4 ft as indicated by Fig. 1 (which also shows the design and location of the stop-log slots). The conduits are steel-lined for a reach of 48 ft in the vicinity of the slide gates but are unlined above and below this reach. The intake ends of the conduits, therefore, are unprotected by metal lining over the initial 12.89 ft, this measurement including the stop-log slot and guide.

(b) SECTION A-A

FIG. 1.—ORIGINAL CONDUIT ENTRANCE, MADDEN DAM

The reservoir was placed in operation in 1934, and the conduits were in use at various times during the process of filling the reservoir. By March 12, 1935, the water level had been lowered to an elevation one foot above the spillway crest by discharging over the crest while making spillway tests, and the conduits were then placed in operation to continue the release of impounded water. It was observed at once that the operation of the conduits was accompanied by a loud crackling and popping noise which was particularly noticeable in the slide-gate galleries. However, operation was continued at the full capacity of the conduits until March 15, 1935, when a porous tile drain in the partition wall between Conduits 1 and 2 began to leak water into the gallery. It was then concluded that the crackling noise and the leak which had developed were the result, respectively, of cavitation and its damaging effect in the entrance portion of the conduit. It was decided to reduce the cavitation action by throttling the discharge by partial closure of the slide gates. The crackling noise or crepitation ceased when the gates were closed to the 90% open position, and the gates were left in that position during the remaining process of draining the reservoir.

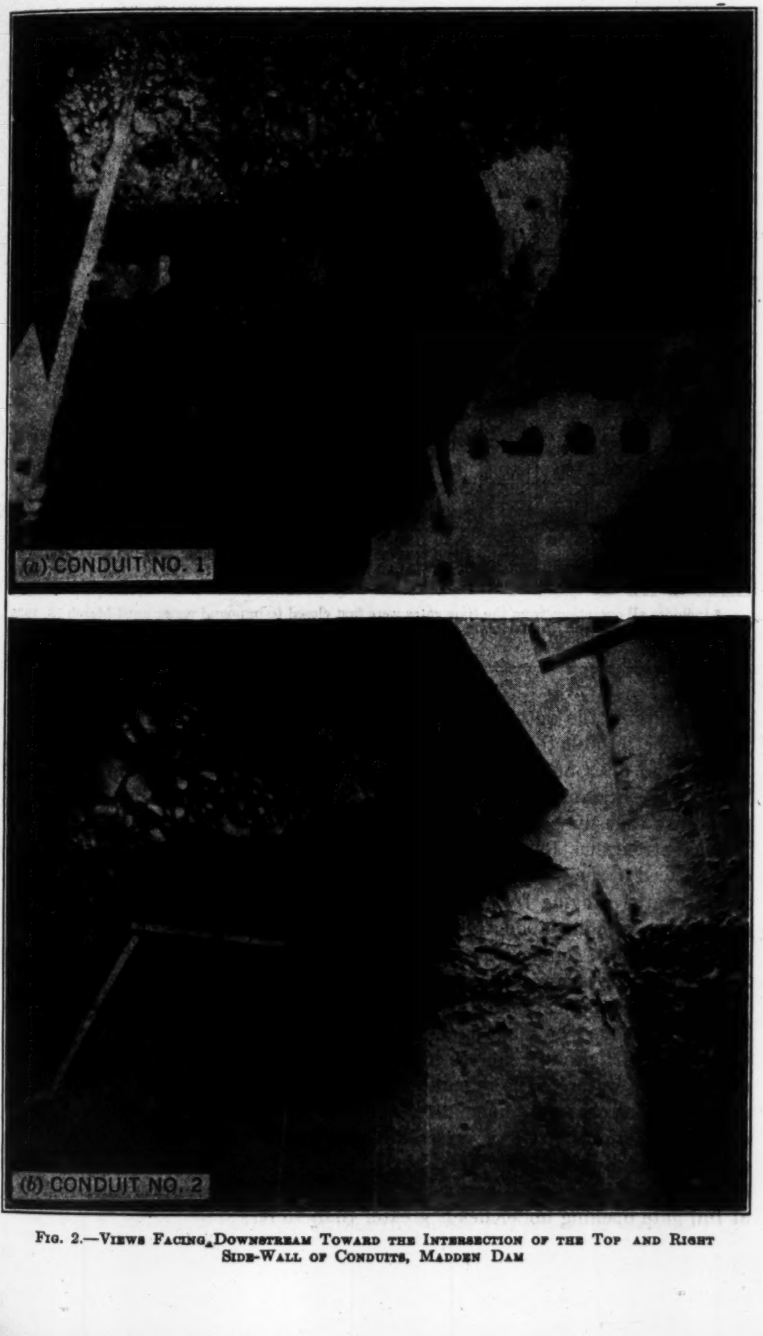
[4] "Hydraulic Tests on the Spillway of the Madden Dam," by Richard R. Randolph, Jr., *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1080.

After the reservoir had been completely drained, the conduits were inspected and the damage that had resulted from cavitation was recorded. The inspection revealed the fact that the cavitation action had seriously eroded the walls and tops, or ceilings, of the conduits by pitting the concrete to depths of as much as almost 2 ft and in many places by exposing reinforcing bars that had originally been 10 in. from the surface of the concrete. The severity of the damage may be noted in Fig. 2, which shows erosion typical of that which occurred in all of the units except Conduit 3. In the latter conduit, damage was slight because it had been operated at high heads for only a comparatively short total period of time. Fig. 2(*a*) is a view of Conduit 1, facing downstream. It shows pitting of the concrete on the top and upper part of the right side-wall. Note the reinforcing bars exposed on the top of the conduit, and also note the beginning of the steel lining on the right side-wall at the left. Fig. 2(*b*) is a view facing toward the intersection of the top and right side-wall at the extreme upper end of Conduit 2 and shows damage to those two surfaces of the conduit. Note the intersections of the top and side-wall entrance curves with the upstream face of the dam. Also note the stop-log slot at the extreme right.

For the most part, the damage was found to be confined to the tops or ceilings and the upper parts of the side-walls of the conduits as is indicated by Fig. 3, which shows, by contours and cross sections, the damage to the top and side-walls of Conduit 5. This also is typical of the damage to all units except Conduit 3.

A résumé of the number of hours and minutes that each conduit was operated at various heads during the first season of operation, and the resulting damage as indicated by the maximum depth of pitting and the volume of concrete disintegrated and removed, is given in Table 1.

Disregarding Conduit 3, where damage was comparatively slight, analysis of the data in Table 1 indicates that the concrete on the tops of the conduits was pitted to maximum depths of more than 1.0 ft to 1.5 ft, whereas the side-walls were pitted to maximum depths of more than 0.5 ft to 1.75 ft. Neglecting the time in which the conduits were operated at 90% gate opening (when, as previously explained, cavitation was reduced to a minimum), the data for Conduits 1, 2, 5, and 6, as given in the table, indicate a progressive increase in the volume of concrete disintegrated and removed with increased hours of operation at heads greater than 45 ft. However, comparison of the data for



(a) CONDUIT NO. 1
(b) CONDUIT NO. 2

FIG. 2.—VIEWS FACING DOWNSTREAM TOWARD THE INTERSECTION OF THE TOP AND RIGHT SIDE-WALL OF CONDUITS, MADDEN DAM

Conduits 1 and 2 with those for Conduits 5 and 6 shows a tendency for the rate of disintegration and removal of concrete to become less as the conduits are subjected to greatly increased hours of operation at high heads. This may be explained by the tendency for the erosion on the top of the conduit to become stabilized but to continue to progress down the side-walls, as will be discussed more fully in comparing the cavitation region or pocket with the eroded area in the section, "Behavior of Original Madden Entrances in Models."

[a] Includes all operations from the time gates were first closed to impound water until March 28, 1935.

[b] Values given correspond to maximum depth contours shown on drawings for each conduit similar to those of Fig. 3.

In studying the data of Table 1, it may be noted that Conduit 4 was apparently better able to withstand the ravages of cavitation than were Conduits 1, 2, 5, and 6. Conduit 3 was in operation under high heads for only a few hours. No explanation can be given for this inconsistency other than the possibility that the concrete in the region of the entrance to Conduit 4 was of unusual strength. Records of compression tests made on samples of the concrete placed in the regions of the various conduit entrances gave 28-day breaking strengths ranging from about 3,230 lb per sq in. to about 4,680 lb per sq in., and averaging about 3,800 lb per sq in. The results of tests of individual cylinders tend to confirm the suggestion that concrete in the walls of Conduits 3 and 4 may be of unusual strength.

As a further indication of the quality of the concrete in the conduit entrances in general, it may be mentioned that the inspection revealed all loose or disintegrated particles of concrete to have been removed by the terrific scouring action of the water. The remaining concrete in all damaged areas was ragged and sharp but otherwise in sound condition. It is evident, therefore, that the cavitation action must have exerted terrific forces on the particles of concrete making up the conduit surfaces, particularly if consideration is given to the comparatively short total periods at which the various conduits were operated at full gate opening under heads greater than 45 ft.

FIG. 3.—DAMAGE TO CONDUIT 5, MADDEN DAM, AFTER TWO SEASONS OF OPERATION

ATTEMPT TO ELIMINATE CAVITATION IN MADDEN DAM BY USE OF BELLMOUTH AND OTHER DESIGN MODIFICATIONS

In an effort to find a solution to the problem of cavitation control, some of the conduit entrances in the Madden Dam were revised during the spring and summer of 1935 by incorporating various modifications in design. These revisions may be summarized as follows:

(*a*) Conduits 1 and 2 were reconstructed to the original entrance design, but with the addition of three air vents, 2.5 in. in diameter, each located 10.5 in. downstream from the stop-log slot, one in the center of the top of the conduit, and one in each top corner.

(*b*) The entrance to Conduit 4 was not changed, because of approaching bad weather, but a metal filler frame was installed in the stop-log slot which served to continue the entrance curve to the downstream corner of the stop-log guide. The filler contained three air vents 3 in. in diameter in the top member, one at the center and one 2 ft 10 in. each side of the center.

(*c*) Conduits 5 and 6 were reconstructed in the form of bellmouths projecting upstream from the face of the dam as indicated by Fig. 4. A metal stop-log, slot-filler frame was placed in Conduit 6 with three air vents 3 in. in diameter in the top member, one in the center and one 2 ft 1½ in. each side of the center.

The installation of the concrete bellmouths at the entrances to Conduits 5 and 6 was completed in June, and the modification of the remaining conduits was completed during the following few weeks. Conduit 3 was not changed. The natural flow of the river was passed through the conduits until early in August when the conduits were closed and the impounding of water began.

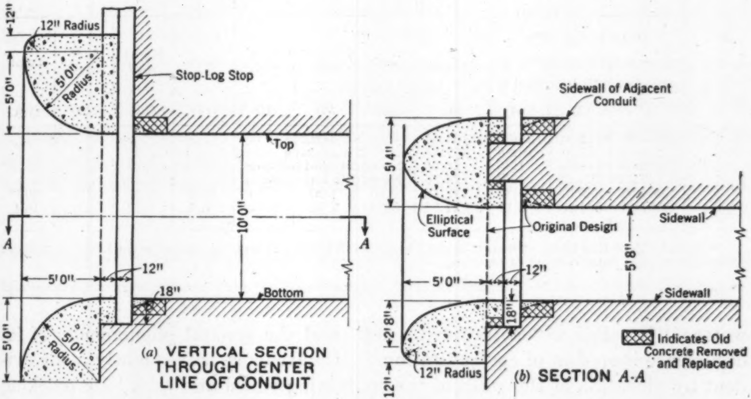
The conduits were in use at various times during the process of filling the reservoir until the latter part of December, when a diver inspected Conduits 5 and 6 under 90 ft of water. Conduits 3, 4, 5, and 6 were later inspected in the dry when unwatered for repairs.

Conduits 1, 2, 3, and 4 had been operated at high heads for only a few hours each during the second season of operation and were found to have suffered practically no damage from cavitation during that season.

The inspection of Conduits 5 and 6 revealed that cavitation had caused considerable damage to the tops and side-walls of the conduits downstream from the stop-log slots, reinforcing bars being exposed and loose in several places. The stop-log slots themselves were in good condition, as were the surfaces of the bellmouths, except for roughening of the concrete on these surfaces immediately upstream from the stop-log slots.

The filler frame which had been fabricated of ½-in. steel plate and placed in the stop-log slot of Conduit 6 was found to be in badly damaged condition. The bottom horizontal member was still in place with the two vertical members attached thereto. However, both vertical members had been forced downstream and downward toward the bottom of the conduit, pivoting about the bottom horizontal member of the frame as an axis. The top horizontal member of the frame was completely missing. Two of the vent pipes leading to the filler frame were snapped off about 7 ft above the top of the frame, and the third was snapped off at the frame.

The location and extent of pitting as a result of cavitation in Conduit 5 during the second season of operation are indicated in Fig. 3. The pitting in Conduit 6 was quite similar. Superimposed on the contours showing this damage are contours indicating the damage to this conduit as a result of operation during the first season—that is, before the bellmouth entrances had been installed. It may be noted that the general proportions and locations of the pitted areas on the top of the conduit were approximately the same in the case of both seasons of operation, although the damage resulting from operation during the second season extended a slightly lesser distance into the conduit than did that resulting from operation during the first season. The deepest pitting of the side-walls occurred 1 to 4 ft downstream from the stop-log slots in the case of the second season of operation, whereas during the first season of operation the deepest pitting of the side-walls occurred 8 to 10 ft downstream from the stop-log slots. During the second season of operation pitting occurred to a minor degree over the full height of the side-walls immediately downstream from the stop-log slots. In these areas pitting was entirely absent, except near the tops of the conduits, at the close of the first season of operation, as indicated by broken lines in Fig. 3.



(*a*) VERTICAL SECTION THROUGH CENTER LINE OF CONDUIT

(*b*) SECTION *A-A*

FIG. 4.—BELLMOUTH ENTRANCE AT CONDUITS 5 AND 6, MADDEN DAM

For comparison with Table 1 and the degree and extent of pitting resulting from operation during the respective seasons, as indicated by Fig. 3, Table 2 gives a résumé of the number of hours and minutes each conduit was operated at various heads during the second season of operation, together with the resulting damage as indicated by the maximum depth of pitting and the volume of concrete disintegrated and removed. The values given for depths of pitting correspond to the maximum-depth contours shown for the respective conduits in Fig. 3.

NATURE AND CAUSES OF CAVITATION

It is well known that under certain conditions of hydraulic flow a persistent void space or cavity will occur at some given location in the stream of moving water. If this cavity is not connected with the atmosphere, and therefore contains practically nothing but water vapor and flying particles or slugs of water, it is called a "cavitation pocket" and the general phenomenon of its occurrence is spoken of as "cavitation." Its existence is frequently made evident by vibration of the walls of the containing vessel and by a loud cracking sound known as "crepitation." Where a cavitation pocket occurs in contact with a solid object, such as the concrete surface of a conduit or the metal blade of a turbine runner, the solid material eventually becomes damaged by destructive disintegration commonly known as "pitting."

TABLE 2.—MADDEN DAM CONDUITS, RESULT OF SECOND SEASON OF OPERATION

Conduit	Hours and Minutes of Operation at Full Gate Opening				Approximate Maximum Depth of Pitting (Ft)			Volume of Concrete Removed (Cu Ft)

[a] 85 to 97% of this time, operation was at heads from 0 to 25 ft to pass natural river flow. [b] Includes 1.0 cu ft removed from bottom of conduit.

Cavitation pockets of the type occurring in diverging tubes are characteristically traversed from end to end by a succession of swiftly moving slugs of water separated by vapor cavities. Prof. H. E. Edgerton has taken remarkable moving pictures,[5] exposed at 3,000 per sec, showing the water slugs and vapor cavities traversing pockets of this type. One group of twenty five of these exposures[6] shows, with marked clearness, the formation, growth, and collapse of a moving vapor cavity during the one hundred and seventy fifth of a second required for it to traverse the length of the region designated as the "cavitation pocket."

Some years ago it was thought that the pitting of turbine runners, ships' propellers, and pump impellers was caused by the chemical action of nascent oxygen released in the cavitation pockets; but this theory has been discarded. It is now generally recognized that damage to materials in contact with a cavitation pocket is caused by the hammering or penetrating effect of extraordinarily high water pressures generated in local regions in connection with the collapse of vacuum pockets. Although to the uninitiated it may seem surprising that a moving mass of water can strike a blow sufficiently severe and concentrated, not only to disintegrate concrete but to indent the hardest metals, abundant experimental evidence proves that such action is possible and of common occurrence.

---

[5] "Cavitation Research," by J. C. Hunsaker, *Mechanical Engineering*, Vol. 57, April, 1935, pp. 211–216.

[6] "Applied Fluid Mechanics," by M. P. O'Brien and G. H. Hickox, Members, Am. Soc. C. E., p. 34.

An analytical demonstration of the hammering power of water under cavitation conditions may be made in two steps: (1) Proof that the collapse of vapor cavities can produce extremely high local velocities; and (2) proof that the sudden checking of such velocities can produce extremely high local pressures. The first step may be explained most conveniently in connection with an arbitrary system in which the dimensions of the vapor cavities can be expressed by a simple formula. Consider for this purpose that Fig. 5 represents a prismatic space of square cross section with diameter d, terminated at one end by a pyramid of altitude a. First, consider this space to be bounded by solid walls, and later as representing a cavitation pocket for which three of the four boundary walls are of water. Suppose that two slugs of water of equal volume and equal original kinetic energy are traveling down this space, the one in the prismatic portion having a volume $b\,d^2$ and a velocity v_0, and the one in the pyramidal portion having the same volume but velocities of v_1 and v_2 at its forward and rear ends, respectively. The three vapor cavities adjacent to these two slugs of water are indicated in Fig. 5. If w represents the weight of a unit volume of water, the kinetic energy of a lamina of volume $y^2\,dx$ having a velocity v is

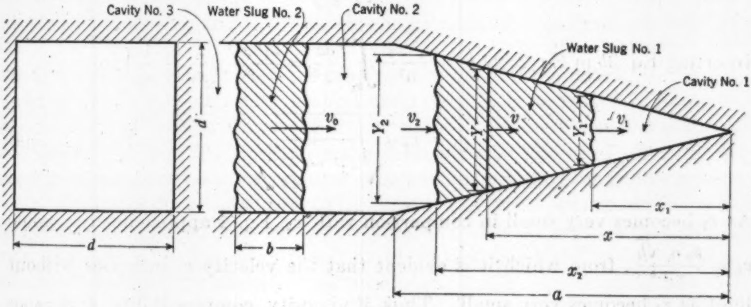

Fig. 5.—Movement of Water Slug into the Confined Region of Diminishing Cross Section

$$E_k = w\,(y^2\,dx)\,\frac{v^2}{2\,g} = w\left(\frac{x\,d}{a}\right)^2\frac{v^2}{2\,g}\,dx \ldots\ldots\ldots\ldots\ldots (1)$$

Therefore, the kinetic energies of the two water slugs in Fig. 5 are given respectively by the first and second members of the following equation:

$$w\,b\,d^2\,\frac{v_0^2}{2\,g} = \int_{x_1}^{x_2} w\left(\frac{x\,d}{a}\right)^2\frac{v^2}{2\,g}\,dx \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which, in addition to symbols shown in Fig. 5: w = unit weight of water and g = acceleration of gravity.

In order to justify equating these two expressions for kinetic energy, it is necessary to neglect the dissipation of energy by hydraulic friction or viscous resistance to deformation, the storage of energy by elastic compression of the water or the conduit walls, and the release of energy by condensation of the water vapor in the cavities as the volumes of the latter decrease. This analysis thus assumes frictionless non-viscous flow, incompressible materials, and negligible vapor pressure. The effect of these assumptions will be discussed subsequently.

In Fig. 5, imagine the cross-sectional plane of abscissa x and area y^2 to consist of a weightless elastic membrane which separates the slug of water into two parts and moves forward with the velocity v. Since the volume of water must thus remain constant between the sections whose respective abscissas are x and x_1:

$$v\,y^2 = v_1\,y_1^2 \qquad \text{(3a)}$$

Since $y = \frac{x\,d}{a}$ and $y_1 = \frac{x_1\,d}{a}$, Eq. 3a becomes $v\left(\frac{x\,d}{a}\right)^2 = v_1\left(\frac{x_1\,d}{a}\right)^2$, or

$$v^2 = v_1^2\left(\frac{x_1}{x}\right)^4 \qquad \text{(3b)}$$

Inserting Eq. 3b in Eq. 2: $v_0^2\,b = \frac{v_1^2\,x_1^4}{a^2}\int_{x_1}^{x_2}\frac{dx}{x^2} = \frac{v_1^2\,x_1^4}{a^2}\left(\frac{1}{x_1} - \frac{1}{x_2}\right)$; or,

$$v_1 = v_0\,a\sqrt{\frac{b}{x_1^3 - \frac{x_1^4}{x_2}}} \qquad \text{(4)}$$

As x_1 becomes very small in comparison with x_2, Eq. 4 approaches the value: $v_1 = \frac{v_0\,a\,\sqrt{b}}{x_1^{1.5}}$, from which it is evident that the velocity v_1 increases without limit as x_1 becomes very small. Thus, if viscosity, compressibility, and vapor condensation did not influence the rate of movement of the water, the velocity at the tip of the slug would become infinite at the final instant of the collapse of the vapor cavity at the apex of the pyramid. It is possible also to prove by similar methods that at this same instant, and under the same assumptions, the velocity v_2 becomes zero. In other words, all of the original kinetic energy of the slug would still exist in the kinetic form; but it would be practically all concentrated into the fluid particles that make the final contact with the solid surface at the point where the last vestige of the collapsing cavity disappears, with the result that these particles would acquire enormous velocity.

It is evident that the latter statement could be proved for spaces of other shapes than the square pyramid in Fig. 5. In fact, if incompressible materials, frictionless flow, and negligible vapor pressure are assumed, the statement is perfectly general and applies to spaces of all shapes, whether bounded by solids or fluids. Under these assumptions, if a slug of moving liquid is brought to rest by traveling into a confined vacuum space of any shape, the velocity of the last particles making the contact must become infinite.

Although the factors specifically neglected in the foregoing demonstration undoubtedly have important effects, the analysis reveals the fundamental reason why intense local concentrations of energy are associated with the collapse of vacuum cavities. From the foregoing it is apparent that if cavitation occurs in large outlet conduits of high dams there is abundant opportunity for tremendous concentrations of energy to occur at local spots along the conduit surfaces.

Under the foregoing assumptions, the pressure developed at the point where the two incompressible materials finally meet with infinite relative velocity would evidently be "super-infinite." The problem of determining the pressure developed by the collision of compressible materials moving at finite relative velocity remains to be discussed. This problem comprises the second part of the analytical demonstration of the hammering power of water, and requires a development of the proof that the sudden checking of high-water velocities can produce extremely high pressures. This proof is analogous to that which shows that high pressures in a pipe can be produced by the sudden closure of a valve. When a rapidly moving mass or slug of water strikes a rigid plane surface normal to the direction of motion, the water particles adjacent to the contact surface and near to the center of the contact area have their velocity suddenly reduced to zero and their kinetic energy suddenly changed to energy of elastic compression. By equating the values of these two kinds of energy, per pound of water, the amount of the pressure rise may be computed.

In order to make this computation accurately, it is necessary to have information regarding the compressibility of water under the unusual conditions considered. At very high pressures the volumetric coefficient of elasticity of water increases to several times the ordinary value published in textbooks.

In discussing the effects of rapid compression of water, the results of ordinary slow-compression tests cannot be used directly. In slow or isothermal tests, the heat of compression has time to be dissipated to the surrounding objects or mediums, practically uniform temperature being maintained in the specimen at the times when readings of deformation are taken. Under such conditions water at 50° F solidifies into ice at a pressure of about 110,000 lb per sq in. In rapid or adiabatic compression, the heat generated has no opportunity to escape to the surrounding objects or mediums, and therefore the temperature of the water rises as the pressure is applied, thus preventing solidification into ice.

The results of an elaborate investigation on the compressibility of water were published in 1912 by P. W. Bridgeman,[7] who presents a diagram which, when translated from metric to English units, gives the volume of one pound of water at all pressures from 0 to 180,000 lb per sq in. in combination with all temperatures from 4° to 176° F, except where the water is in the solid state. He also presents a diagram giving, for the same range of pressures and temperatures, the adiabatic rise in temperature per unit rise in pressure, as determined, not from actual quick-compression tests, but from a thermodynamic analysis of thermal measurements during slow-compression tests. By the use of these two diagrams it is possible to start with one pound of water at atmospheric pressure and any given temperature, and compute its volume and temperature after any number of successive increments of adiabatic compression. It is also possible to compute the total external work or energy contributed to the pound of water during the adiabatic compression, since the work done during any one increment of pressure is equal to the product of the mean pressure and the decrement in volume. The results of such a computation by the writers, starting with one pound of water at 50° F and extending to the limits of Bridgeman's diagrams, are given in the first eight columns of Table 3: Col. 1 gives the pressure in increments of 14,223 lb per sq in. (1,000 kg per sq cm); Cols. 2 and 4 are obtained from Bridgeman's diagrams, with the values converted to English units; Col. 3 is an accumulative summation of the increments in Col. 2; Col. 5 consists of the differences between successive items in Col. 4; Col. 6 contains the averages of successive items in Col. 1; Col. 7 gives the products of the items in Cols. 5 and 6; and Col. 8 is obtained by summing the items in Col. 7.

170,676		112.0	22.10				333,500	1,338	1,545

The kinetic energy of one pound of water moving at velocity v feet per second is $12\,\frac{v^2}{2\,g} = \left(\frac{v}{2.318}\right)^2$ in-lb. Each item in Col. 9, Table 3, gives the initial velocity required to develop kinetic energy equal to the energy of elastic compression at the pressure indicated in Col. 1. This is found by multiplying the constant 2.318 by the square root of the corresponding item in Col. 8. In other words, any pressure value in Col. 1 is that generated when water moving at the velocity given by the corresponding figure in Col. 9 strikes a rigid plane surface normal to its path. For example, if water is moving at 1,338 ft per sec, its impact on such a surface will develop a pressure of 170,676 lb per sq in. Under ordinary conditions, a velocity as high as 1,338 ft per sec could be acquired only in the case of flow into a converging space, according to principles previously explained. Thus, if the aforementioned rigid plane surface were in a position to block the end of such a converging space, the pressure of 170,676 lb per sq in. would be developed against its face. However, if the surface were not a true plane, but contained crevices, depressions, or intracrystalline cracks such as to cause small portions of the water to acquire velocities much higher than the general velocity of 1,338 ft per sec before being finally brought to rest, local pressures much higher than the general pressure of 170,676 lb per sq in. would be developed.

The law governing the foregoing process of pressure multiplication undoubtedly changes when the crevices become so small as to approach molecular dimensions. However, what has been given contains a suggestion as to the source of pressures known to be sufficient to penetrate or deform the hardest metals.

In the foregoing analysis, when the slug of water hits the rigid surface, a pressure wave of intensity p is generated at the contact surface and travels out into the liquid at the acoustic velocity

$$u = \sqrt{\frac{g\,e}{w}} \qquad \text{(5)}$$

the phenomenon being similar to the generation of a water-hammer wave in a pipe by the sudden closure of a valve. However, when the slug of water strikes a water surface normal to the direction of motion, two pressure waves travel out from the contact surface in opposite directions, each moving at the acoustic velocity. This action may be described in more detail by reference to Fig. 6, which shows a slug of water moving at velocity v and striking a water surface. Consider within the slug a rectangular prism of water of cross-sectional area $(dx)^2$, with its sides normal to the contact surface. The enlarged section of a portion of this prism in Fig. 6 indicates that the contact surface is being forced down with a velocity v_c. At an instant dt seconds after contact, the row of particles which were originally in surface $C'C'$ have moved down to CC, and the particles which were in $A'A'$ at the instant of contact have moved down to AA. A pressure wave front having the acoustic velocity u relative to the surrounding fluid has traveled upward from $C'C'$ to AA, and another has moved downward from $C'C'$ to BB. The shaded volume is under a pressure p and has a unit weight w and a coefficient of elasticity E. The volume corresponding to the unshaded area is still under its original pressure. Since the force required to retard or accelerate a mass of water is equal to the mass of water multiplied by the rate of change in velocity: Force on CC = (Mass of $A'A'C'C'$) the rate of reduction in its velocity = (Mass of $C'C'BB$) the rate of increase in its velocity; or

$$p\,(dx)^2 = \left(\frac{w}{g}\,u\,dt\right)(dx)^2\left(\frac{v - v_c}{dt}\right) = \left(\frac{w}{g}\,u\,dt\right)(dx)^2\left(\frac{v_c}{dt}\right) \quad \ldots\ldots(6)$$

Therefore, $v_c = 0.5\,v$.

In other words, the velocity of particles at the contact surface is one half the initial velocity of the slug of water; therefore, one fourth of the original kinetic energy of these moving water particles is still in the kinetic form, and three fourths has been converted into energy of elastic compression. Thus, if v_r and v_w are the initial velocities required to develop a given pressure p in the respective cases of impact against a rigid surface and against a water surface:

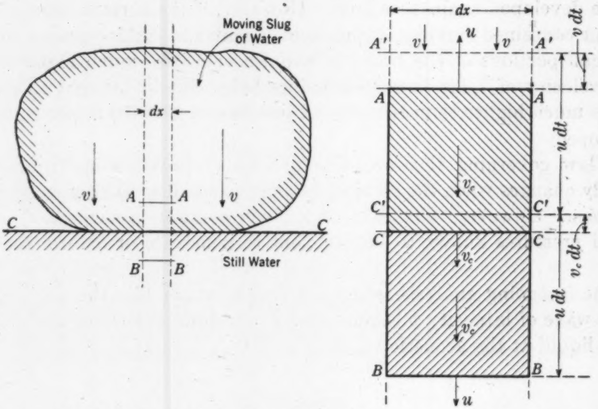

FIG. 6.—MOVING SLUG OF WATER STRIKING STILL WATER SURFACE NORMAL TO THE DIRECTION OF FLOW

$$\frac{3}{4}\,\frac{(v_w)^2}{2\,g} = \frac{v_r^2}{2\,g} \quad \ldots\ldots\ldots\ldots(7)$$

and from this it is seen that $v_w = v_r\sqrt{\frac{4}{3}} = 1.155\,v_r$. In other words, a velocity 15.5% higher is required to produce a given pressure if the impact is on a water surface than if it is on a rigid surface. Col. 10 of Table 3 is computed on the basis of this principle.

From the foregoing it is seen that when a cavity in water collapses, the pressure developed at the final point of contact may be very high if this point is in contact with a solid surface and partly surrounded by water, although not quite as high as if it were fully surrounded by solid materials.

The familiar effects of water hammering sufficiently intense to indent and disintegrate the surfaces of hard metals furnish abundant proof that pressures approaching or exceeding the higher values of Table 3 actually occur in engineering machines and structures.

In the case of metal surfaces the development of deep pitting is a slow process, usually requiring months of continuous operation. The long-continued intense hammering on tiny local spots overstresses the surface of the metal until fatigue cracks appear. The enormous pressure developed in such cracks, in accordance with the foregoing theory, then quickly enlarges and spreads them. In the case of concrete surfaces slightly permeable to water, the penetration of enormous pressures into the pore spaces easily breaks the bond between the aggregate particles, so that extremely destructive effects can occur within comparatively few hours.

Description of Apparatus for Cavitation Tests

Cavitation may occur at any point in a hydraulic system when the pressure at that point is reduced to the vapor pressure of the liquid flowing in the system. This requirement for the cavitation phenomenon to occur, therefore, precludes the study of its possible occurrence in hydraulic structures by means of small undistorted models of the usual laboratory type in which air at ordinary barometric pressure and water at room temperature are used and relative headwater and tailwater depths are represented to scale. In such a model, the whole atmospheric pressure is effective on the free surfaces of the liquid used in the model and is transmitted throughout that liquid so that the absolute pressure in the regions of the model corresponding to the cavitation regions of the prototype is far greater than the vapor pressure of the liquid in the model. In order that the basic conditions which produce cavitation in certain regions of the prototype may be correctly represented in the model, it is necessary that the pressures in these regions of the model be reduced to the vapor pressure of the liquid used in the model.

In planning the cavitation tests of the conduits at Tygart River and Madden dams, modification of the vapor pressure of the liquid by thermal or chemical means was eliminated from consideration because of its inconvenience from the standpoint of laboratory practice. Therefore, two possible means of simulating the basic conditions which produce cavitation in the critical regions of the prototype presented themselves—namely: (1) The design of a testing apparatus in which absolute pressure could be reduced in such a way as to simulate reduction of the atmospheric pressure on the headwater and tailwater surfaces in the model; and (2) the design of a testing apparatus such that, by distorting the headwater pressure and the discharge scale, the correct cavitation potentiality would be produced in the critical area of the conduit. The first of these testing facilities was used exclusively in the earlier tests, but for the later tests the second was also used, particularly to facilitate tests involving the admission of air into the conduits to alleviate or cushion the shock of cavitation. For the purpose of this paper these two testing devices are designated "enclosed-tank cavitation apparatus" and "diverging-tube cavitation apparatus," respectively.

Enclosed-Tank Cavitation Apparatus.—A general understanding of the design of the enclosed-tank cavitation apparatus may be had from Fig. 7.

In testing models in this apparatus, the absolute pressures on the surfaces corresponding to the headwater and tailwater surfaces in the prototype had to be reduced in almost direct proportion to the model scale. Consequently, the entire fluid medium had to be subjected to subatmospheric pressure, thus necessitating that the apparatus constitute an enclosed system in which the water supply was continuously circulated. As indicated by Fig. 7, the apparatus consisted essentially of a head tank (*A*), 32 in. in diameter and flattened on the top at the outlet end (*B*), where it was welded to a rectangular section (*C*) containing the model, the outlet end of the rectangular section in turn being connected by an 8-in. pipe line through a centrifugal pump (*D*) and control valve (*E*) to the inlet end of the head tank. An air trap (*F*) was placed in the top of the head tank and connected to a vacuum pump (*G*) which supplied the necessary reduction in pressure to the system of the testing apparatus. An opening was placed in the top of the rectangular section of the apparatus to facilitate the insertion and removal of models. A one-inch plate of annealed glass (*H*) served as a cover for the opening and also as an observation window to facilitate study of flow conditions and the action of cavitation in the model. The glass plate was protected against direct contact with the concrete of the model by a rubber gasket and was sealed against leakage by an application of sculptor's plastic waterproof clay between the edge of the glass plate and the edge of the opening in the tank. For tests involving measure-

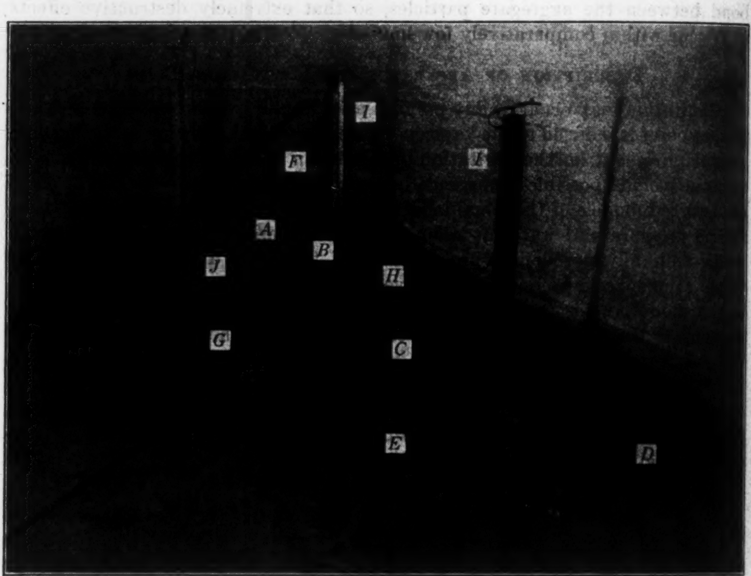

FIG. 7.—ENCLOSED-TANK CAVITATION APPARATUS

ments of the pressure distribution over a longitudinal section of the conduit, the annealed plate glass cover was replaced by a brass plate containing a network of piezometer openings. Mercury gages (*I*) of the cistern manometer type were provided at each end of the model to determine pressures at those points (corresponding to points *H′* and *R′* of Fig. 8). Baffles were provided

FIG. 8.—TYPICAL DAM SECTION SHOWING PRINCIPLES OF MODEL OPERATION TO SIMULATE CAVITATION

at the inlet end of the head tank to eliminate excessive turbulence in the water and to provide good approach conditions to the model. Provision for measuring the discharge through the model was made by a pitot tube (*J*) in the 8-in. pipe line, the pitot-tube installation having been calibrated by traversing the cross section of the pipe.

The models tested in this apparatus were generally constructed of concrete, with such appurtenances as stop-log slots and guides constructed of wood or sheet metal. In tests to study pitting, inserts of a specially designed concrete of low strength (see section "Experiments to Find a Material to Simulate Pitting") were cast in the critical regions of the model.

To facilitate observation and study, it was necessary with this testing apparatus to construct and test models representing only one half of the prototype cross section; that is, the prototype was represented in the model as halved by a diametrical plane, the inclination of the plane being chosen to represent the prototype to the best advantage for the purpose of the particular test.

In placing the models in the testing apparatus, the diametrical plane was coincident with the bottom surface of the glass (or brass) cover plate for the rectangular section of the apparatus. In many cases, therefore, it was necessary to represent the prototype in a revolved position—that is, with the conduit inverted or turned on its side. However, tests of models of the same conduit, shown in various revolved positions, indicated that such orientation had no noticeable effect on the results of the tests.

In conducting tests in this apparatus, it was found necessary to operate for several minutes to exhaust air entrapped and dissolved in the water of the system before actual test results could be obtained. For this reason, it was found impracticable to conduct tests, with this apparatus, that required the admission of air into the model to alleviate or cushion the shock of cavitation. The diverging-tube cavitation apparatus was designed to facilitate such tests.

Diverging-Tube Cavitation Apparatus.—A general understanding of the design of this apparatus may be had from Fig. 9. The horizontal pipes along the wall behind the gage boards are not a part of the testing equipment. As indicated, the apparatus consisted essentially of a head tank (*A*) 15 in. in diameter, to the outlet end of which was connected the model to be tested (*B*), constructed of a pyroxylin material and representing the full cross section of the prototype. The outlet end of the model in turn was connected to a diverging tube (*C*) which led to the laboratory sump. The transparent nature of the pyroxylin material made unnecessary any orientation of the conduit away from its normal position. Since at the outlet end of the diverging tube the pressure was atmospheric and the velocity of flow relatively low, this tube served, through the smaller cross section and higher velocity at its throat, to provide sub-atmospheric pressure at the outlet end of the model. It was possible by means of this apparatus to test models at headwater pressures greatly beyond those represented by direct scale reductions of the ones in the prototype, with the result that velocities were correspondingly exaggerated. Such exaggeration of the head and velocity scales was necessary in order that absolute pressures in the critical regions of the conduit be in correct relation to the absolute pressures which would exist in the prototype. Provision for measuring the pressures at each end of the model (corresponding to points *H'* and *R'* of Fig. 8) was made by mercury gages (*D*) of the U-tube type.

Connection of the gage to the lower end of the model was by means of a piezometer opening on each of the four sides of the conduit, the individual openings being connected through a common header to a single gage. An air cushion consisting of a glass jar (*E*) was provided in the line connecting the piezometer opening in the head tank with the mercury gage for determining the pressure at that point. Suitable baffles were provided in the head tank to eliminate excessive turbulence and to provide smooth approach conditions to the model. The rate of discharge of water through the model was measured by a venturi meter in the pipe line leading from the pump.

In operating this testing apparatus, water was drawn from the laboratory sump and returned to it, and therefore the elimination of entrapped and dissolved air in the system was greatly simplified. It was possible, thus, to study the effect on cavitation of venting the conduits without encountering the difficulty of having the air that was admitted to the model reappear in the head tank. To facilitate the tests of venting the conduits, provision was made for introducing air into the model at the inlet end of the conduit (*F*) and also immediately below both the emergency (*G*) and service (*H*) slide-gate slots However, since the emergency slide gates would be operated only on rare occasions, only the service slide gate was simulated in the model; but slots for both were included. The rate of flow of air into the model during venting tests was measured by means of circular, round-edged, brass orifices (*I*) provided with U-tube water manometers (*J*) to measure the head loss. The valve (*K*) in the upper end of the diverging tube served as a bleeder to adjust the pressure at the lower end of the model.

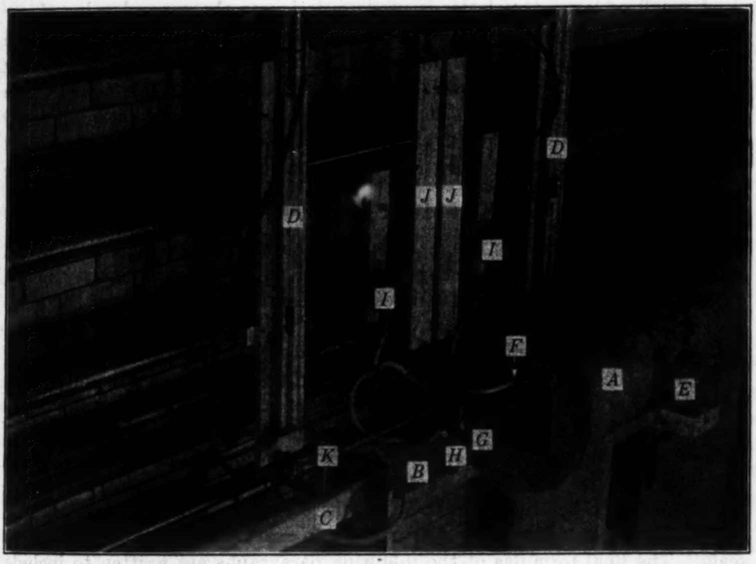

FIG. 9.—DIVERGING-TUBE CAVITATION APPARATUS

NOTATION

The notation adopted in this paper conforms essentially with American Standards Symbols for Hydraulics[8] compiled by the American Standards Association with Society representation, and approved by the Association in 1929.

---

[8] ASA—Z10b—1929.

Frequent mention will be made of three points whose locations in the prototype are indicated in Fig. 8. The point R is at the center of a reference cross section of the conduit, H is in the quiet water of the headwater reservoir at the same elevation as R, and T is on the streamline portion of the boundary of any given cavitation pocket. The points in the model corresponding geometrically to R and T are designated as R' and T', whereas a point in the quiet water of the headwater tank at the same elevation as R' is designated as H'. The elevation of T above R is designated as z_T and the elevation of T' above R' is designated as z_T'. It is to be noted that if the orientation of the model with respect to the direction of gravity does not duplicate that of the prototype, the ratio of z_T' to z_T will not necessarily be equal to the linear scale L used in constructing the model.

A small or lower-case letter is used to designate the general value of any given quantity pertaining to the prototype structure or water, and the same letter primed is used to denote the general value of the corresponding quantity pertaining to a model of this structure or the liquid used in this model. The same capital letter is used to denote the corresponding scale ratio. For example: If l designates the length of any line in the prototype, then l' designates the length of the corresponding line in the model, and L denotes the linear scale ratio $\frac{l'}{l}$. The value of a quantity at any particular point in the prototype or model is designated by using the letter denoting that point as a subscript on the lower-case letter denoting the general value of that quantity in the prototype. For example: p_R' denotes the pressure at the center of the reference section in the model conduit.

All models described herein are geometrically similar to the prototype, in so far as their solid parts are concerned, and therefore have a definite linear scale L. However, "gravitational distortion of scale" occurs when the orientation of the model with respect to the direction of gravity does not duplicate that of the prototype, and "operational distortion of scale" occurs when the absolute pressures due to headwater and tailwater are not reduced in exact accordance with the linear scale L, or where the liquid in the model is not chilled to reduce its absolute vapor pressure in exact accordance with the same scale. The final formulas of the following paragraphs are written to include cases where these distortions are used.

In accordance with Torricelli's theorem, the velocity of flow in the prototype at point T is given by

$$v_T = c_T \sqrt{2\,g\left(\frac{p_H}{w} - z_T - \frac{p_T}{w}\right)} \ldots\ldots\ldots\ldots (8a)$$

and the velocity at point T' in the model is given by

$$v_T' = c_T' \sqrt{2\,g\left(\frac{p_H'}{w} - z_T' - \frac{p_T'}{w}\right)} \ldots\ldots\ldots\ldots (8b)$$

in which: v_T = the velocity of a streamline filament at point T; c_T = coefficient of velocity for flow from point H to point T written to give the filament velocity

v_T; and z_T = the elevation of point T above point R. At first it will be assumed: (*a*) That the model is built to a definite linear scale L; (*b*) that it is set in the apparatus without gravitational distortion; (*c*) that the headwater and tailwater depths are adjusted to the linear scale; (*d*) that the water in the model is chilled until its vapor pressure is reduced in the same scale; and (*e*) that the atmospheric pressure on the headwater and tailwater surfaces is reduced in the same scale. If these conditions are satisfied, Eq. 8*b* can be written in the form,

$$V\,v_T = c_T'\sqrt{2\,g\left(\frac{L\,p_H}{w} - L\,z_T - \frac{L\,p_T}{w}\right)} \qquad \text{(8c)}$$

in which: V = scale ratio, for velocity $= \frac{v'}{v}$; L = scale ratio for length $= \frac{l'}{l}$; p_T = absolute pressure at point T, or vapor pressure of water at the given temperature; and p_H = absolute pressure at point H, given by

$$p_H = w\,h_H + p_A$$

in which: h_H = head of water above point H, p_A = absolute pressure of air on the free surfaces of the liquid, and w = unit weight of the liquid. If it is assumed that the roughness of the model surface has been adjusted until $c_T' = c_T$ and that the values of g and w are alike in the model and prototype, the expression, $V = \sqrt{L}$ (known as Froude's law) may be obtained by dividing the two members of Eq. 8*c* by the corresponding members of Eq. 8*a*. This result means that if the model is operated according to Froude's law (that is, with all the aforementioned adjustments) the velocity at any point in the model will become equal to that of the corresponding point in the prototype multiplied by the square root of the linear scale, and the absolute pressure at the point T' will become equal to the vapor pressure of the water used in the model. If this is true for all points in the model corresponding to points on the boundary of the cavitation pocket in the prototype, a cavitation pocket must open up in the model, and will correspond exactly to the prototype pocket in shape, size, and location.

In the foregoing it was assumed that the coefficient of velocity c_T' for flow from H' to T' could be considered equal to c_T. For pockets near the conduit entrance where the friction losses are small in comparison with the total head, this assumption is not likely to be appreciably in error. For pockets farther from the inlet to the conduit, where the friction losses are larger, the problem of adjusting the roughness of the model surfaces to make c_T' equal to c_T presents difficulties if a high-precision solution is desired. Similar difficulties are encountered in all hydraulic model systems where the effects of gravity and viscosity are both important, and therefore require the satisfaction of the two mutually conflicting laws of Froude and Reynolds. Fortunately, a highly precise duplication of this coefficient is not required in typical cavitation studies, since a design which approaches even near the cavitation limit may be classed as unsatisfactory.

In the aforementioned method of model operation in accordance with Froude's law, the absolute pressure in the model not only at T' but at every other point in the liquid is equal to the absolute pressure at the corresponding point in the prototype multiplied by the linear scale ratio L. In spite of the simplicity of this method of operation, numerous occasions arise for deviating from it in conducting miscellaneous cavitation studies by means of models. These occasions are usually created by the limitations of the available apparatus. Because of the location of an observation window, a conduit of rectangular cross section in the prototype may have to be inverted or laid on its side in the model; or because of the inconvenience of chilling the water in the model to reduce its vapor pressure, a slight variation from the linear-scale representation of the atmospheric pressure may be made; or the suction apparatus may not develop sufficiently low pressure to permit undistorted scale testing. When such departures are made from operation in accordance with a single linear scale for all dimensions and pressure heads, the absolute pressures are no longer to scale over the entire region occupied by the liquid in the model. This means that a group of several cavitation pockets in the model cannot be studied simultaneously. Attention must be focused on a limited region in which the occurrence of a cavitation pocket is known or suspected; and the general pressure and flow conditions of the model must be adjusted to produce the correct cavitation potentiality in that limited region. A readjustment of the general conditions must be made when a pocket in another location is studied. The equations for making these adjustments are given subsequently.

Referring to Fig. 8, it is assumed that the "reference section" R in the prototype corresponds to the location of an accurate mercury piezometer in the model. In most of the cavitation tests at Pittsburgh, the models did not represent the entire conduit, but only the upstream portion, and the piezometer was placed near the downstream end of the model. In the application of these formulas it is assumed that, for a given water elevation in the reservoir, either the mean velocity V_R or the pressure head h_R at the prototype reference section is known by computation or by actual experiments on the prototype. For reasons already mentioned, a direct determination of both of these quantities by model studies is not feasible, because the effects of gravity and viscosity are both involved to an important degree.

Referring again to Fig. 8, the mean velocity at the prototype reference section may be expressed by:

$$v_R = c_R \sqrt{2\,g\left(\frac{p_H}{w} - \frac{p_R}{w}\right)} \qquad (9a)$$

and the corresponding mean velocity in the model by:

$$v_R' = c_R' \sqrt{2\,g\left(\frac{p_H'}{w} - \frac{p_R'}{w}\right)} \qquad (9b)$$

in which: v_R = mean velocity in a conduit cross section at point R; c_R = coefficient of velocity for flow from point H to point R, written to give the mean velocity v_R; and p_R = absolute pressure at point R, equals

$$p_R = w\,h_R + p_A$$

in which: h_R = pressure head at point R. By assuming that the model roughness is adjusted so that c_R' and c_R are equal and eliminating them between these equations, considering again that g and w are alike in model and prototype, there is obtained:

$$\frac{v_R'}{v_R} = \sqrt{\frac{p_H' - p_R'}{p_H - p_R}} \qquad \text{(9c)}$$

If m represents the ratio of v_T to v_R, Eqs. 8a and 8b may be expressed in the form:

$$m\,v_R = c_T\sqrt{2\,g\left(\frac{p_H}{w} - z_T - \frac{p_T}{w}\right)} \qquad \text{(10a)}$$

and

$$m'\,v_R' = c_T'\sqrt{2\,g\left(\frac{p_H'}{w} - z_T' - \frac{p_T'}{w}\right)} \qquad \text{(10b)}$$

Considering that m and m' must be identical if the flow patterns for prototype and model are to be geometrically similar, and assuming as before that c_T' and c_T are made identical by proper adjustment of the model roughness, and eliminating these quantities from Eqs. 9 and 10, there results:

$$\frac{v_R'}{v_R} = \sqrt{\frac{p_H' - w\,z_T' - p_T'}{p_H - w\,z_T - p_T}} \qquad \text{(11)}$$

Eqs. 9c and 11 may be combined in various ways to determine the proper methods of model operation to develop a given pressure p_T' at any given location in a model, such as point T' in Fig. 8. If this value of p_T' is the vapor pressure corresponding to the temperature of the water in the model, and if point T is on the boundary of a cavitation pocket in the prototype, then point T' must also be on the boundary of a corresponding cavitation pocket in the model.

Suppose that the values of p_H, p_R, z_T, and p_T are known for the prototype, that cavitation in the model is to be investigated in a limited region for which z_T' is known, that the vapor pressure p_T' for the liquid of the model is known, and that by means of the vacuum pump or other suction device a known low absolute pressure p_R' can be maintained at the reference section in the model. To operate the model properly, it would be required to determine the absolute pressure p_H' which must be carried in the model headwater tank at the point H'. The desired value may be obtained by eliminating $\frac{v_R'}{v_R}$ in Eqs. 9c and 11, resulting in the following equation:

$$p_H' = \frac{p_R'\,(p_H - w\,z_T - p_T) - (w\,z_T' + p_T')\,(p_H - p_R)}{p_R - w\,z_T - p_T} \qquad \text{(12)}$$

If the model is correctly built and its surface roughness correctly adjusted, simultaneous setting of the two control piezometers at the values of p_H' and p_R' prescribed by Eq. 12 will automatically cause the velocity in the conduits to assume the value v_R', and the pressure at point T' to drop to the vapor pressure p_T', thereby causing the model cavitation pocket to appear in its proper form and location.

If it is desired to regulate the model by controlling the discharge with the aid of a valve and a venturi meter or other meter in the supply pipe, instead of regulating the pressure at point H' in the model head tank (the known quantities being the same as in the preceding paragraph except that v_R is given instead of p_H), the equation for determining the necessary model conduit velocity v_R' may be found by eliminating p_H' between Eqs. 9c and 11, resulting in the following:

$$v_R' = v_R \sqrt{\frac{p_R' - w\,z_T' - p_T'}{p_R - w\,z_T - p_T}} \qquad (13)$$

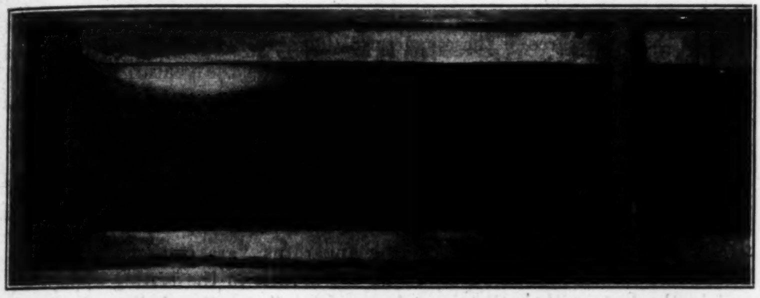
If the model is correctly built and adjusted for roughness, the setting of v_R' and p_R' at the values prescribed by Eq. 13 should give exactly the same flow conditions as those described in the preceding paragraph. Actually, however, due to natural and unavoidable errors in the meters and gages and to small imperfections in the model and its adjustment, minor discrepancies are likely to occur in the results of the two methods of operation. A perfect roughness adjustment is not usually feasible in actual laboratory practice, as the highest polish which can be produced on the available materials is insufficiently smooth.

In connection with the discussion of principles of model operation, mention may be made of the comparative advantages of the diverging-tube and enclosed-tank types of apparatus. The relative merits of the former are as follows: (1) It is much cheaper, provided that a good-sized pump or other source of fairly liberal flow under moderate head is already available; (2) its operation is much simpler, quicker, and more convenient, since it dispenses with the procedure for freeing the tank from entrained air; (3) it lends itself to studies of problems of cavitation mitigation by air admission; and (4) its higher throat velocity is advantageous in conducting actual pitting tests on models. The principal disadvantage of this apparatus is that feature which limits the conduit velocity to values greater than the spouting velocity of water at a head equivalent to atmospheric pressure. Unless a liberal flow of water is available, this requires that the models be quite small. Furthermore, unless an enclosed water storage tank is provided, this apparatus cannot be used advantageously in studies in which close control of the air content of the water is required. The principal feature of the enclosed-tank apparatus which justifies its use, in spite of its greater cost and lesser convenience, is that it permits the use of much lower conduit velocities. For a pump of given discharge capacity, a lowering of conduit velocity results in an increase in the model conduit cross section, thus allowing the use of larger models.

A third type of apparatus could also be built, in which the necessary degree of vacuum would be obtained by a vertical non-flaring draft tube about 34 ft high, but this was not feasible in the laboratory.

Computation of Gage Settings for Cavitation Tests on a Model Conduit

Models of various conduit entrances on several different scales have been built and tested at the laboratory in Pittsburgh in either the enclosed-tank apparatus or the diverging-tube apparatus. The first step in making such a



(*a*) Model Scale, 1 : 15, Enclosed-Tank Apparatus

(*b*) Model Scale, 1 : 20, Enclosed-Tank Apparatus

(*c*) Model Scale, 1 : 40, Diverging Tube Apparatus

FIG. 10.—ORIGINAL CONDUIT ENTRANCE, MADDEN DAM, OPERATING AT A 168-FT HEAD

test is to compute the necessary settings of the control gages. In each apparatus there are three of these gages: (1) The headwater pool gage, (2) the conduit reference-section gage, and (3) the gage on the venturi meter, pitot tube, or other flow meter in the supply pipe. If the prototype quantities p_H, p_R, and v_R are known, the setting for any one of these gages may be assumed, and the settings for the other two computed from them by Eqs. 11 and 12. However, the assumption must be such as to make all three settings fall within the capacity of the apparatus. The various models tested were geometrically similar to the prototype in their solid portions. However, in practically all the tests in the enclosed-tank apparatus, "gravitational distortion" was introduced by tipping or inverting the models in the testing apparatus; and in the tests with both types of apparatus "operational distortion" was introduced by omitting to chill the liquid until its vapor tension was reduced in proportion to the linear scale, or by the arbitrary choice of one of the three aforementioned gage settings. Under such conditions, as previously explained, the pressure scale would not be constant at all points in the model liquid, and the same is true of the velocity scale. The adjustment of gage settings was made to give the correct pressure condition only in a small local region containing the upstream boundary of a single known or suspected cavitation pocket.

The following example shows a typical computation for testing a 1 : 20 scale model of a pair of conduits of the Madden Dam in the enclosed-tank apparatus. Distortion of both of these types is used. A photograph of this model is reproduced in Fig. 10(*b*). The model conduits are split along the horizontal plane passing through their axes, the upper halves of the conduits being reproduced in the model and tested in the inverted position, and the top of the prototype conduit being represented in the bottom of the model. The purpose of the inversion is to make visible the large cavitation pocket known to form against the top of the conduit just inside the entrance. The computation establishes the gage settings necessary to develop the pressure corresponding to the vapor pressure of the water in this critical region of the model. The dimensions of the model were chosen to utilize most of the capacity of the pump when operating under the condition corresponding to full head on the conduits. In this example a pump discharge of 2.343 cu ft per sec is assumed. This fixes the necessary setting of the flow-meter gage, leaving the readings of the other two gages to be computed. The prototype dimensions required in the computation are shown in Fig. 11; the headwater is assumed at El. 204.7. This value of headwater elevation is used in the example since it represents the greatest head under which the conduit discharge has been verified by actual discharge measurements on the prototype. While conducting the tests on the Madden models, the feasibility of including certain refinements in the settings of the apparatus did not become apparent until near the close of the work. For this reason the computation procedure in the example is not exactly the same as that used in the actual tests.

The assumptions used in this example may be listed as follows:

Applying in General.—The headwater elevation is 204.7 ft and the tailwater elevation is at a level below the bottom of the conduit; water temperatures, in degrees Fahrenheit, are, for the prototype, 77, and for the model, 68; and the barometric pressures, in inches of mercury, are, for the prototype, 29.500, and in the laboratory at the time of the model tests, 29.655. During the test the discharge setting of the pump is 2.343 cu ft per sec; and the rating equation for the prototype conduit (based on pitot-tube tests) is

$$v_R = 7.06 \sqrt{h_H} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

The model setting was such as to produce the correct cavitation potentiality at the top of the conduit, just inside the entrance.

Applying to the Prototype.—The total head on the conduit, h_H, is 110.0 ft (see Fig. 11); and the corresponding velocity v_R at the conduit reference section is $7.06 \sqrt{110.0} = 74.0$ ft per sec. Since the water temperature is 77° F, the vapor pressure p_T is 65 lb per sq ft; and, for a barometric pressure of 29.500 in. Hg, the atmospheric pressure p_A equals $\frac{29.500}{12}(13.59 \times 62.4) = 2{,}085$ lb per sq ft. Since the elevation of point T, Fig. 11, is 100.00, the value of $z_T = 100 - 94.7 = 5.3$ ft. The absolute pressure at point H is $p_H = w\,h_H + p_A = 62.4 \times 110.0 + 2{,}085 = 8{,}949$ lb per sq ft.

DETAIL A

FIG. 11.—SECTION OF MADDEN DAM SPILLWAY AND CONDUIT

Applying to the Model.—The linear scale ratio $L = \frac{l'}{l} = \frac{1}{20}$. With the axis of the conduit horizontal, the model is inverted in the apparatus; therefore, $z_T' = \frac{-5.3}{20} = -0.26$ ft. For a water temperature of 68° F, $p_T' = 48.8$ lb per sq ft; and corresponding to a barometric reading of 29.655 in. Hg, p_A' = 2,096 lb per sq ft. With the cross-sectional area of the two half conduits equal to 0.1417 sq ft, the velocity $v_R' = \frac{2.343}{0.1417} = 16.53$ ft per sec. Finally, the absolute pressure required in the headwater tank at point H' (at the level of the glass window) may be obtained from Eq. 11, thus:

$$\left(\frac{16.53}{74.0}\right)^2 = \frac{p_H' - [62.4 \times (-0.26)] - 48.8}{8{,}949 - (62.4 \times 5.3) - 65}$$

from which $p_H' = 459$ lb per sq ft. This corresponds to a vacuum of 2,096 − 459 = 1,639 lb per sq ft, or 11.35 lb per sq in. less than the atmosphere of the room.

In the enclosed-tank apparatus the gage on the headwater tank is of the mercury-cistern type, having a rating formula to give the pressure in the tank at the level of the glass window. By this formula the gage setting necessary to give the foregoing value of p_H' is readily found.

After setting the model in the enclosed-tank apparatus, sealing the glass observation plate (window) in place with waterproof plastic clay, and filling the apparatus with water, it is necessary to remove as much of the entrained and dissolved air as possible before attempting to make accurate settings of the headwater mercury gage and of the flow-meter gage. This is done by applying the vacuum gradually, while slowly circulating the water in the apparatus, and occasionally stopping the flow by the main valve in the pipe line. This permits the bubbles of entrained air to collect in the air dome, from which they are removed by the vacuum pump. Observation through the glass observation plate (window) indicates when the water no longer contains visible traces of air bubbles. The final accurate settings of the gages are then made by trial and error, alternately adjusting the vacuum by means of the vacuum pump and adjusting the conduit velocity by means of the main valve in the pipe line. As the vacuum increases the cavitation pockets appear and become stabilized in size, shape, and location as the final adjustment is made.

The computations for gage settings in the diverging-tube apparatus are exactly similar to the foregoing, except that a higher conduit velocity must be assumed. In a diverging tube of infinite divergence and negligible friction, the ideal throat velocity required to raise the pressure from a vapor pressure of one foot of water at the throat to an atmospheric pressure of 14.7 lb per sq in., or 33.9 ft of water, at the exit would be $\sqrt{2\,(32.2)\,(33.9-1.0)}$ or 46.1 ft per sec. Making some allowance for friction and exit losses requires a velocity somewhat higher than this—say about 50 ft per sec—in the model conduit, since the latter is used as the venturi throat.

In many cavitation tests it is not necessary to compute the gage setting with as much refinement as that used in the foregoing illustration. For example, in the enclosed-tank apparatus it is possible to produce so low a vacuum at the conduit reference section as to cause long cavitation streamers to open up in the body of the water, usually along the axis of the conduit and in contact with the glass window. Under such conditions, the cavitation potentialities simulated at all places along the model conduit surfaces are far more severe than those of the prototype. If a design shows no cavitation pockets in contact with the conduit surfaces under such operation, it can be classed as excellent from the cavitation standpoint. In the diverging-tube apparatus, a similar exaggeration of the severity of the prototype cavitation conditions can be secured by increasing the velocity in the model conduit.

BEHAVIOR OF ORIGINAL MADDEN DAM CONDUIT ENTRANCES IN MODELS

Those dimensions of the original entrances of the Madden conduits which are significant from a hydraulic standpoint are shown in Figs. 1 and 11. Fig. 11 also indicates at point *T* the approximate location of the pitting in the prototype. As noted in Fig. 1, the conduit entrances are not symmetrical about a horizontal plane through the conduit axes, but the bottoms of the stop-log recesses terminate in a horizontal step or shelf 18 in. below the level of the conduit bottom. This shelf suppresses the contraction of the jet to such an extent that no pitting on the bottom occurs in the prototype or models, and no visible cavitation pockets appear in contact with the bottom in the models.

Fig. 10(*a*) shows a 1 : 15 scale model of one of the original Madden conduits, split along a vertical diametrical plane. Fig. 10(*b*) shows a 1 : 20 model of a pair of the same conduits split along a horizontal diametrical plane, the model being inverted so that the portion reproducing the top of the conduit is seen through the glass window. Fig. 10(*c*) shows a 1 : 40 scale transparent model of one of the original Madden conduits. Figs. 10(*a*) and 10(*b*) show the first two models being tested in the enclosed-tank apparatus and the third (Fig. 10(*c*)) in the diverging tank apparatus under pressures equivalent to a 168-ft head in the prototype. A photograph showing pitting in one conduit of the twin model of Fig. 10(*b*) is reproduced in Fig. 12. In all these views the large cavitation pocket against the top of the conduit just inside the entrance is very conspicuous. No other cavitation pockets are present anywhere in the entrance region, except the faint streamers just visible near the conduit bottom in Fig. 10(*a*). These streamers do not come in contact with any solid material, and therefore do not cause pitting. In a test of a 1 : 15 scale model of one of the Madden conduits after installation of the bellmouth, the size of the cavitation pocket was seen to be nearly as large as in the original conduits.

One of the most puzzling problems encountered during the conduct of the tests described herein was to find a reason for the fact that in the original Madden conduits, and in those models of these conduits which were actually subjected to pitting tests, deep erosion of the side-walls of the conduits occurred at places where absolutely no cavitation could be observed visually in the uneroded models. Contours of the side-wall erosion in Madden Conduit 5 after the first season's operation are shown in Fig. 3, whereas the photographs reproduced in Fig. 10 indicate the area covered by the aforementioned large cavitation pocket. The edges of this cavitation pocket are in contact with the side-walls of the conduit near the top, but, as noted in Fig. 3, the side-wall erosion not only occurs in the area touched by this pocket, but also extends a considerable distance downstream and downward toward the bottom of the conduit. The point of deepest side-wall erosion is entirely outside the area touched by the cavitation pocket in Fig. 10(*a*).

The explanation of this phenomenon is as follows: There is an outstanding difference between the process that controls the growth of the pit eroded in the top of the conduit and that which controls the growth of the pits eroded in the two side-walls. However, the excavation of all three of these pits is started by the action in the same large cavitation pocket. In the case of the pit in the top of the conduit, the enlargement and deepening of the eroded region provides a stilling pool which helps to absorb the energy of the rapidly moving water filaments and to cause the vapor cavities to collapse in water rather than in contact with solid material. Eventually, this pit tends to attain a certain stability in dimensions. The action is closely analogous to the erosion of a pit in the bed of a river below a dam whose apron is not specifically designed to prevent such erosion. The scouring out of such a pit is very rapid until it becomes large enough to stabilize the hydraulic jump and form a natural stilling pool where the energy of the spillway jet is dissipated. As this condition is attained, the growth of the excavation becomes slower and finally ceases.

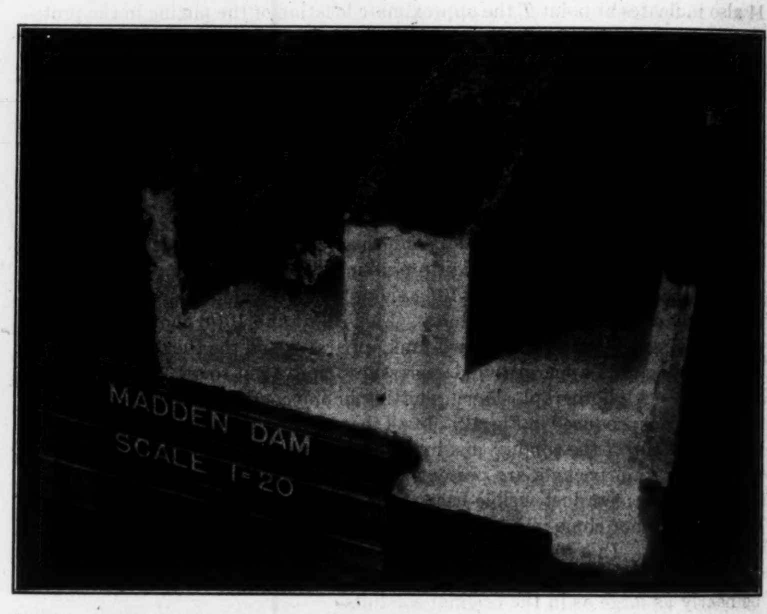

Fig. 12.—Original Conduit Entrance, Madden Dam, Showing the Pitting in a 1 : 20 Scale Model After One Hour of Operation (Prototype Velocity, One Conduit, 128 Ft per Sec)

In the case of the pits in the side-walls of the Madden conduits, the process of growth is radically different from the foregoing. As shown in Fig. 12, the pit first develops along the edge of the large cavitation pocket, where especially intense impacts are caused by collisions between the swiftly moving water of the streamline filaments and the broken masses of water and vapor hurled against these filaments from the interior of the pocket. As the pit develops, it becomes in itself a source of cavitation. As the swift water of the streamline filaments passes over the edge of the pit, vapor cavities form beneath or pass in from the main cavitation pocket, and the violent collapse of these vapor cavities enlarges the excavation. This growth of the pit in the downward direction, or toward the bottom of the conduit, causes it to eat in under the swift water of the streamline filaments and thereby tap new sources of destructive energy. Along this edge of the pocket there is no opportunity for the impact to become cushioned by enlargement of the excavation, but swift water is constantly fed in over the edge of the pit, inducing violent collapse of vapor cavities at a place in immediate contact with solid material. This action causes the excavation to grow rapidly in a direction toward the bottom of the conduit and downstream, and thus the pit eventually extends itself into a region far beyond the boundary of the original cavitation pocket.

The value of model studies of cavitation by visual observation of the occurrence of cavitation pockets is not destroyed by the fact that such observation does not furnish full information regarding the final location of the pitting. If any cavitation pockets are observed in contact with the surfaces of a model conduit, it is safe to assume that destructive effects will be induced in the prototype, although the exact nature of such effects may be uncertain.

Experiments to Find a Material to Simulate Pitting

In spite of theoretical difficulties, it was thought that there might be a possibility of developing, by empirical methods, some material that would pit at a rate determinable experimentally in terms of the intensity of cavitation. It would have been very convenient to make a model conduit of such a material, run it in the cavitation apparatus for a definite number of hours, remove it and measure the depth of pitting, if any, and then state that the same degree of pitting must occur at the same location in the prototype after a definite period of operation. A considerable amount of thought and work was expended in efforts to develop such a material, but these efforts were not rewarded with complete success.

The accurate measurements available of the depth and location of destructive pitting in the original conduit entrances of the Madden Dam furnished an excellent opportunity to check the pitting in a model against that of a prototype. Materials were found which (after a reasonable number of hours of operation in models of the original Madden conduits) would undergo pitting simulating that of the prototype quite accurately in depth and location. However, full success was not obtained in controlling the uniformity of manufacture of these materials to such a degree that they would always pit to the same depth in the same number of hours.

Portland cement concrete or mortar, of approximately the same strength as that of the prototype, is altogether too hard for use in pitting tests in the enclosed-tank apparatus. In a 1 : 15 scale model of a Madden conduit constructed of this material, the depth of pitting after more than a hundred hours of operation amounted to less than an eighth of an inch, whereas the desired depth of cutting to simulate the prototype pitting was more than an inch.

In order to obtain more rapid rates of pitting, various materials were tried in the model conduits, the best results being obtained with mixtures of plaster of Paris, portland cement, and sand. When a mixture of these materials was made sufficiently weak to pit to the required depth in two or three hours of operation, there was a general tendency for the surface to soften or dissolve and wash away. This action was more rapid in places where the velocity was high, and cutting from this cause could not be distinguished easily from that due to cavitation. This difficulty was overcome by painting the surface of the material with a grout of portland cement and water. After setting twenty-four hours or more this gave a brittle skin surface which afforded perfect protection against erosion by smoothly flowing water, but was easily disintegrated by the hammering effect of cavitation.

The following material when used in a 1 : 15 scale model of the original Madden conduits was found to reproduce the pitting approximately to scale during a test period of about two to four hours: 1 part portland cement, 12 parts plaster of Paris, and 16 parts sand, mixed with 7.23 cc of water per ounce of dry material. The wash used on the surface consisted of a portland cement grout containing 17 cc of water per ounce of cement. The pitting obtained by operating a model made of this material for one hour is shown in Fig. 12.

Although skin formed by the portland cement wash was quite successful in eliminating general erosion and localizing the pitting to the cavitation areas, much difficulty was found in duplicating the thickness and total strength of this skin in models built at different times. In fact, this was one of the principal difficulties that prevented the attainment of full success in securing sufficient uniformity in the manufacture of model conduits to justify the placing of complete reliance on the results of pitting tests on such models.

MODEL STUDIES OF VARIOUS METHODS PROPOSED TO ELIMINATE OR MINIMIZE CAVITATION DAMAGE IN THE CONDUIT ENTRANCES OF MADDEN DAM

In the course of the model studies leading toward a solution of the cavitation problem at Madden Dam, tests were made of various methods proposed to eliminate or minimize damage in the conduit entrances. These various methods or measures may logically be arranged in two general groups—namely: (1) Those which have as their purpose the provision of conduit boundaries conforming more nearly to the paths naturally sought by the boundary filaments of the flowing water, and (2) those which have as their purpose a general adjustment of pressure within the entire conduit or upstream part of it. Among the methods tested in the laboratory may be mentioned the following:

Group 1.—

(*a*) Reconstruction of the conduit entrance to provide more liberal curvature;

(*b*) Extension of the conduit entrance upstream from the face of the dam to provide a bellmouth entrance (with and without stop-log slot filler or cover); and

(*c*) Construction of a venturi throat in the critical region of the conduit.

Group 2.—

(*a*) Operation of the conduits at partial gate closure;
(*b*) Provision of a constriction or nozzle at the outlet end of the conduit;
(*c*) Venting of the conduit by admission of air at the stop-log slot; and
(*d*) Venting of the conduit by admission of air at the slide gates.

In addition to studies of these various methods proposed for solving the problem, tests also were made to indicate what effect debris accumulations on the trash racks would have in altering flow conditions at the entrances to the conduits, and what effect such altered flow conditions would have on cavitation within the entrances.

In the case of the Madden Dam, all of the measures of Group 2 were found to have the disadvantage of reducing the discharge capacity of the conduits, and were therefore considered applicable only as temporary expedients. In Group 1, under item (*a*), extensive tests on streamlining the conduit entrances resulted in the development of "Design No. 2," shown in Fig. 13. This was recommended for actual incorporation in all the units except Conduits 5 and 6. The model studies showed this design to be free from cavitation even under a head much greater than the maximum possible in the prototype. Under item (*b*) it was found that in Conduits 5 and 6, which were already provided with bellmouths extending upstream from the entrance, cavitation could be eliminated or minimized by providing the stop-log slot with a strong cover or filler. Under item (*c*), the venturi throat was found to have no advantage over "Design No. 2" to compensate for its greater cost. In the case of the Tygart River Dam, the models showed only faint or incipient flashes of cavitation at the conduit entrances. However, since the conduits were to be steel-lined and the entrance castings already had been fabricated and delivered, it was decided

to complete the installation in accordance with the original design, but to observe carefully the effect of operation by regular inspection of the conduits, and to make such repairs as necessary if pitting of the entrance casting and lining is found to occur. The entrance bells of the Hiwassee, Bluestone, and Redbank conduits, designed with exceptionally liberal curvature in the light of information regarding the Madden difficulties and the model studies, proved to be entirely free from cavitation, but in the cases of the latter two of these three dams the models detected quite serious cavitation at gate slots in the preliminary designs, which was later eliminated through revision of these designs.

ACKNOWLEDGMENTS

Various engineers from the Panama Canal Office, the Pittsburgh and Huntington (W. Va.) District Offices of the United States Engineer Department, and the Hydraulic Research Laboratory of Carnegie Institute of Technology have made contributions toward solving the problems of controlling or eliminating cavitation in the structures which have been mentioned. W. E. R. Covell, M. Am. Soc. C. E., district engineer at Pittsburgh, has taken a keen and helpful interest in the cavitation studies. E. S. Randolph, M. Am. Soc. C. E., chief of the Design Division for the Panama Canal, had a responsible part in the design, construction, test, and repair of the conduits of the Madden Dam, and contributed extensively to the original investigations leading to the tests described herein. J. C. French, junior engineer in the Canal Zone, assisted in the model studies of the Madden conduits. W. S. Hamilton, Jun. Am. Soc. C. E., instructor in Civil Engineering at Carnegie Institute of Technology, and Harold A. Thomas, Jr., instructor in Sanitary Engineering at Harvard University, in Cambridge, Mass., worked extensively on the cavitation experiments. C. F. Merriam, hydraulic engineer for the Pennsylvania Water and Power Company, reviewed the manuscript of this paper and contributed a number of valuable suggestions. For authority to publish information pertaining to the Madden Dam the writers are indebted to Brig. Gen. C. S. Ridley, Governor of the Panama Canal Zone.

DISCUSSION

JEROME FEE,[9] ASSOC. M. AM. SOC. C. E. (by letter).—A subject of great practical importance is presented in this paper. It deals with a difficult problem in physics, challenging modern devices of experimental technique. The authors have made available a valuable record of experience with cavitation phenomena, both at Madden Dam and from their extensive model tests.

The writer wishes to discuss the analytical methods whereby the authors demonstrate: (1) The occurrence of high local velocities; (2) the production of high intensity pressures; and (3) the percentage relation between impact forces on water and rigid surfaces, respectively.

Eq. 1 is based on the assumption that the "slug" of water travels with constant kinetic energy. In the following development, the writer assumes, instead, that the momentum remains constant. Using the same notation, the momentum of a lamina of volume $y\,dx$, having a velocity v, is (compare Eq. 1):

$$M = w\,(y^2\,dx)\,\frac{v}{g} = w\left(\frac{x\,d}{a}\right)^2 \frac{v}{g}\,dx$$

Therefore, the total momentum of each of the slugs (a regrettable term applied to anything with the properties of a fluid) is (compare Eq. 2):

$$w\,b\,d^2\,\frac{v_0}{g} = \int_{x_1}^{x_2} w\left(\frac{x\,d}{a}\right)^2 \frac{v}{g}\,dx \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

Also, from Eq. 3b, $v = v_1\left(\frac{x_1}{x}\right)^2$. Therefore, $v_0\,b = \frac{v_1\,x_1^2}{a^2}\int_{x_1}^{x_2} dx = \frac{v_1\,x_1^2}{a^2} \times (x_2 - x_1)$; or:

$$v_1 = \frac{v_0\,b\,a^2}{x_1^2\,(x_2 - x_1)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

Eq. 16 should now be compared with Eq. 4, which may be written

$$v_1 = v_0\sqrt{\frac{b\,a^2\,x_2}{x_1^3\,(x_2 - x_1)}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

It is clear that Eqs. 16 and 4 are incompatible. Hence, if the kinetic energy is constant, as the authors assume, the momentum must change; but this means that some external force is acting of which the authors have taken no account. Their entire argument must therefore be regarded as unsound. Of course, it has no bearing on the question to say that the authors' conclusion is correct. The occurrence of high velocities in connection with cavitation is known from other evidence; but it might well be doubted if it rested on the analysis presented in this paper.

What would be the fate of this slug of water, for example, if the pyramidal section of the narrowing passage, shown in Fig. 5, had suddenly ceased to taper at a certain point, and had continued, instead, as a constant rectangular section of indefinite length? The writer can only imagine that the slug of water would tear itself to pieces in an effort to conform to the assumption that the kinetic energy is constant.

---

[9] San Francisco, Calif.

The neglect of viscosity forces is a serious defect of another character. With diminishing volumetric dimensions, approaching the apex of the pyramid in Fig. 5, the viscosity forces would become an important factor.

Referring next to Table 3, there are two very different phenomena that should be distinguished. Case (1) is illustrated by a steady stream of water, issuing from a nozzle and striking a plate normal to the direction of flow. The distinguishing feature is that the flow, although non-uniform, is steady and continuous. Case (2) is represented by the impact of a column of water flowing in a confined space, such as the inside of a pipe, and being suddenly stopped, as by the closure of a gate. In this case, the flow is neither steady nor continuous. From the instant that impact begins, ordinary flow ceases and the water particles merely oscillate about an equilibrium position, while a wave of pressure travels through the liquid.

The authors apparently have no difficulty in transferring quantitative results from one case to the other. In fact, they seem to make little distinction between them. Presumably, they have the first case in mind when they restrict the water particles to those "adjacent to the contact surface and near to the center of the contact area" (see heading "Nature and Causes of Cavitation"). Their conclusions, however, are expressed in general terms: Water moving with the velocities shown in Col. 9 of Table 3 will produce the pressure shown in Col. 1, on striking a rigid plane surface normal to its path.

The writer believes that the maximum pressure usually will be different in the two cases, for the same velocity; and that the pressure in Case (2) is the upper limit in Case (1), which may be approached but not exceeded, even in the central region of the contact area.

Case (2) is of particular interest to hydraulic engineers from its connection with water hammer. The problem is readily transformed into that of a still body of water in a pipe, which is suddenly struck by a plane surface, such as the end of a piston. An account of tests made under such conditions was given in 1929 by H. Diederichs and W. D. Pomeroy.[10]

Although the results have long been known, for moderate velocities, from the theory of sound, it is believed that the following analysis, suggested by the method of Messrs. Diederichs and Pomeroy, is somewhat simpler than other methods of development that have appeared. Let: A = area of piston, in square feet; v = velocity of piston, in feet per second; p = pressure against piston, in pounds per square foot; m = density of water, at 62.4 lb per cu ft; g = acceleration of gravity (32.2 ft per sec per sec); C = velocity of sound, in feet per second; W = work, in foot-pounds; and K = modulus of elasticity for water (43,200,000 lb per sq ft). For moderate velocities, this modulus will serve for both adiabatic and isothermal compression.

---

[10] "The Occurrence and Elimination of Surge or Oscillating Pressures in Discharge Lines from Reciprocating Pumps," by H. Diederichs and W. D. Pomeroy, *Transactions*, A. S. M. E., Vol. 51, 1929, p. 9.

The piston is originally at rest at the end of a pipe full of water; the static pressure is negligible. Suddenly, the piston starts to move with constant velocity, v. (Actually, some finite time, however short, is required for acceleration. This has only a transient effect.) A pressure equal to p is produced in the layer of water adjacent to the piston, and a pressure increase travels down the pipe with the speed of sound. After t seconds, the wave front has covered a distance, $C\,t$ feet, and a column of water of length $C\,t$ is now under pressure, p, and is moving at a velocity v. The work done by the piston during time, t, is: $W = A\,p\,v\,t$. This work is expended in two ways: (a) In increasing the kinetic energy of a water column of length $C\,t$ by changing its velocity from 0 to v; and (b) by increasing the potential energy of the same column, owing to the increase of pressure from 0 to p. This means that

$$W = A\,p\,v\,t = \frac{1}{2} A\,C\,t \frac{m}{g} v^2 + \frac{1}{2} A\,C\,t \frac{p^2}{K} \quad \text{(18)}$$

or

$$\frac{C}{2\,K} p^2 - v\,p + \frac{C\,m}{2\,g} v^2 = 0 \quad \text{(19)}$$

From the theory of sound

$$C = \sqrt{\frac{g\,K}{m}} \quad \text{(20)}$$

which, substituted in Eq. 19, gives

$$\frac{1}{2}\sqrt{\frac{g}{m\,K}}\,p^2 - v\,p + \frac{1}{2}\sqrt{\frac{m\,K}{g}}\,v^2 = 0 \quad \text{(21)}$$

Multiplying by $2\sqrt{\frac{m\,K}{g}}$ gives

$$p^2 - 2\,v\sqrt{\frac{m\,K}{g}}\,p + v^2\frac{m\,K}{g} = 0 \quad \text{(22)}$$

or $\left(p - v\sqrt{\frac{m\,K}{g}}\right)^2 = 0$; whence

$$p = \sqrt{\frac{m\,K}{g}}\,v \quad \text{(23)}$$

The foregoing shows that the pressure p is proportional to the velocity v. Substituting numerical values, $p = \frac{1}{144}\sqrt{\frac{62.4 \times 43{,}200{,}000}{32.2}}\,v = 63.5\,v$.

The values of p for various values of v are shown in Fig. 14 which shows also the authors' values. The two curves agree very well to about 205 ft per sec, but for higher velocities there is a marked difference.

Although it is interesting to have the data of Table 3 for excessively high velocities, it should be recognized that the authors present no quantitative evidence to demonstrate that velocities of this order do occur, in connection with cavitation. The maximum pressure of Table 3 is about ten times the maximum internal pressure in a 12-in. gun. Under such extreme conditions, the usual theory of sound no longer applies. Indeed, tests have shown that the sound from such a gun starts with about twice its ordinary velocity, but drops to normal in the short space of 300 ft or 400 ft. Returning to Table 3, it is not surprizing to find that the pressures determined by the theory of sound are too low.

Following Table 3, the authors develop a numerical ratio between the pressure of impact on water, and that on a "rigid" surface, illustrating their remarks by Fig. 6. The writer feels certain that the analysis is unsound.

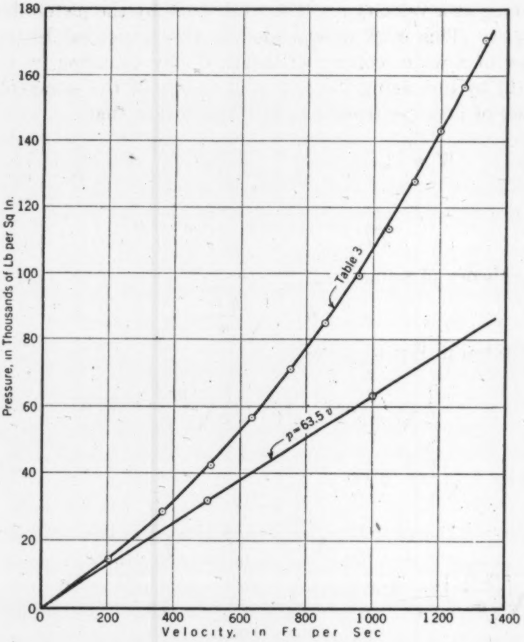

FIG. 14

The conclusion (see paragraph following Eq. 6) that "the velocity of particles at the contact surface is one half the initial velocity of the slug of water" is not merely incorrect, as to the magnitude of this velocity. It is based on an idea that is wholly unreal. There are no "particles at the contact surface" that can be distinguished in this manner from other particles, and whose velocity is susceptible of measurement or analysis.

Eq. 6, which the authors intend as a proof of their proposition, is nothing more than an arbitrary statement that assumes, to begin with, that the impinging particles, and those impinged upon, move during a finite interval of time with a common velocity v_c, which is constant. In other words, the impact between these particles is assumed to be totally inelastic. It might be well to mention that when a velocity is constant during a differential time interval it must necessarily be constant during a finite time.

In discussing these three topics, the writer is conscious that they are not indispensable to the main topic. In so far, however, as they may be subject to correction, it is important that they should be clarified.

V. E. **Leman**,[11] Esq. (by letter).—Efforts, made in recent years, to arrive at a clear conception of the processes relating to the behavior of water in the cavitation zone, have not met with much success. J. C. Hunsaker[5] has referred to this condition, as follows: "We cannot describe the exact mechanism by which wall damage results, but there must be some connection with the fluctuation of pressure resulting from the collapse of water vapor which periodically becomes unstable in such vapor phase."

In the light of such developments, Messrs. Thomas and Schuleen have rendered a most valuable service in giving an analytical demonstration of the hammering power of a slug of water traveling into a confined space.

The writer feels, however, that the full scope of the analysis has not been exploited by the authors, who limited themselves to a single aspect of the process—namely, to the action of a slug of water sandwiched in between two vapor cavities, without taking into consideration other factors instrumental in producing pitting in the cavitation zone.

Under the heading, "Behavior of Original Madden Dam Conduit Entrances in Models," the authors describe the character of flow at the collapse zone as one "where especially intense impacts are caused by collisions between the swiftly moving water of the streamline filaments and the broken masses of water and vapor hurled against these filaments from the interior of the pocket."

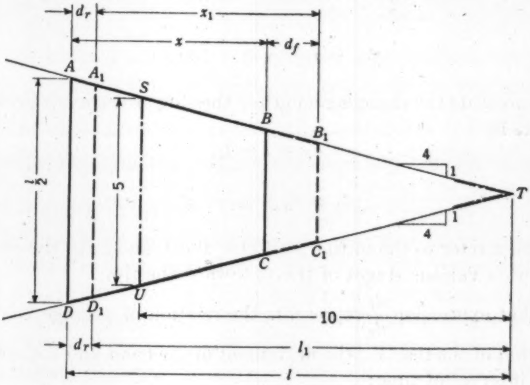

Fig. 15

It seems to be an established fact that, when a vapor cavity collapses, water rushes into it, eventually reaching the wall, not in the shape of broken masses but usually retaining, in substance, its pattern of continuity. It is the writer's contention that both the broken masses and the streamline filaments contribute to the destruction of the wall.

---

[11] Civ. Engr., New York, N. Y.

To substantiate his point of view, the writer presents a "physical picture" of what, he considers, happens when water enters a crevice, either in the form of an isolated slug or of a solid column. The picture may be helpful also in visualizing the processes inherent in the travel of water into converging spaces under ideal conditions (as assumed by the authors), these processes being, ordinarily, somewhat puzzling. The case of a slug, in accordance with the authors' analysis, will be first presented.

For the sake of simplicity the crevice is assumed to be not a pyramid, as used by the authors, but wedge shaped, as shown in Fig. 15. To facilitate the calculations the sides of the wedge are assumed to slope at a rate of 1 on 4, which makes the spread of the wedge equal to one half the distance to the tip T.

A slug of water (of a width 1 normal to the plane of the drawing) moves from its position $A\ B\ C\ D$ to a new position $A_1\ B_1\ C_1\ D_1$, with its rear traveling a distance d_r, and its front a distance d_f. Due to convergence of space, d_f is larger than d_r, as volume $A\ A_1\ D_1\ D$ must be equal to volume $B\ B_1\ C_1\ C$. This faster movement of the front in relation to that of the rear becomes more and more pronounced as the slug travels toward the tip of the wedge. The following analysis will express this algebraically:

Suppose the slug $A\ B\ C\ D$ moves from a position, where its rear is l units away from the tip T, to its final position when its front hits the tip—this final position being represented by a triangle $S\ T\ U$, with a base 5 and a height 10. As the volume $A\ B\ C\ D$ is equal to the volume of the triangular prism $S\ T\ U$:

$$\tfrac{1}{2}\left(\frac{l}{2} + \frac{l - x}{2}\right) x = \frac{5 \times 10}{2} = 25;$$

or

$$x = l - \sqrt{l^2 - 100} \quad \text{.....................} \quad (24)$$

in which x represents the changing length of the slug as it travels toward the tip.

From Fig. 15:

$$d_r = l - l_1 \quad \text{.........................} \quad (25a)$$

and

$$d_f = d_r + x_1 - x \quad \text{....................} \quad (25b)$$

in which l and x refer to the initial positions, and l_1 and x_1 to the new positions of the slug in its various stages of travel toward the tip.

Noting that expression $\frac{d_f}{d_r}$ represents the relation of average velocity of the front V_f to that of the rear V_r, the movement of the front and the rear occurring in the same interval of time:

$$\frac{V_f}{V_r} = \frac{d_f}{d_r} = \frac{l - l_1 + x_1 - x}{l - l_1} \quad \text{...................} \quad (26)$$

and, as the energy changes with the square of velocity:

$$\frac{E_f}{E_r} = \left(\frac{V_f}{V_r}\right)^2 \quad \text{.......................} \quad (27)$$

in which E_f and E_r represent the energies of particles at the front and the rear of the slug, respectively.

Eqs. 24, 26, and 27 have been used to plot the curves in Fig. 16, the values of l being selected in such a way as to give the more characteristic points shown. One can readily see that, for an ideal case of motion (no viscosity, no elastic deformations and absolute vacuum), the relations of velocities and energies of front and rear may become infinite, with practically all energy concentrated at the tip of the crevice. This is in complete agreement with the authors' statement to that effect in presenting Eqs. 3 and 4.

The case of streamline flow involves conditions differing in many ways from those of a slug; whereas the latter is comparable to a flying projectile, the former is characterized by a water column reaching back to the free water surface of the reservoir.

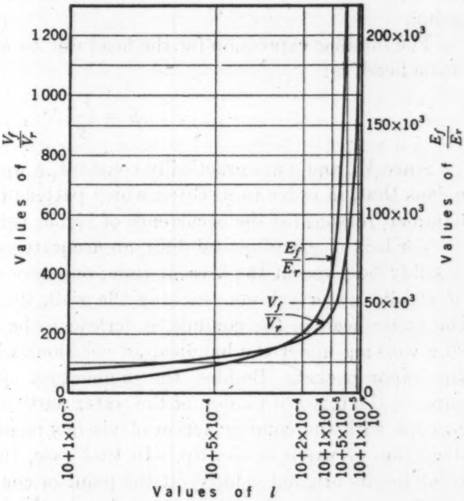

FIG. 16

The purely kinetic energy formulas (Eqs. 1 and 2) must now yield to the total energy equations that would include the pressure energy as well, no matter how small this factor appears to be in the low-pressure zone.

Fortunately, however, these considerations need not be taken in account as far as the "physical picture" of the process within the crevice is concerned. Referring again to Fig. 15, imagine that the space to the left of line $A\,D$ is not a vacuum but is filled with water extending to the free surface of the reservoir, the line $A\,D$ being merely a dividing line, separating a volume $A\,B\,C\,D$ from the column of water to the left. The reasoning used in establishing the curves in Fig. 16 can now be applied, without reservations, to the case of a solid water column entering a crevice; in spite of a difference in absolute values of velocities and energies in the two cases, the process of their respective increase remains identical. The final result (accumulation of energy at the tip) is also identical.

A comparison of the actions of the two flow patterns from the point of view of destruction may be proper.

The writer is unable either to agree with the authors' theory of water-hammer action in respect to the slug, or to deny it. He would not be willing to go far beyond the assumption that, a pressure wave within the slug itself being a certainty, its propagation farther out, over the vapor cavities, remains an open question.

This uncertainty, coupled with insufficient information as to the actual velocity of the slug, precludes any accurate estimation of the relative destruction capacities of the two flow patterns. The following, therefore, is merely an attempt to evaluate such capacities in a rather general manner, under the assumption that some kind of water-hammer action does exist in the case of a slug.

The familiar expression for the head due to water hammer (in excess of the static head) is:

$$h = \frac{V_w}{g} V \qquad (28)$$

Since V_w and g are practically constant, h would depend on V alone. This means that, in order to discover which pattern of flow creates a greater water hammer, reasons for the occurrence of higher velocities should be investigated.

For lack of experimental data, an accurate solution of this problem cannot possibly be given at the present time; one may feel, however, that, in the case of a solid water column reaching the wall, its velocity, being dependent on the static head in the conduit, is certain to be higher than that of a minute slug working under the handicap of collisions with broken masses of water in the vapor pocket. Besides, the momentum of such a column is certain to support the forward motion of the water particles in the crevice, helping them to cope with the counter action of viscous resistance, elastic stresses, or condensation of vapor in the tip. In that case, the flow has a better chance of retaining its original velocity at the point of contact with the wall.

These considerations lead the writer to the belief that, provided the water column has a chance to reach the wall as a solid mass, its eventual effect is certain to be more violent than that of a slug. This does not necessarily mean that all destruction is the result of such action. The fact that the collapse of cavities occurs periodically, whereas the slugs are continuously at work, makes the problem rather indeterminate. Experiments by P. De Haller,[12] in Switzerland, are worth being mentioned in this connection: Metal specimens have been subjected to heavy hammering by water slugs. The results are indicative of the fact that, to a high degree, such slugs are instrumental in producing erosion which, in its sponge-like appearance, is strikingly similar to the pitted surfaces resulting from collapse of cavities.

The writer has one more remark to make: The authors state (under the heading "Model Studies of Various Methods Proposed to * * *: Group 2") that the reason for not using vent pipes in their final design was their unwillingness to reduce the discharge capacity of the conduits. No matter how important this consideration, the writer is under the impression that vent pipes have not been given a chance to prove their worth. The three 3-in. pipes, installed in connection with the modified design of 1935, could not help being more of a nuisance than a remedy, owing to their quite insufficient size. Judging by the standards of the U. S. Bureau of Reclamation,[13] the cross-sectional area of the pipes should have been about 8 times larger than the one used.

---

[12] *Schweizerische Bauzeitung*, May, 1933, p. 243.

[13] "Dams and Control Works," U. S. Dept. of the Interior, 1938, p. 180.

P. S. O'Shaughnessy,[14] Esq., and E. S. Randolph,[15] M. Am. Soc. C. E. (by letter).—In 1928, when plans were first made for the Madden Dam, sluiceways near the level of the Chagrés River bed were specified. These outlets were to permit lowering of the reservoir for purposes of inspection, cleaning out debris, and routine maintenance and repairs. The sluiceways became a part of the flood-control plan, to be used when and if floods occurred in excess of the spillway capacity. During construction of the dam, the six 5-ft 8-in. by 10-ft sluiceways proved to be a valuable aid in diverting the flow of the river.

The flare provided at the sluiceway entrances in the original design was limited to permit the construction of slots to accommodate stop logs of reasonable size. When the laboratory tests were made, one of the objects was to preserve the stop-log slots and thereby confine any required modifications to the part of the conduit downstream from the slots. This was accomplished in the case of sluiceways 1 to 4, where the model studies showed that the entrance could be reconstructed in such a manner that cavitation was eliminated with very slight changes in the stop-log slots. However, for sluiceways 5 and 6, the most satisfactory means developed to reduce cavitation consisted of providing covers at the stop-log slots.

Between September and December, 1934, as part of a comprehensive program of hydraulic tests on the Madden Dam, the sluiceways were operated at various heads from 71.5 to 138.5 ft during the rise of the reservoir. After December, 1934, the sluiceways (except sluiceway 3 in which the testing equipment had been installed) were used at times to control the reservoir level.

From the beginning of the sluiceway operation, it was noticed that the flow was accompanied by popping and crackling noises that were very loud within the sluice-gate galleries and were audible even on the parapet of the dam. Apprehension was felt at the time that damage was occurring, but definite evidence was lacking until the cavitation had progressed to such a depth that a porous tile drain began to discharge into the dam on March 15, 1935 (see heading "Introduction," in the paper). The knowledge that cavitation had occurred coincided closely with the appearance of the paper by Mr. Hunsaker,[5] which was of assistance in understanding the matter. Remedial measures were undertaken immediately. It was hoped that small air vents would prevent or diminish the cavitation by serving as a cushion, but they did not produce the desired result of eliminating cavitation completely.

After the collapse of the air-vented filler in sluiceway 6, which had been fitted with a bellmouth inlet, attention was directed to the great intensity of the force acting downward through the slot. Consideration was given to a stronger filler for closing the four sides of the slot, but sufficient confidence existed in the efficacy of a tight-fitting cover, alone, to result in its selection as a means of closure. This was done prior to making the model tests, which eventually justified the selection of this method. The covers were placed on the two sluiceways provided with bellmouths—5 and 6. These covers were designed to withstand full hydrostatic head in addition to atmospheric pressure.

---

[14] Asst. Engr., Special Eng. Div., The Panama Canal, Balboa Heights, Canal Zone.

[15] Cons. Engr., The Panama Canal, Balboa Heights, Canal Zone.

Steel cables were attached to the covers to permit their removal without the services of a diver.

During the second season of operation of sluiceways 5 and 6, after installation of the bellmouths, there was a noticeable difference in the volume of concrete removed. As shown in Table 2, the operating periods at high heads were, respectively, 1,248 and 1,421 hours. The volumes of concrete removed were, respectively, 30.5 and 16.4 cu ft. It appears that the vented stop-log slot filler in sluiceway 6 remained in place for some time after its installation but collapsed at some unknown date. Vacuum measurements were made at the entrance to sluiceway 6 on December 11 and 16, 1935. On the former date, with the sluiceway operating under a head of 134.3 ft, a vacuum of 24 in. of mercury was recorded. On December 16, under a head of 124.3 ft, no vacuum was developed.

It seems reasonable to assume that the collapse of the frame occurred between these two dates. Since most of the sluiceway operations, both in point of time and of high heads, had occurred by December 16, it would appear that the lesser damage to sluiceway 6 may have been due to the beneficial action of the vented filler frame before its collapse. That the frame did not collapse under the higher heads prevailing at the beginning of operation can be explained by assuming that the force acting upon it was not constant but of a pulsating character. It was noticed throughout the sluiceway tests that the stream issuing from the conduits was of this type.

During the first season of operation, sluiceways 1 and 2 were badly damaged by 138 and 130 hours, respectively, of operation under high heads. After these sluiceways were repaired, they were operated 134 and 107 hours, respectively, at high heads without suffering damage. It is probable that the concrete used in the repairs was denser and, since it was mixed and placed in smaller batches, its placing was done more carefully than that of the original concrete. It is possible, also, that the air vents installed after repairs were made were of some use in decreasing the effect of cavitation collapse.

It is not made clear in the paper how the air measured in the model tests on the diverging tube apparatus can be related quantitatively to the air that would be required in venting the prototype. Even if the quantity of air can be expressed in terms of the prototype, it appears doubtful that venting is the best approach to most problems of eliminating cavitation in outlet conduits.

Mr. Hunsaker[6] showed that for a given hydraulic system the product of the frequency and the length of the cavitation pockets is equal to the product of the throat velocity and a substantially constant non-dimensional number. If the velocity remains constant, venting will lengthen the cavitation pocket and decrease the frequency in direct proportion. In this case, the pockets will form farther downstream and the immediate effect of cavitation will be decreased. However, this is not a satisfactory solution to the problem since cavitation is not eliminated unless a large volume of air is introduced; and, in this case (as stated by Messrs. Thomas and Schuleen), a reduction in discharge will result.

Difficulties similar to those at the Madden Dam may have been encountered in other structures. These, if reported and discussed, may serve to focus attention on the importance of considering cavitation in designing.

Since the completion of the model tests, it has been determined to limit sluice-gate openings on sluiceways 1 to 4 to 70% until they have been repaired. Sluiceways 5 and 6, provided with bellmouths and cover plates over the stop-log slots, may be operated at full capacity for the passage of extreme floods.

Acknowledgments.—The designs for the Madden Dam were prepared by the U. S. Bureau of Reclamation, in collaboration with engineers of the Panama Canal. The chief engineer and the chief designing engineer of the Bureau of Reclamation were engaged as consulting engineers by the Governor of the Panama Canal Zone. The bellmouth entrances that were attached later to sluiceways 5 and 6 were designed also by engineers of the Bureau of Reclamation.

CARROLL F. MERRIAM,[16] ESQ. (by letter).—There is much food for thought in the similarities and the differences to be noted in the work of experimenters in the field of cavitation. The striking point is that interest in cavitation is not confined to the builders and users of hydraulic machinery. It proves that the research conducted primarily through interest in the mechanical aspects finds application in a problem that is essentially structural. At the present stage of development at least, there is one outstanding difference in approach. In the case of discharge conduits, which may be operated at full capacity but a relatively short period of time, the idea of the designer is to avoid all danger of cavitation, whereas the builder of high-speed hydraulic machinery is seeking the economic balance between operating revenue and cost of repairs. Consequently, he must strive for quantitative measurement, always seeking to evaluate risk of damage and resistance of materials, together with the value of increased capacity. The former is more interested in qualitative tests which give reasonable assurance that the design proving best in the model is the most suitable for the prototype. Under these conditions it would appear that the authors' experimental results have greater immediate practical application than their mathematical analysis.

The mathematical analysis affords an interesting approach that is not to be discredited by any means, for, even though exact agreement with practice can never be expected, it is true that only through mathematics does the investigator gain insight into the complicated play of factors which influence the results.

Obviously, the action that takes place is far too involved to permit prediction of the exact pressure, at any given region, in model or prototype, under any given conditions. However, the authors' development of the conception of a slug of water striking a converging passage explains, excellently, why it is that, when pitting has once started and has gained a little foothold, further damage is likely to progress at an accelerated rate. The test pieces removed from the Holtwood stand[17] showed deep pitting along the edge where the sides of the flume make a right angle.

[17] "Pitting Resistance of Metals Under Cavitation Conditions," by J. M. Mousson, *Transactions*, A. S. M. E., July (1939), Vol. 59, No. 5, pp. 399–408.

It should be emphasized in addition that this multiplication of impact leads to tremendously high concentration of stress over an exceedingly limited area. This is well illustrated by the experiments cited in the paper,[5] in which ordinary methods of measuring high pressures such as are used in internal combustion engines, gun barrels, etc., failed completely as criteria of cavitation severity. Finally, the use of thin diaphragms, backed up by perforated plates, proved in vain because they were punctured merely by accidental hits like bullets rather than by a widespread blow.

The principal point of disagreement with the authors lies in their not entertaining the theory advanced by W. Watters Pagon,[18] M. Am. Soc. C. E., in 1935, at least as an alternative explanation. His conception of eddies as the fundamental form of the cavities demonstrates not only the possibility of extremely high local pressure concentrations, resulting from bombardment of the walls by particles propelled at terrific velocity generated by progressive but sudden collapse, but also explains the location of the more seriously pitted areas with relation to the form of the cavitation pocket.

The authors recognize that any mathematical treatment is beset with factors that are extremely difficult to evaluate since they enumerate the many things that must be neglected in order to justify equating kinetic energies. To this number should be added the rotational energy in the eddies.

Although the action within the cavitation pocket, particularly at the downstream fringe, is extremely complicated, as shown by the high-speed moving pictures to which the authors refer,[5] the reader should not gain the impression of a confusion of slugs of water being hurled about promiscuously, these slugs striking with destructive violence upon the walls of the conduit. Careful study of these moving pictures, together with stop-motion stills and examination of the models in operation illuminated by ordinary light as well as by electric spark, reveals that at the upstream edge there seems to be an orderly leaping of the water away from the walls. Behind this region, when cavitation is well developed, there is undoubtedly a part of the channel boundary that is never wetted. The most important part of the pocket, from the point of view of damage, is where the stream apparently returns to the walls. If the phenomenon were perfectly continuous and could take place smoothly and uniformly, the stream would merely deliver a glancing blow with little probability of doing any harm.

Instead, the action is far from stable and is characterized by an alternate lengthening and shortening of the pocket so that the downstream boundary is a fringe of extreme turbulence. In this region slugs of water can be imagined as being hurled through an environment of water vapor; or the opposite, which would mean bubble-like cavities filled only with condensable water vapor tossed about in a seething mass of turbulent currents of water. The chances are that neither of these conceptions is entirely correct.

The point is that eddies are set up by viscous sheer and are shed by passing around the lip at the entrance where the water finally leaves the surface of the conduit. It has been shown mathematically, by Mr. Pagon and others, that at the heart of such eddies the pressure is much lower than in the surrounding environment. Consequently, when the absolute pressure drops, these eddies are open and can remain as open cavities even after the pressure is partly restored; but they are extremely unstable. It seems more likely that the final collapse of these cores is the direct cause of the destruction rather than any pelting by slugs of water as assumed by the authors. In support of this idea there is the observation that in two-dimensional, venturi-shaped passages the damage comes where the axes of the eddies would terminate against the side walls rather than on the profiles, which would be more likely to receive the onslaught of slugs of water.

---

[18] "Cavitation and Erosion Investigated as a Problem in Fluid Mechanics," by W. Watters Pagon (unpublished papers, A. S. M. E., 1935). On file for reference in Engineering Societies Library.

Regardless of the theory of the collapse, there is an excellent field for further research. In the first place the authors' pressure gradient curve in Fig. 8 is well confirmed by other experiments and shows a rising pressure in a channel of uniform cross section. This cannot be explained by the principle of Bernoulli. What is the origin of this pressure increase?

Furthermore, a strong similarity has been noted between this pressure rise and the surface of the hydraulic jump. The action appears to be similar, at least from visual observation. In addition, it should be noted that in expanding passages both phenomena are stable. In passages having parallel sides both are particularly unstable. In one model which consisted of a venturi-shaped passage, terminating in a parallel section, there was a sharp increase in noise as well as damage just as soon as the cavitation pocket was made to extend into the parallel section. This phenomenon was reported by W. Spannhake.[19] The disruptive effort seems to be definitely associated with the instability of flow.

A most important precaution taken by the authors was to free the water from dissolved air as much as possible. It is doubtful whether they were completely successful although the small volume of air remaining probably had no appreciable effect upon their results. It should be emphasized, however, that even a small amount of dissolved air is sufficient when very low pressures are encountered to upset the laws of hydraulic similitude. Under these conditions the water expands as an emulsion with the air coming out of solution. The result is that Q is no longer equal to $A \times V$. In hydraulic model testing, in which at any point there are pressures less than a half an atmosphere, there is danger of trouble from this source.

With further reference to the aforementioned hydraulic grade line, detailed exploration will show that the valley has a flat bottom rather than rounded as reported.

Although the authors are correct in stating that in practice it usually requires months to develop deep pitting in metal surfaces, it should not be overlooked that in certain laboratory tests it is possible to see the first signs of pitting after several seconds and to produce satisfactory results in the course of an hour.[20] Nevertheless, attempts to force metal to pit in models as it would be expected to do in service have not been particularly successful. Perhaps one of the most fruitful fields for further investigation is to establish relations between actual service and the results of various accelerated tests.

---

[19] "Cavitation Research," Progress Report, by Carroll F. Merriam based on work of Wilhelm Spannhake, New England Hydraulic Power Committee of the New England Electrical Utilities Engrs., 1933. Filed for reference in Engineering Societies Library.

Many investigators have been forced to rely upon indications of surface damage, such as the removal of paint, and consequently the authors are to be congratulated for attaining any success at all in finding a material to simulate pitting. The principal difficulty would seem to lie in there being a threshold value of severity below which no damage is done but above which failure takes place with surprising rapidity. Quantitative measures of the extent of pitting either by loss of weight or volume are also very difficult.

In indicating an interest in cavitation outside of the field of hydraulic machinery, this paper suggests the possibility of even more extended application. So far, cavitation has always been regarded as the "villain in the plot"—the bane of the designer. The word cavitation itself carries a bad connotation. It would be interesting if some day a useful purpose could be found for it. Experimenters have noticed a similarity between cavitation and the hydraulic jump; furthermore, the hydraulic jump has been used to produce an intimate mixture of liquids.[21] Do not these two statements suggest that cavitation might be used to secure an intimate mixture of two chemicals when, for some reason or other, it was desired to have the time of mixing reduced to an extremely small fraction of a second? Another possible application may be found in the fact that cavitation is capable of extracting dissolved gases from liquids. Air content in water is reduced in the cavitation zone faster than it can be dissolved in the following turbulent zone. When such gases have harmful effects, such as the oxidation of fats in milk, there is at least a possibility of the content being quickly and materially reduced by cavitation.

HUNTER ROUSE,[22] ASSOC. M. AM. SOC. C. E. (by letter).—Cavitation research has progressed to a comparatively refined stage in several of the engineering professions, but Messrs. Thomas and Schuleen appear to be the first to have investigated, by laboratory experiments, the occurrence of cavitation in masonry structures. Although it might be argued that the phenomenon is the same regardless of the surroundings in which it occurs, the writer feels that much credit is due the authors, both for the development of the experimental technique which they describe and for calling the attention of the civil engineer so forcibly to the dangers of poor hydraulic design.

While the writer therefore voices only commendation for the major part of the paper under discussion, he believes that the authors' comments on the "Nature and Causes of Cavitation" leave much to be desired. The attempted proof of the existence of enormous local intensities of pressure seems particularly subject to criticism, owing to the artificial (if not physically impossible) nature of the assumption of constant kinetic energy in the specimen slug of water. Perhaps quite as artificial, although considerably more elegant, would have been the assumption of a momentary spherical bubble of water vapor within an initially stagnant, incompressible liquid of arbitrary volume; the work done by external pressure in accelerating the liquid toward this center would then yield the ultimate kinetic energy as the bubble collapsed, leading in a more reasonable manner to the same conclusion of an infinite local velocity and an infinite local pressure intensity at the point of collapse. Indeed, one need only hear the violent shocks which are produced by discharging steam under water to concede the issue that the collapse of such vapor pockets might well lead to exceedingly high local stresses. Of particular interest, in the adaptation of this approach to the case of a compressible liquid, is the fact that a two-dimensional or three-dimensional positive pressure wave must invariably be followed by a negative wave of similar order of magnitude.[23] Such conditions would seem to point even more strongly to the stress-reversal theory of boundary failure.

On the other hand, high-speed motion pictures by H. Mueller[24] of the collapse of vapor bubbles produced in cavitation would indicate that the bubbles tend to flatten on the downstream side rather than to dwindle concentrically. In other words, the impact area is then of finite magnitude rather than infinitesimal, and the computed terminal velocities are therefore finite even if the fluid is assumed incompressible. Conclusions of this nature would tend to invalidate much of the authors' basic hypothesis, as do piezoelectric measurements by J. Ackeret[25] of only moderately high instantaneous stresses in zones of cavitation. Moreover, the effect of pitting has been noted in Pelton-wheel buckets, where there is no reason to expect the formation of vapor pockets, and the method of passing test specimens repeatedly through free jets of water has been used by Professor Ackeret in comparing the resistance to pitting of various materials.

Although the authors' assumption of unbelievably high intensities of pressure has long been a favorite explanation of the pitting effect, it is possible that the theory of fatigue through repeated impact of not-too-great magnitude will eventually be more generally accepted. In other words, whereas vaporization of the liquid is the essential feature of cavitation itself, the existence of the vapor state apparently is not essential, but merely contributory, to the phenomenon of pitting through liquid impact. The term "impact," however, is so often used erroneously in connection with liquid motion that its true import has become obscured. For instance, a continuous jet of liquid deflected by a vane is frequently cited in hydraulics to illustrate the "impact" of a liquid upon a solid boundary, and the stagnation pressure at the point of zero velocity is even more frequently called the "impact pressure." This is in no way related to the case of impact dealt with in theoretical or applied mechanics, for no discontinuity or unsteadiness of the liquid is involved. It is not surprising, therefore, that such a fictitious case of impact—the steady deflection of a continuous liquid jet—produces no sign of pitting in the solid boundary. On the other hand, if the free jet is not continuous, but composed of drops or even slugs of liquid, pitting of the solid by true liquid impact is readily obtained.[26]

[25] *Loc. cit.*, p. 239.

Nevertheless, it is difficult for the hydraulic engineer to conceive of liquid impact as having essentially the same capacity for destruction as the impact of one solid upon another. Yet this was simply demonstrated by H. Föttinger[27] through the use of a glass tube partly filled with liquid, evacuated, and sealed at both ends. By inverting the tube, the slug of liquid within was made to drop to the bottom, producing a shock akin to that of a metal rod falling the same distance; indeed, the shock was once so great as to break the lower end of the tube, atmospheric pressure then driving the liquid upward with such force as to break the upper end as well. Needless to say, air left within such a tube would tend to cushion the blow, just as the presence of air in any zone of liquid or solid impact tends to reduce the destructive effect of repeated momentary stresses.

G. H. Hickox,[28] M. Am. Soc. C. E. (by letter).—The authors of this paper have done the engineering profession a service in setting before it an analysis of some of the problems connected with cavitation in sluices of high dams. The writer wishes to add a few comments relative to the cause of cavitation in such sluices and some criticism and questions regarding the authors' methods of testing and calculation.

Cavitation will occur whenever and wherever the pressure at a point in a liquid is reduced to the vapor pressure of the liquid. At the vapor pressure of the liquid, evaporation occurs and cavities form which are filled with vapor and dissolved gases. These cavities pass downstream with the liquid, eventually entering a region of higher pressure where they collapse, generating extremely high pressures. If the cavities collapse in the vicinity of a solid wall, there is a considerable destructive effect known as pitting. It should be noted that cavitation and pitting are not synonymous terms. It should also be noted that, whereas the phenomenon of cavitation is always due to a lowering of liquid pressure to the vapor pressure, the corresponding pitting always occurs somewhere downstream in a region of considerably higher pressure.

The reduction of pressure may be due to two causes: (1) A general lowering of the pressure caused by an increase in the average velocity of flow or a rise in the conduit; or (2) a "local" pressure reduction caused by curvature of flow. A siphon spillway offers examples of all of these phenomena. The pressure at the throat is low because the throat is the highest part of the siphon. Frequently its area is less than that of either the intake or discharge legs, which causes an increase in velocity and a corresponding reduction in pressure. There is also curvature of flow that results in a further reduction of pressure on the inside of the curve. The cumulative result of these effects may be to lower the pressure to such a point that cavitation may exist.

[27] *Loc. cit.*, pp. 251–254.

[28] Senior Hydr. Engr., TVA, Hydraulic Laboratory, Norris, Tenn.

A number of sluice conduits through high dams have been built in such a manner that cavitation occurred at their inlets. In a large conduit, the friction loss is not excessive and the hydraulic grade line may not be far above the roof, particularly if the conduit is inclined downward. The shape of the entrance is very important. If the entrance is gradually curved, or bell-mouthed, the local pressure reductions are low, and there may be no cavitation. If the curvature of the entrance is sharp, however, the local pressure reduction is much greater and cavitation may be suspected. In the case of the original Madden entrance shown in Fig. 1, there was an angle at the intersection of the conduit with the upstream face of the dam. Water flowing along the surface was required to make a sudden change of direction, necessitating an infinite acceleration at that point. The probable actual occurrence was that water flowing around the corner described as sharp a curve as could be effected by the maximum force available—that is, the difference between the pressure in the sluice and the vapor pressure of the water on the inside of the curve. In other words, the angular corner caused a region of extremely low pressure immediately below the entrance. Vapor cavities formed in this region and traveled downstream to a region of higher pressure where they collapsed, causing the pitting shown in Fig. 2.

A sharp-cornered entrance is not the only cause of local pressure reduction that may cause cavitation. Fig. 17 shows pitting that occurred below weep holes in the liner of the Norris sluice conduit during the first year of operation. The probable flow condition existing at these holes during operation is shown diagrammatically in Fig. 18. The downstream edge of the hole deflected the high velocity current away from the wall toward the center of the conduit. The flow returned to the wall almost immediately but the velocity and radius of curvature of flow were such that the pressure next to the wall was reduced to the cavitation point. Cavities forming in this region collapsed in the higher pressure area immediately downstream and attacked the liner with the result shown. Repairs were made by welding up the pitted areas, filling the holes with steel rods, welding them in place, and grinding the joints smooth. No further trouble is anticipated.

The writer is not quite in agreement with the authors' definition of a "cavitation pocket" as a void space filled with flying slugs of water. The photographs referred to[6] show clearly that there is not a cavity traversed by random slugs of water but rather a region in which cavities form, travel with the stream, and finally collapse. The rapid succession of these cavities has the appearance shown by the light areas in Fig. 10; but it is erroneous to refer to these regions as "pockets." More correctly, they should be called "cavitation regions" or "cavitation areas." The term "pocket" should be reserved for the individual cavities that traverse this region.

The writer is not convinced that it is necessary to produce cavitation in models in order to design structures that will be free from cavitation. If the method proposed by the authors is to be followed, however, its limitations should be clearly stated. In general, the treatment is fairly clear, but there are a few places where the meaning is ambiguous and seems to require further explanation. At the end of the first paragraph in the section "Description of Apparatus for Cavitation Tests" it is stated:

FIG. 17.—CAVITATION PITTING BELOW WEEP HOLES IN NORRIS SLUICE CONDUIT LINER

FIG. 18.—REGIONS OF LOW PRESSURE AND PITTING IN NORRIS SLUICE CONDUIT

> "In order that the basic conditions which produce cavitation in certain regions of the prototype may be correctly represented in the model, it is necessary that the pressures in these regions of the model be reduced to the vapor pressure of the liquid used in the model."

This statement is correct but the reader who attempts to follow the authors' methods of representing prototype cavitation conditions in the model is likely to become confused. The cases in which such a model may be operated in accordance with Froude's law while at the same time reducing the absolute pressures to the linear scale as indicated by Eq. 8*c* are the rare exceptions rather than the rule. Such operation can be accomplished only if the ratio of the vapor pressure of the model liquid to the vapor pressure of the prototype liquid is equal to the model scale. The authors have pointed this out in a discussion of "operational distortion of scale." It is also included in the assumptions immediately preceding Eq. 8*c*.

It is very seldom possible to adjust the model vapor pressure to a value that will be in the correct ratio to the prototype vapor pressure. The limitations of model testing make the largest practical model scale about 1 : 15. The water temperatures in the lower parts of deep reservoirs are relatively low. At Norris Dam, the average temperature of the water discharged through the sluices is approximately 50° F. The vapor pressure of water at this temperature is 0.36 in. of mercury. The vapor pressure at 32° F is 0.18 in. of mercury. It is evidently impossible to reproduce the vapor pressure to scale in a model of a Norris sluice using water as the model liquid. With water at 32° F for the model liquid at a scale of 1 : 15, the corresponding prototype vapor pressure is 2.70 in. of mercury, which occurs at 112° F. This temperature seldom occurs in prototype structures. The difficulty is further aggravated by the enclosed-tank apparatus. It is extremely difficult to work with low temperatures using this apparatus, as energy at the rate of several kilowatts is constantly being added to the system by the pump.

It might be assumed from the authors' remarks following Eq. 8*c* that operation of a model in accordance with Froude's law requires that the ratio of absolute pressures in model and prototype be equal to the model scale. This is not correct. It is sufficient that the ratio of pressure differences between corresponding points be equal to the model scale. This can be illustrated by writing Eq. 8*c* in the form

$$V\,v_T = c_T'\sqrt{2\,g\left[L\left(\frac{p_H - p_T}{w}\right) - L\,z_T\right]} \ldots\ldots\ldots\ldots (29)$$

In Eq. 29 p_H and p_T are not necessarily equal to p_H'/L and p_T'/L but may have any convenient values as long as $\frac{p_H - p_T}{w} = \frac{p_H' - p_T'}{w\,L}$. In fact this is the manner in which hydraulic models are usually operated. The results are completely satisfactory except in those cases where the model indicates pressures which would be below the vapor pressure in the prototype. Even in these cases, similarity can be obtained if the model pressure is adjusted so that the boundary of the vapor pressure region in the prototype corresponds with the boundary of the vapor pressure region in the model. It should be noted that point *T* is on the boundary dividing the vapor pressure region from the region of normal flow. This is necessary since the pressure gradient is discontinuous at this boundary and Eqs. 8 are not applicable across it. Hence, in order to produce similar performance in model and prototype, it is necessary to know the boundary of the vapor pressure region. Unfortunately the need for model tests of any particular structure means that the vapor pressure region in the prototype is not known. Therefore, such adjustment, while theoretically possible, cannot be made by the experimenter.

The foregoing discussion has been confined to models geometrically similar to their prototypes and properly oriented. Rotating a vertical section into a horizontal plane would seem to introduce still further difficulty. The exact location of the cavitation region under the roof of a conduit must be influenced by the increasing pressures at greater depths. In a section rotated to a horizontal position, the pressures in the section cannot increase with depth, and consequently correct reproduction of the cavitation region cannot be expected. The relationships expressed in Eqs. 9 to 12 represent an attempt to overcome this difficulty. As pointed out by the authors, however, the best result that can be obtained is correspondence at only one point. For this reason, tests made with a rotated section of model are open to question, particularly with respect to the location of the pitted area.

It is noted that the use of Eq. 13 usually fails to result in model operation similar to that obtained by the use of Eqs. 9 to 12. This may be explained by the fact that in Eqs. 9 to 12 the velocity ratio is fixed in accordance with Froude's law, as may be seen by inspection of Eqs. 9. Eq. 12 expresses the adjustment of p_H' necessary to maintain this velocity ratio. Eq. 13, on the other hand, expresses the ratio of velocities that will exist for a given set of pressures and elevations in model and prototype. It would be a remarkable coincidence if this ratio did satisfy Froude's law.

The application of the equations to an actual model test raises further questions. In the example given, it is stated that a discharge of 2.343 cu ft per sec was assumed. It is doubtful if the discharge can be assumed arbitrarily. In order that the model flow pattern shall approximate that of the prototype, there should be at least a semblance of agreement with Froude's law. The discharge used gives a model velocity of 16.53 ft per sec which, compared with the prototype velocity of 74.0 ft per sec, gives a velocity scale of 1 : 4.47. This is exactly the square root of the length scale, 1 : 20, and indicates perfect agreement with Froude's law. One is led to believe that the authors meant to include this explanation since such good agreement could hardly be fortuitous.

The analysis following Eq. 14 is based on the assumption that the pressure at point T in the prototype for the reservoir elevation shown is the vapor pressure of the water. This was probably true in the case of the original Madden Dam sluices where there was an angle at the entrance. The application cannot be general, however, for the object of successful design is to build a conduit in which cavitation will not occur. The entire discussion is based on the assumption that the pressure at T is known, either in model or prototype, or both. When cavitation occurs, the pressure at this point is obviously the vapor pressure of the liquid and is thus fixed. When cavitation does not occur, as in a properly designed entrance, the pressure is much higher, and is not determinable by any of the equations of this paper. If the model is adjusted to operate in conformity with Froude's law, and the absolute pressures in reservoir and conduit barrel are adjusted to conform to the linear scale ratio, the model may indicate cavitation that would not occur in the prototype because of the lack of conformity of the vapor pressure ratio. Assuming a vapor pressure of 1 ft of water in both model and prototype, cavitation would occur in the model at an absolute pressure corresponding to 15 ft of water in the prototype, a condition that would be quite safe. It is needless to state that the cavitation region would not be correctly reproduced. The authors seem to present no method of adjusting the model to insure correspondence if the pressures in the region where cavitation is suspected are not known in advance. Of course, if the pressures are known beforehand, the reason for experimental determination becomes rather obscure. The writer would like to know how the methods of the paper were applied to a rotated vertical diametrical section of the entrance of the Hiwassee sluice, for example, which was found to be entirely free from cavitation.

It is believed that Eqs. 8*a* and 8*b* are not in strict accordance with Torricelli's theorem. This theorem merely states that the velocity of efflux from an orifice under a given head is equal to the velocity that would be attained by a body falling freely through a distance equal to the head, and may be written as $V = \sqrt{2\,g\,h}$. Eqs. 8*a* and 8*b* are derived from Bernoulli's equation, of which Torricelli's theorem is a special case. The additional terms representing pressure were introduced by Bernoulli much later.

It is not intended that these criticisms should detract from the value of the paper as a whole. The authors have done the profession an invaluable service by pointing the way toward a solution of a very troublesome problem in the design of high dams. It is probable, however, that the experience of other designers and other hydraulic laboratories with similar problems may eventually lead to simpler techniques that will accomplish the same purpose.

J. M. MOUSSON,[29] M. AM. SOC. C. E. (by letter).—This paper is very timely in many respects. It is of particular interest to hydraulic engineers because the form-giving criteria for water passages are often overlooked and, as in other fields of endeavor, it needs an extreme case of unfavorable conditions entailing expensive repairs to bring the matter to the renewed attention of the profession as a whole. With no physical damage to structures, and with inadequacies limited to disappointing coefficients (that is, low efficiency), usually no one ever hears anything of it.

It is surprising how little thought is often given to entrance conditions on conduits or intakes for turbine installations. Although a negligible sum would provide ideal conditions free from vortices, the crudest forms of transitions persist at many new power plants; and they affect the efficiencies of the wheels adversely, due to trains of vortices or uneven flow distribution. The accrued deficiencies in power output, even if only 1% or 2% are involved, entail large monetary losses unnecessarily wasted to the detriment of the national economy.

---

[29] Project Engr., Rustless Iron & Steel Corp., Baltimore, Md.

As to the specific theories on cavitation proposed by the authors, some caution would seem advisable, particularly in the light of other researches. For instance, it is stated that (see heading, "Nature and Causes of Cavitation"):

> "The familiar effects of water hammering sufficiently intense to indent and disintegrate the surfaces of hard metals furnish abundant proof that pressures approaching or exceeding the higher values of Table 3 actually occur in engineering machines and structures."

(Table 3 gives values to 170,676 lb per sq in.)

It is well to remember that cavitation is a high-frequency phenomenon to the effect that any breakdown of material exposed to this punishment is primarily due to fatigue. The numbers of stress applications even in most severe cases may run into the tens of thousands,[30] and under these conditions it is reasonable to assume that the lower values in Table 3 (say 14, 223 ± lb per sq in.) may be entirely sufficient to cause severe damage rather than those near the upper limit. Furthermore, values in the upper part of the range are not likely to occur since damage would be so severe in a matter of minutes as to endanger any structure within the same time interval.

Additional items of evidence against the high pressures thought likely by the authors are the results obtained by means of a cavitation test stand at Holtwood, Pa., where steels and alloys of a large variety and in various conditions were exposed to cavitation.[31] The most resistant materials could be attacked within 16 hr with the adopted standard throat velocity of 265 ft per sec corresponding to the lower limit of the range in Table 3.

It could be argued, of course, that the throat velocity is not the primary criterion but that the velocity of cavity collapse and subsequent impact of water on water, or water on solid matter, is only to be considered. If this were true, then the degree of pitting found in any test stand would be little influenced by the throat velocity so long as cavitation exists. This, however, has not been indicated by any of the researches in the United States and abroad. The throat velocity was found to be one of the most important variables with respect to the severity of pitting.

Regarding the process of destruction by cavitation, it may be stated that the detailed microphotographic analyses of a large number of metallurgical specimens revealed that surface deformation with subsequent fatigue failures is but one form of disintegration. In many cases the breaking up or disintegration starts from within rather than from without, which again suggests caution with respect to the theory proposed by the authors as to the importance of cracks. Some of the reasons conducive to breakdown from within are the following: Uneven shape of crystals or grains, flake formations of metallic or nonmetallic substances in base matrix, metallic or nonmetallic inclusions, impurities, unfavorable stratifications, etc. All of these factors lead to possible failure due either to stress concentrations, or to surfaces providing little bond or poor interlocking. These same factors are certainly coming into play with concrete where fatigue cracks may develop due to unfavorable stress concentrations at sharp and pointed surfaces of the coarse or fine aggregate, or where failure may occur along the flat surfaces of sand particles or stones, providing little bond, or "break-throughs" of cracks may develop between inclusions. Although possible surface deformations on concrete should not be ignored, nevertheless a microphotographic analysis would seem advisable to prove this point, particularly because the plasticity of concrete is low when compared with certain alloys.

---

[30] "Ueber die Zerstoerung von Werkstoffen durch Tropfenschlag und Kavitation," by J. Ackeret and P. De Haller, *Schweizerische Bauzeitung*, September 5, 1936.

[31] "Practical Aspects of Cavitation and Pitting," by J. M. Mousson, Edison Electric Inst. *Bulletin*, September and October, 1937.

Another factor that would appear to discredit the importance of surface cracks is the experience gained on turbine installations. For the repair of a badly pitted cast-iron turbine runner a straight stainless chrome steel of low ductility was used some years ago. In the course of welding, hair cracks developed, checking the entire welded areas. These cracks were so deep that they could not be smoothed off by grinding; yet despite these cracks no pitting whatever has developed, although stainless chrome nickel steel at the same location showed surface deformation. Similarly, on a turbine throat ring, with appreciably wider surface cracks due to contraction on an area welded with the same straight stainless chrome steel referred to, no cracks were found after a number of years.

In view of the foregoing, great caution seems advisable with respect to certain theories advocated by the authors regarding the necessity of stresses of extreme magnitude and the importance attributed to surface cracks and crevices.

J. H. DOUMA,[32] JUN. AM. SOC. C. E. (by letter).—Undoubtedly, this paper has been read with much interest by hydraulic engineers who have been concerned with the cavitation problem. It is especially noteworthy for being one of the first in this relatively new field of model investigation. In addition to a detailed outline of the procedure in conducting a model study for an investigation of cavitation, the authors have presented data that are useful in some degree to designing engineers. No attempt, however, has been made to establish a design criterion for outlet conduit entrance curves. Such a criterion would eliminate the seeming necessity for a model study of every proposed design.

For any given high velocity of flow, the boundary conditions of a closed system may be so varied that a pressure intensity equal to the vapor pressure will be approached at some point on the boundary. When the pressure intensity is reduced to the vapor pressure at any point, the liquid will just begin to vaporize. The region of vaporization will grow in size as the pressure intensity is further reduced, and cavities composed of water vapor and flying particles of water will form. The abrupt collapse of these cavities as they are carried into regions of higher pressure intensities causes the destructive disintegration of boundary surfaces known as pitting.

To prevent the formation of cavities the boundary conditions must be such that the outermost streamlines of the resulting flow conform approximately with the boundary profile over their entire length. This requirement can be fulfilled by proportioning any conduit inlet passage to fit the shape of a jet issuing from a sharp-edged orifice of the same cross section as the maximum inlet section. The effect, on the flow, of entrance surfaces so designed is to modify the outermost streamlines so that positive pressure intensities exist at all points on the boundary surfaces.

---

[32] Asst. Hydr. Engr., War Dept., Los Angeles, Calif.

In Fig. 19, the upper surfaces of free jets issuing from a sharp-edged circular orifice and from a long narrow slit are shown plotted for a unit *vena contracta* thickness. With the origin of coordinates at the orifice edge, x and y are the horizontal and vertical distances from the origin, and D is the jet thickness at the *vena contracta*.

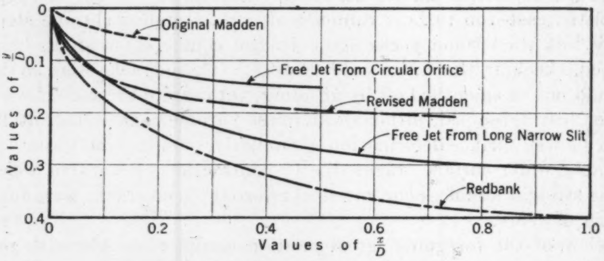

FIG. 19.—COMPARISON OF UNIT ENTRANCE CURVES

For comparative purposes, similar unit top curves of the original and revised entrance sections of the Madden Dam conduit, and of the final design of the entrance section of the Redbank Dam conduit, are also plotted in Fig. 19. The original Madden Dam curve falls far short of the free-jet curves, a condition conducive to the development of cavitation, which is borne out by the severe pitting of the prototype conduits. The revised entrance curve for Madden Dam, shown to have no cavitation potentialities by the model study, approximates the free-jet curve for a slit at its upstream end and lies between the free-jet curves for the circular orifice and the slit at its downstream end. The Redbank curve lies well beyond the free-jet curves, and a model study indicated satisfactory performance with regard to cavitation.

As noted in Fig. 1, the entrances of the Madden Dam conduit are not exactly symmetrical about a horizontal plane through the conduit axis, but the bottom of the stop-log recess terminates in a horizontal step some distance below the beginning of the entrance curve. Lowermost streamlines obviously begin to curve at the upstream end of this shelf. By plotting the circular orifice and slit free-jet curves with their upstream ends at this point, the original Madden Dam bottom entrance curve was found to lie between the free jet curves. No visible cavitation pockets appeared in the stop-log recess during model tests, and, as shown in Fig. 3, no cavitation damage occurred on the bottom of the prototype conduit. Apparently, the recess was filled with liquid, which was effective in easing the streamlines through this region to the entrance curve.

A similar comparison of the side-wall entrance curves with the free-jet curves indicated that they were inadequate to preclude cavitation potentialities, which is substantiated by the cavitation damage occurring at the prototype side-walls. In plotting unit entrance curves for the rectangular conduit, the conduit height was taken as *d* for the top and bottom curves, and the width as *d* for the side curves.

Inasmuch as the jet issuing from a square orifice approaches the shape of the circular orifice jet, and as the opening changes to a narrow rectangular cross section the jet approaches the shape of the slit jet, unit curves for a properly designed entrance to any given rectangular conduit would lie between the circular orifice and slit unit curves. A model investigation of free jets issuing from rectangular sharp-edged orifices, covering a useful range of height to width-of-opening ratio, would provide a basis for determining the exact shape of entrance curves to any rectangular conduit.

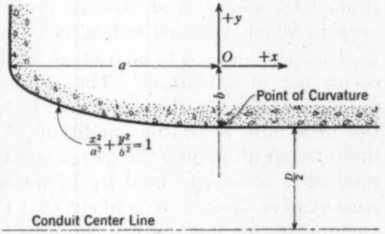

FIG. 20.—ENTRANCE CURVE SHAPE

To evolve a conservative basis of design until definite data relative to rectangular orifice jets are available, the entrance passages to circular conduits might be proportioned to approximate the shape of the free jet issuing from a sharp-edged circular orifice and for rectangular conduits the shape of the jet from a slit. Referring to Fig. 20, the free-jet surface curves approximate an ellipse in shape, expressed in the general form

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

The *vena contracta* of the circular orifice jet is located 0.5 D from the aperture, and the jet diameter at this point is 0.77 D_o, in which D is the jet diameter at the *vena contracta* and D_o the orifice diameter. This gives a semi-major axis equal to 0.5 D and a semi-minor axis equal to 0.15 D for the surface curve. The design equation of the entrance curve for a circular conduit becomes

$$4\,x^2 + 44.4\,y^2 = D^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

The location of the *vena contracta* for the slit jet is approximately equal to the *vena contracta* jet thickness from the opening, and the jet thickness at the *vena contracta* is equal to 0.62 times the slit opening. These dimensions give a semi-major axis equal to D, and a semi-minor axis equal to 0.31 D for the surface curve. The design equation for the entrance curves of rectangular conduits becomes

$$x^2 + 10.4\,y^2 = D^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

in which D is the conduit height for the top and bottom curves and the width for side curves.

The writer contends that Eqs. 31 and 32 can be used reliably, in designing entrances to conduits, with reasonable assurance that cavitation would not occur in the prototype, except in the vicinity of gate slots, if they are not properly designed. As a matter of fact, the adequacy of Eq. 31 already has been verified by model studies of the entrances to the circular outlets of Grand Coulee Dam. These entrance curves fit closely that given by Eq. 31, and the model study indicated satisfactory performance relative to cavitation by showing positive pressures at all points.

Although, as the authors state, the cavitation phenomenon cannot be studied by means of small-scale undistorted models of the usual laboratory type in which no scale reduction is made in the atmospheric pressure, such models may be used to advantage in checking any conduit design for possible occurrence of cavitation. The method is to locate piezometer openings at numerous points in the region in which cavitation might occur. Then, under the maximum operating conditions, if at least a slight positive pressure is indicated at all points, the design is satisfactory for averting cavitation. This method is ordinarily used by hydraulic laboratories, and, since it results in conservative designs, it is likely that this procedure rather than the so-called vacuum testing method will continue to be favored. A comparison of the required entrance for any given conduit as determined by each of the two methods would be of interest.

Harold A. Thomas,[33] **M. Am. Soc. C. E., and Emil P. Schuleen,**[34] **Assoc. M. Am. Soc. C. E.** (by letter).—That so many distinguished engineers have seen fit to contribute to the discussion of this paper is a source of gratification to the writers, and they are glad to acknowledge the constructive nature of the comments and suggestions received in this way. Their appreciation should not be obscured by the argumentative tone of this final closure, which, of necessity, must be devoted largely to answering specific questions or criticisms.

Mr. Fee makes a number of criticisms of the analytical methods of the paper, but the writers cannot concede the validity of any of his arguments. In his discussion of Fig. 5 and Eqs. 1 to 4, Mr. Fee discards the writers' assumption that the slug of water travels with constant kinetic energy and assumes instead that its momentum remains constant. He develops Eqs. 15 to 17 on the latter basis, and, because Eq. 17 does not agree with Eq. 4, he states that the writers' "entire argument must therefore be regarded as unsound." The writers would like to point out that in this problem the assumption of constant momentum is quite inapplicable. In accordance with Newton's laws of motion, the momentum of a mass of material remains constant only if no unbalanced external forces act on the material. In this problem a large unbalanced force acts on the slug of moving water—namely, the upstream component of the pressure exerted on the slug by the walls of the tapering channel. Under the action of this force, the momentum of the slug is quickly reduced to zero. Therefore, to assume that the momentum is constant in this problem is entirely incorrect.

To confirm his statement that the writers' assumption of constant kinetic energy is unsound, Mr. Fee includes the following sentences in his discussion:

---

[33] Prof., Dept. of Civ. Eng., Carnegie Inst. of Technology, Pittsburgh, Pa.

[34] Senior Engr., U. S. Engr. Office, Pittsburgh, Pa.

> "What would be the fate of this slug of water, for example, if the pyramidal section of the narrowing passage, shown in Fig. 5, had suddenly ceased to taper at a certain point, and had continued, instead, as a constant rectangular section of indefinite length? The writer can only imagine that the slug of water would tear itself to pieces in an effort to conform to the assumption that the kinetic energy is constant."

It is not necessary to use imagination to determine that the slug will "tear itself to pieces" under these conditions, as this fact can be readily verified by computation or experiment. An application of the method used in deriving Eqs. 1 to 4 will demonstrate that the pressure in the water of the slug becomes negative just after it enters the smaller rectangular section, thus causing the slug to break into fragments as it enters the smaller section. A simple experimental demonstration of this action may be made with a quart bottle whose form approximates two cylindrical tubes connected by a tapering section. If the bottle is filled about a quarter full of water and is then held mouth upward in the hands and is jerked suddenly downward, the jet issuing from the mouth of the bottle will not be solid but will be broken into spray. The action can be shown to even better advantage in a piece of apparatus consisting of a 1-in. glass tube about 1 ft long, drawn down to a diameter of about $\frac{3}{8}$ in. in its middle third. About an ounce of water may be placed in the tube, and the ends sealed after exhausting the air with a vacuum pump. When this apparatus is jerked back and forth, the disintegration of the slugs of water as they enter the constricted section is clearly apparent. The existence of this phenomenon is a confirmation rather than a contradiction of the correctness of the writers' assumption of constant kinetic energy.

Mr. Fee's discussion contains the following sentences: "Referring next to Table 3, there are two very different phenomena that should be distinguished" —steady continuous flow and impact. "The authors apparently have no difficulty in transferring quantitative results from one case to the other. In fact, they seem to make little distinction between them." The writers feel that the comment contained in these sentences is quite unjustified. The entire phenomenon under discussion is one of impact caused by a detached mass of water striking a stationary solid or liquid. In preparing the condensed column headings for Table 3 and the accompanying explanation, the writers felt that this point would be so thoroughly appreciated by the reader that it would be unnecessary to include specific statements that the data were inapplicable to cases of steady continuous flow.

Mr. Fee's discussion devotes more than a page to a derivation (suggested by the method of Messrs. Diederichs and Pomeroy[10]) of the ordinary formulas for water-hammer pressure in a pipe. The writers do not consider that this material is pertinent to the discussion of the paper or that any point is gained by plotting the results of an ordinary water-hammer computation in Fig. 14. However, they will refer to this derivation again in discussing a criticism of Eq. 6.

The following sentences are contained in Mr. Fee's discussion:

> "The writer feels certain that the analysis [leading to Eq. 6] is unsound. The conclusion (see paragraph following Eq. 6) that 'the velocity

> of particles at the contact surface is one half the initial velocity of the slug of water' is * * * based on an idea that is wholly unreal.* * *
>
> "Eq. 6, which the authors intend as a proof of their proposition, is nothing more than an arbitrary statement that assumes, to begin with, that the impinging particles, and those impinged upon, move during a finite interval of time with a common velocity v_c, which is constant."

Perhaps the significance of the analysis leading to Eq. 6 could be made clearer by considering conditions within a closed pipe, rather than those at the stagnation point on the contact surface where an irregular slug of moving water meets a horizontal water surface as in the diagram at the left of Fig. 6. Mr. Fee's derivation of the water-hammer formulas, previously referred to, assumes a still body of water (in a cylinder or pipe) that is suddenly struck by a (rigid) plane surface such as a piston, and leads to the maximum pressure rise given by Eq. 23. Now, instead of this, assume a still body of water in a cylinder or pipe to be suddenly struck by an elastic piston consisting of water. Imagine the contact surface between the water which was originally still and that which was moving to be defined by a thin film or web, say tissue paper. If one applies himself to the solution of this new problem, he will recognize the fundamental nature of the requirement that in each of the two elastic bodies the front of a pressure wave must travel away from the tissue-paper contact surface at the acoustic velocity. Starting from this fact and proceeding by irresistibly logical steps, using Mr. Fee's method or any other of the ordinary derivations of the water-hammer formulas, one is led to the necessary conclusion that (before reflected waves return) the tissue-paper contact surface must move with a velocity equal to half the original velocity of the water piston, exactly as expressed in Eq. 6, and that the pressure rise must be exactly as expressed by Eq. 7. It is unnecessary to repeat the algebraic details of this proof, since the case is precisely similar to that shown in Fig. 6 and explained in connection with it, the vertical lines *AB* being interpreted as representing the walls of the pipe.

Mr. Leman reveals the fact that high pressures can be produced by the sudden checking of the velocity not only of a detached slug of water, but also of a larger mass of water extending continuously to the source, as in the more familiar case of water hammer in an ordinary pipe. Although the writers agree with him fully on this point, they chose a detached slug for demonstration of the fundamental principle of velocity concentration because the mathematical analysis seemed simpler and because close observation of cavitation phenomena under many different experimental conditions seemed to emphasize the importance of the part played by flying fragments of detached or semi-detached water.

Messrs. O'Shaughnessy and Randolph contribute additional data of much interest in connection with the use of fillers for the stop-log slots in the Madden Dam, and the admission of air through vents in the stop-log slot fillers. They offer the comment that "It is not made clear in the paper how the air measured in the model tests * * * can be related quantitatively to the air that would be required in venting the prototype." In reply to this comment, it may be stated that the analysis of the experiments did not attempt to establish such a quantitative relation. Since air entrainment is a function of bubble size, which in turn is primarily dependent on surface tension, it follows that Froude's law is entirely inadequate to relate the percentages of air entrained in the respective waters of a model and its prototype. During the model tests on the Madden conduits, the quantity of air drawn into the vents was measured as a control for repeating experiments, but it was not considered feasible to relate this air flow to that of the prototype.

Mr. Merriam's discussion contributes interesting information on the objectives and methods for cavitation tests on metal in hydraulic machinery as contrasted with the writers' tests on concrete surfaces in the outlet conduits of dams. The writers appreciate Mr. Merriam's clear statement of the fact that

> "In the case of discharge conduits, which may be operated at full capacity but a relatively short period of time, the idea of the designer is to avoid all danger of cavitation, whereas the builder of high-speed hydraulic machinery is seeking the economic balance between operating revenue and cost of repairs. Consequently, he must strive for quantitative measurement * * *. The former is more interested in qualitative tests which give reasonable assurance that the design proving best in the model is the most suitable for the prototype."

Considerable difficulty has been experienced in making this point clear to various engineers visiting the laboratory during the tests described in the paper, or in convincing them that, in the case of cavitation tests on models of fixed concrete structures, it is a waste of time and money to duplicate the elaborate technique used by hydraulic machinery cavitation laboratories for controlling the air and gas content of the water.

Mr. Merriam states that his principal point of disagreement with the writers lies in their not entertaining the theory advanced by Mr. Pagon[18] in 1935. This theory is discussed by the writers with some detail in their original full-length manuscript, which is on file in the Engineering Societies Library.[3] In essence, Mr. Pagon emphasizes the importance of the low-pressure region at the center of an eddy as a primary source of a "vapor void," and attributes a sudden collapse of the tubular vapor void along the eddy axis to dynamic instability of the eddying motion. In condensing the paper for publication, the writers decided to omit the discussion of this theory because, in their opinion, its tube-collapse feature did not seem to offer an adequate or complete explanation of the principal experimental facts in the type of cavitation under consideration. Granting the importance of curvilinear or eddying flow as a source of low pressure for opening up vapor voids, the writers nevertheless believe that in the types of cavitation under discussion the most important cause of the sudden collapse of vapor voids is simply the impact of swiftly moving water containing such voids against less swiftly moving water or solid objects, and that such collapse will occur whether or not the water is eddying. An important light is thrown on this topic by the analogy (mentioned by Mr. Merriam) between the downstream region of a cavitation pocket where such impacts are most active and the turbulent region in an ordinary hydraulic jump. Moreover, Professor Edgerton's motion pictures[6] of cavitation convey no suggestion of the existence of tubular eddy-voids.

In support of the eddy-tube-collapse theory, Mr. Merriam mentions that

> "* * * there is the observation that in two-dimensional, venturi-shaped passages the damage comes where the axes of the eddies would terminate against the side walls rather than on the profiles, which would be more likely to receive the onslaught of slugs of water."

As mentioned in the paper, in introducing Fig. 12, a similar phenomenon was observed in the tests on models of the Madden conduits, the side-wall pitting being shown, and its cause explained by the words

> "* * * the pit first develops along the edge of the large cavitation pocket, where especially intense impacts are caused by collisions between the swiftly moving water of the streamline filaments and the broken masses of water and vapor hurled against these filaments from the interior of the pocket."

The writers believe that this explanation of side-wall pitting conforms with the physical facts more accurately than that based on the eddy-tube-collapse theory.

The writers appreciate Professor Rouse's commendation of the paper in general. However, they disagree with the reasoning by which he attempts to disprove the analytical and experimental evidence that the essential cause of cavitation damage is the production of very high pressures by the collapse of vapor voids. It does not seem probable that Professor Rouse means to deny the possibility that high local pressures occur, since his discussion contains the sentence: "Indeed, one need only hear the violent shocks which are produced by discharging steam under water to concede the issue that the collapse of such vapor pockets might well lead to exceedingly high local stresses." It seems more likely that he merely intends to take issue with the writers regarding the actual numerical values of the maximum pressures. It is to be noted that the writers have not established any such numerical values, but have simply carried the computation of Table 3 to the maximum value permitted by the best available compression tests, those of Bridgeman.[7]

Professor Rouse bases his criticism of the writers' analytical work on the "artificial * * * nature of the assumption of constant kinetic energy in the specimen slug of water," presumably referring to the neglect of the items of viscosity, vapor pressure, and rotational energy. However, the writers believe that in the types of cavitation encountered in the large stationary structures under consideration, the preponderance of evidence indicates strongly that these neglected items are of secondary importance in comparison with the main item of kinetic energy. The writers' analysis is not intended to establish precise values of maximum pressure, but merely to furnish a qualitative conception of the fundamental cause of pressure concentration. They feel that the assumption of constant kinetic energy is satisfactory for this purpose, and that the "artificial nature" of this assumption is not of sufficient consequence to otherthrow this position.

Professor Rouse mentions that the assumption of a moving slug of water in a tapering channel is less elegant than that of a momentary spherical bubble of water vapor within an initially stagnant, incompressible liquid of arbitrary volume. The writers feel that, although the latter would be a reasonable assumption to illustrate the shock caused by discharging a steam bubble under water, it has little pertinence in connection with cavitation of the type under discussion, where the kinetic energy of the flying masses of water is very large in comparison with their potential energy of position with respect to the centers of the adjacent voids.

This point may be explained in more detail as follows: The kinetic energy developed by the collapse of a vacuum bubble in initially stationary water under atmospheric pressure is equal to the volume of the bubble times the atmospheric pressure, the latter corresponding to a water column about 34 ft high. The kinetic energy of a slug of water moving at a given velocity is equal to the volume of the slug times the pressure developed by a column of water of height equal to the velocity head. In the case of flow in an outlet conduit of a dam 350 ft high, the latter column might be about 340 ft high. Professor Edgerton's moving pictures[6] of cavitation in a diverging tube show a succession of vapor bubbles separated by moving slugs of water having approximately the same size as the bubbles. Thus, if cavitation of this kind occurred in the conduits of a dam 350 ft high, the initial velocity of the moving slugs would provide about ten times as much kinetic energy for destructive cavitation effects as would be provided by the release of potential energy during the collapse of the voids from initially static conditions.

Professor Rouse mentions that "high-speed motion pictures by H. Mueller[24] of the collapse of vapor bubbles produced in cavitation would indicate that the bubbles tend to flatten on the downstream side rather than to dwindle concentrically," and that "Conclusions of this nature would tend to invalidate much of the authors' basic hypothesis, as do piezoelectric measurements by J. Ackeret[25] of only moderately high instantaneous stresses in zones of cavitation." The writers have already pointed out that Professor Rouse's conception of cavitation shock as arising from the collapse of spherical vapor bubbles in a static liquid is not applicable to the types of cavitation under consideration. The flattening of the vapor cavities is also observed in Professor Edgerton's photographs.[6] This flattening strongly disproves the spherical-bubble-collapse theory and confirms the writers' thesis that the collapse of a void under typical cavitation conditions occurs when the void is caught and compressed between swiftly moving water on its upstream side and stationary or less swiftly moving water or solid material on its downstream side.

With regard to J. Ackeret's piezometric measurements of pressures in cavitation zones, attention may be called to the utter lack of success of elaborate attempts by other experimenters to attain direct measurements of cavitation pressures. This point is mentioned by Mr. Merriam, who states that it should be emphasized that the multiplication of impact leads to tremendously high concentrations of stress over an exceedingly limited area, and that this is well illustrated by the experiments cited in the paper by J. C. Hunsaker,[5] in which ordinary methods of measuring high pressures such as are used in internal combustion engines, gun barrels, etc., failed completely as criteria of cavitation severity. Mr. Merriam also states that the use of thin diaphragms, backed up by perforated plates, proved in vain because they were punctured merely by accidental hits rather than by a widespread blow. The impossibility of obtaining consistent piezometric measurements in, or closely adjacent to, cavitation pockets was amply verified during the writers' experiments on models of the outlet conduits of the Madden Dam and other dams.

The writers do not disagree with Professor Rouse's point that a positive wave must invariably be followed by a negative wave of equal magnitude, and that fatigue due to the resulting repeated stress reversal is of importance in causing the ultimate failure of the material. This fact, together with the fact that the negative pressure is especially important in destroying concrete because the latter is much weaker in tension than in compression, is implied in a paragraph of the paper preceding "Description of Apparatus for Cavitation Tests." Moreover, the writers feel that their main thesis is not jeopardized by Professor Rouse's prediction that the "theory of fatigue through repeated impact of not-too-great magnitude will eventually be more generally accepted" as a cause of cavitation. Experiments to determine the fatigue of metals in indentation tests are apparently not available, but from a knowledge of the great pressure intensity required to produce a perceptible permanent indentation under the Brinnell ball or Rockwell diamond in hardness tests, and from a knowledge of the relationship of the stress-reversal fatigue limit to the ordinary elastic limit in tensile or cross-bending tests, it does not seem at all unlikely that the indentation fatigue limit in the harder metals known to be attacked by cavitation may be at least of the order of the highest values of Table 3. If Professor Rouse's words "not-too-great magnitude" refer to stresses of an order considerably lower than this, the writers would take issue with him. In this connection, the writers are not referring to soft or mild metals of the ordinary structural grade, but to harder materials having an elastic limit of the order of several times that of ordinary structural steel. Since no upper limit has been found to the hardness of metals pitted in accelerated cavitation tests, and in view of the intense forces required to produce any type of permanent displacement among the molecules of the hard metals by either single loading, repeated loading, or successively reversed loading, it seems impossible to escape the conclusion that extremely high pressures on at least pin-point areas can be produced by the action of water under cavitation conditions. Further considerations bearing on this topic will be mentioned in the writers' reply to Mr. Mousson's discussion.

The writers are pleased that Mr. Hickox agrees with their findings and conclusions in so many respects, a considerable number of these conclusions being restated in his discussion. What seems to be an essential disagreement between Mr. Hickox and the writers is stated as follows in his derivation of Eq. 29:

> "It might be assumed from the authors' remarks following Eq. 8c that operation of a model in accordance with Froude's law requires that

> the ratio of absolute pressures in model and prototype be equal to the model scale. This is not correct."

The source of this disagreement apparently results from a difference in the definition used to extend Froude's law to cover phenomena affected by pressures due to other sources than the action of gravity. In the sentences preceding and following Eq. 8c the writers have defined Froude's law as stating essentially that the ratios of all heads including vapor pressure heads in the model and prototype must vary as the square of the ratio of the velocities in model and prototype, whereas the definition used by Mr. Hickox omits the words "including vapor pressure heads." The actual physical facts, independently of this definition, are expressed correctly by the writers' equations. The same remarks apply to Mr. Hickox's comments on Eq. 13, the apparent difference of opinion lying merely in the definition used for Froude's law. The discrepancy that Mr. Hickox thinks would occur between the physical results of tests based on Eqs. 12 and 13 does not actually exist, both of these equations being derived from Eqs. 9c and 11 by simple algebraic transposition.

It might be argued that the best method of extending the definition of Froude's law to cover phenomena not investigated by Froude himself is a matter of personal opinion. However, the writers feel that their extension of this definition has important advantages from the standpoints of logic and convenience.

Mr. Hickox is not quite in agreement with the writers' description of a cavitation pocket "as a void space filled with flying slugs of water," but regards it rather as "a region in which cavities form, travel with the stream, and finally collapse." The latter description is especially applicable to the cavitation phenomenon that occurs in a gradually diverging tube, as illustrated by Professor Edgerton's photographs.[6] However, the former description is better fitted to the cavitation occurring behind sharp corners or projections. Although the writers feel some sympathy toward Mr. Hickox's statement of the reasons why he dislikes the use of the term "cavitation pocket," they feel constrained to use this term until a better one is suggested. "Cavitation area" is objectionable for the designation of a volumetric space, and "cavitation region" is more properly applied to the entire region in which the phenomenon is occurring, including not only the space actually traversed or occupied by vapor voids, but also that of the surrounding flow pattern.

In the fourth paragraph following Eq. 29 Mr. Hickox states that "It is doubtful if the discharge can be assumed arbitrarily. In order that the model flow pattern shall approximate that of the prototype, there should be at least a semblance of agreement with Froude's law." The writers disagree completely with this statement. Works on hydrodynamics contain numerous illustrations of streamline patterns that are fixed by the physical boundary conditions and are independent of the velocity, that of the ordinary jet from a sharp-edged orifice being a familiar example. In the same paragraph, Mr. Hickox calls attention to the fact that the writers have used a numerical example in which the velocity scale is exactly equal to the square root of the head scale, and states that "One is led to believe that * * * such good agreement could hardly be fortuitous." Since the enclosed tank apparatus was originally designed for the accommodation of models of scale conforming to the foregoing relationship, it was often found convenient to assume a pump discharge that would fit this relation exactly. This had the advantage of making the velocity scale come out in even figures. The discharge used in this particular example was assumed in this way. However, other arbitrary pump settings could have been used as well (and were actually used in many tests) without distorting the flow pattern. In operating the diverging-tube apparatus, great deviations from the Froude's law setting were used normally, since a velocity scale far in excess of the square root of the linear model scale was required to produce the necessary pressure reduction in the critical cavitation regions.

In the third from the last paragraph of his discussion, Mr. Hickox states or implies that, if a model were operated according to the equations given by the writers, it might be possible for the model to indicate cavitation that would not occur in the prototype. The writers would like to emphasize that Mr. Hickox is mistaken on this point. His misunderstanding of their equations in this connection probably arises again from the lack of an accepted generalization of Froude's law, applicable in cases where pressure heads other than those due to gravity are involved. Consider a model of the conduit entrance of a dam on which the head is variable, and suppose this to be operated without gravitational or operational distortion and in accordance with the writers' equations. At low head, there will be no cavitation in the model or prototype. At a certain head, incipience of cavitation will appear at some point in the prototype, and the writers' equations provide that the adjustment of pressures and velocity in the model will cause incipient cavitation to appear in the model at exactly the head corresponding to this prototype head and at exactly the corresponding point. At higher heads, stronger cavitation will appear in both model and prototype at this point and other pockets may possibly open up. There is no possibility for cavitation to occur in the model where it does not appear in the prototype, or vice versa. The analytical reasoning establishing the correctness of the foregoing statement is given in the paper in such detail that it seems unnecessary to repeat it. The sentence on which Mr. Hickox's argument is based is stated in the following words by him:

> "If the model is adjusted to operate in conformity with Froude's law [as defined by Mr. Hickox this does not require vapor pressure head scale to be proportional to the square root of the velocity scale], and the absolute pressures in reservoir and conduit barrel are adjusted to conform to the linear scale ratio, the model may indicate cavitation that would not occur in the prototype * * *."

This statement is perfectly ture, but the fallacy of the argument lies in the fact that the words quoted do not state the same thing as the writers' equations.

As stated in the paper, if the model is operated with gravitational or operational distortion, the gage settings to produce incipience of cavitation in the model at exactly the same comparative head and at the same point at which it occurs in the prototype cannot be made to apply to the entire fluid system of the model, but a separate setting must be used to test each point at which it is desired to know whether cavitation would occur in the prototype. For example, Mr. Hickox states that he "would like to know how the methods of the paper were applied to a rotated vertical diametrical section of the entrance of the Hiwassee sluice, for example, which was found to be entirely free from cavitation." The Hiwassee cavitation tests are described in the original manuscript on file in the Engineering Societies Library.[3] Since the entrance bell of this circular conduit is nearly a surface of revolution, the first and most likely point to be tested for possible cavitation was at the conduit roof just inside the entrance, where the general pressure was lower than at the floor, because of shallower submergence, and where the velocity was as high as anywhere else. The gage settings were made according to the equations of the paper and the model showed no cavitation at this point, thus proving that there would be no cavitation at the corresponding point in the prototype. Other suspected points, near the rails carrying the closure bulkhead, etc., were investigated in a similar manner but no cavitation was found. By exaggerating the general cavitation-severity condition in the model, it was easily proved that no doubtful points had been overlooked.

The writers appreciate the constructive criticisms by Mr. Mousson, and in particular they are glad to accept his word of caution regarding the importance of the opening up of fatigue cracks as a feature in the mechanism of cavitation damage to metals. As they have stated in the paragraph preceding Eq. 5, the writers realize that "The law governing the * * * process of pressure multiplication undoubtedly changes when the crevices become so small as to approach molecular dimensions." Since the theoretical investigation of the action taking place in very small crevices is definitely a problem for the molecular physicist rather than for the engineer; since direct experimental measurement of pressures in such crevices appears to be totally lacking; and since Mr. Mousson is able to cite practical cases, where cavitation damage to turbine runners was not increased by the presence of hair cracks, and laboratory tests, where subsurface disintegration occurred without surface cracking, the writers are quite willing to hold in abeyance further speculations regarding cavitation action in fine cracks.

Mr. Mousson joins with Professor Rouse in questioning the probable occurrence of pressures approaching or exceeding the higher values of Table 3, and in believing that cavitation damage to metals can be explained satisfactorily as a fatigue phenomenon due to stresses comparable to the lower values of the table. Because of the failure of the most painstaking experiments to give any inkling of true cavitation pressures, this entire topic lies in the realm of speculation. However, the writers believe that the preponderance of evidence points to the conclusion that the harder metals cannot be destroyed in the absence of local pressures of at least the order of magnitude of the higher values in Table 3. A striking illustration of the high intensity of pressure that can be sustained on a local area of a plane surface of a hard metal without producing a permanent deformation is found in the classic series of tests of the bearing of locomotive wheels on steel rails, reported by the late C. L. Crandall,[35] M. Am. Soc. C. E., and in the discussion by the late J. B. Johnson,[36] M. Am. Soc. C. E. In these tests pressures of 164,000 lb per sq in. produced no permanent set.

After reading Mr. Mousson's discussion, one of the writers made some experiments with the Brinnell-ball apparatus to check the pressure intensity required to produce a perceptible permanent indentation in the surface of a hard metal. The first steel specimen selected at random for this test had a Brinnell hardness number of 524, which is about "file hard." Under a load of 500 kg on the Brinnell ball, a slight but definitely perceptible indentation 1.1 mm in diameter was produced on the surface of this specimen. A little arithmetic shows the average pressure on the contact area to have been just less than 750,000 lb per sq in. It is probable that the maximum pressure intensity at the center of the indentation was materially greater. A similar test was run on a piece of metal from an ordinary structural steel angle, the Brinnell hardness number of this steel being 90.4, and a perceptible indentation of 1.40 mm in diameter being produced by a load of 150 kg on the Brinnell ball. The mean pressure under the latter loading thus was about 139,000 lb per sq in., whereas the maximum at the center of the indentation was probably higher. These values carry an implication that, in view of the enormous local pressures required to produce slight permanent indentations (or permanent displacements of the molecules) on the surfaces of hard metals, it might reasonably be expected that pitting would not take place on such metals unless the pressures developed within the cavitation pocket were at least as high as the larger values of Table 3. Although no cavitation tests have been made on the particular pieces of steel mentioned, experience with such tests indicates definitely that extreme hardness or toughness of the metal is no barrier to ultimate pitting and disintegration under severe cavitation conditions.

Analogy with various types of fatigue tests makes it highly probable that the fatigue limit or repeated pressure intensity required to produce a permanent disintegration of the metal would be at least a large fraction of the pressure producing the first permanent set. Moreover, numerous short-time cavitation tests of metals are on record[18] where fatigue has not had time to become effective and where the first evidences of damage are a few scattered tiny pits or prick-punch indentations due to individual blows. Because of the minuteness and the scattered nature of the individual pits or areas in which the extreme pressures act, the writers do not concur with Mr. Mousson's argument that pressure "values in the upper part of the range [of Table 3] are not likely to occur since damage would be so severe in a matter of minutes as to endanger any structure within the same time interval."

Mr. Mousson states that another item of evidence against the theory of local high-pressure points in cavitation regions is the fact that, in tests on metals in cavitation stands, throat velocity has been found to be one of the most important variables with respect to pitting. The writers do not recognize the soundness of this argument, since the rate of pitting would obviously increase with the energy content of the individual blows and their frequency, even if the maximum pressure at the center of each affected spot did not increase. However, in this connection it seems desirable to repeat that the writers' analytical work in Eqs. 1 to 7 and in Table 3 was not intended as a complete analysis of the mechanism by which high-pressure points are developed in cavitation regions, but was intended merely to explain or illustrate one of the most salient features of this mechanism—namely, the tendency toward energy concentration at the final point of a void collapse. It should by no means be thought that the writers regard the neglected items of viscosity, vapor pressure, and rotational energy as so unimportant that the maximum intensity of pressure developed by a vapor pocket collapse is entirely independent of the total quantity of energy in the moving water that is brought to rest.

[35] "Friction Rollers," by the late C. L. Crandall and A. Marston, *Transactions*, Am. Soc. C. E., Vol. XXXII, July-December, 1894, p. 99.

[36] *Loc. cit.*, p. 270.

The discussion by Mr. Douma calls attention to the desirability of establishing methods or criteria, based on free-jet profiles, for designing conduit entrances that will be free from cavitation. The writers are much interested in Mr. Douma's ideas on this topic, since they have done considerable analytical and experimental work along somewhat similar lines (described in some detail in the original manuscript on file in the Engineering Societies Library[3]). The rigid space requirements for publication made it necessary to eliminate somewhat more than three fifths of the original subject matter, the section on the design of entrance bells being one of those deleted. The writers are in full agreement with Mr. Douma on the principle that the nappe of a free jet issuing from a sharp-edged orifice has the ideal shape for a cavitation-free entrance bell, and that entrance bells having solid parts projecting inside the location of this nappe surface are especially liable to cavitation. However, it may be remarked that it is not feasible to use this principle in designing an entrance bell unless the upstream face of the dam in the vicinity of the entrance is a plane normal to the conduit axis. Moreover, entrance bells designed with the "ideal" profile will usually have a considerable factor of safety, since the pressure on all surfaces of the bell is equal to that in the upstream end of the conduit proper, and therefore considerably above atmospheric pressure (if the conduit is level or nearly so), whereas the pressure head required to induce cavitation is about 33 ft below atmospheric pressure. This fact may be utilized to achieve economy in the design of entrance bells for conduits under comparatively low head. In the original manuscript, a table of coordinates for the profile of an ideal entrance bell is given, based on G. Kirchoff's exact equations for the free-jet profile[37] rather than on the ellipse used as an approximation by Mr. Douma. Also, a table is included, based on original experiments, giving the end and side contractions of the jet for conduits of rectangular cross sections having various slenderness ratios.

DESIGN OF ACCELERATION AND DECELERATION LANES

By ADOLPHUS MITCHELL,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. H. F. Holley, D. W. Loutzenheiser, Hawley S. Simpson, Milton Harris, T. F. Hickerson, W. L. Waters, R. A. Moyer and Donald T. Davidson, Stephen E. Butterfield, and Adolphus Mitchell.

Synopsis

Mark Twain once said: "Everybody talks about the weather, but nobody does anything about it." The design of acceleration and deceleration lanes is in a position similar to that of the weather. This paper is an attempt to do something about it. The writer hopes discussers will present data sufficient to preclude argument on some of the controversial factors involved.

Introduction

The purpose of a deceleration lane is to provide a means for vehicles to leave the highway at cruising speed and come to a stop or a lower speed before entering a street, filling station, or other destination. The purpose of the acceleration lane is to provide a means by which slow-moving traffic can reach the cruising speed of a highway before entering its lanes. The deceleration lane should be long enough to provide for a "weaving distance," motor deceleration to a speed at which braking can be done safely, and a comfortable braking distance from that point on. ("Weaving distance" is used herein to describe the transverse movement from one lane to another whether converging to, or diverging from, the traffic stream.) The acceleration lane should provide for full acceleration to cruising speed, and a weaving distance sufficient for the driver to enter the highway, provided there is a space between cars into which he can turn. In the event no such space is available, or made available by cars on the outside lane moving over, sufficient perception and brake reaction distance should be allowed in addition to a braking distance which would not necessitate pitching the passengers to the floor of the car. A sketch of the elements of the deceleration and acceleration lanes, as proposed, is shown in Fig. 1. The function of the insulation strip is for channelization, to encourage

---

Note.—Published in March, 1941, *Proceedings*.

proper use of the speed-change lanes, and to eliminate points of conflict. As will be seen in the illustration, the side entrance to the lanes is tapered so as to permit gradual merging with, or diverging from, the traffic stream on the highway.

Deceleration Lanes

The first element of the deceleration lane as detailed in Fig. 1 is the weaving distance. This distance should be sufficient to allow safe turning at cruising speed from the highway into the deceleration lane. The curves in Fig. 2 give the weaving distance for any cruising speed with or without an insulation strip. (An insulation strip—see Fig. 1—is any physical barrier separating the deceleration lane from the highway proper. This barrier guarantees correct use of the deceleration lane.) The curves are based upon the formula derived in the Appendix. The width w (see Fig. 1) varies with the speed of the vehicle as follows:

The assumption of an S-path of travel is a theoretical expedient entirely, and there is no doubt that drivers would find a spiral path more natural than a reverse circular path. The formula derived on the basis of the S-path contains all the variables involved in the natural path. For this reason it is necessary only to determine suitable constants for this formula. Grade is a negligible factor as shown in theoretical studies. Field studies of the weaving distance as measured in terms of time and speed lead to an average coefficient of friction of 0.16. This value is identical with that used everywhere as a comfortable factor for determining the degree of curvature for highways and should not be confused with the maximum obtainable coefficient of friction between tire and pavement. A comfortable coefficient of friction is one that does not make it difficult to keep one's seat while traversing a curve. A comparison of results shown by the curves in Fig. 2 with accepted values of weaving distances is very favorable. Most studies of weaving distances have been made in perfecting the operation of traffic circles where sharp curvatures make the maneuver difficult.

Motorists traveling at high speeds do not like to apply their brakes. This reluctance on the part of the driver must be considered in the determination of the distance required for deceleration, or "slowing" on the highway will result. Values of motor deceleration have been determined by Donald W. Loutzenheiser,[2] Jun. Am. Soc. C. E., for passenger cars on a level grade.

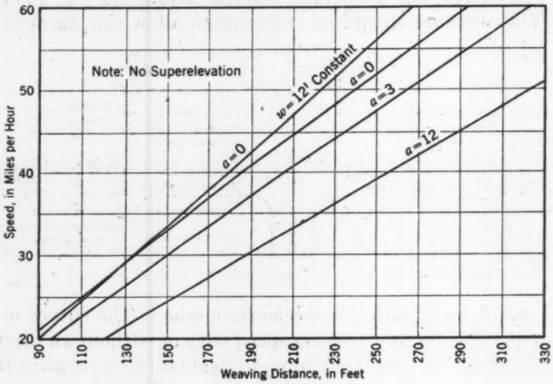

FIG. 2

"Motor deceleration" is the process of slowing the car in gear, with the foot off the accelerator. Fig. 3 gives motor deceleration distances for passenger cars on grades from 3% upgrade to 3% downgrade. These curves are based upon an extension of the results found by Mr. Loutzenheiser. The derivation of the mathematical formulas to include the effect of grade is presented in the Appendix. It was found that motor deceleration from a speed of 40 miles per hr or faster to a speed of 25 miles per hr or less, without resorting to braking, severely taxed the driver's patience. Drivers interviewed by the writer indicated that a preponderance of them think they do not apply brakes until they reach 35 miles per hr or 30 miles per hr, unless it is necessary to do so. Studies, by John Beakey,[3] of normal deceleration from speeds of 50 to 60 miles per hr by the public on approaching a "stop" sign at a highway intersection indicate that there is very little braking at 40 miles per hr, and to all practical purposes substantiate the belief of the persons interviewed. Best results should be obtained by varying the speed to which motor deceleration is assumed with the design speed of the highway (that is, assume 40 miles per hr for a 70-mile-per-hr highway and 30 miles per hr for a 50-mile-per-hr highway). This would be in keeping with the sensation of speed as felt by the driver as well as the time element involved.

The last part of the deceleration lane is that required for a comfortable braking distance from the end of the motor deceleration period to the speed at which it is desired to bring the motorist at the end of the lane. Fig. 4 shows curves for the comfortable braking distance from a given speed to a full stop

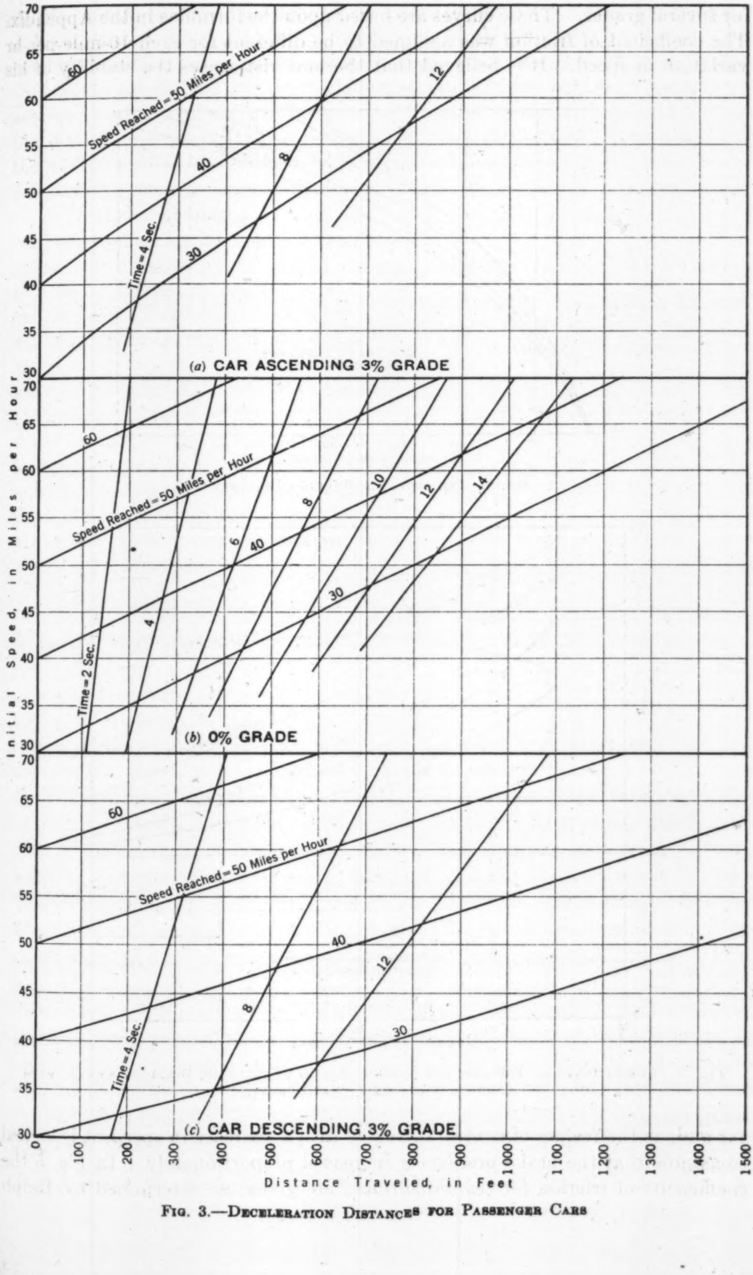

FIG. 3.—DECELERATION DISTANCES FOR PASSENGER CARS

for several grades. These curves are based upon the formulas in the Appendix. The coefficient of friction was assumed to be different for each 10-mile-per-hr variation in speed. It is believed that the motorist senses the stability of his car and, as the feeling of control increases with a decrease in speed, it is logical to assume that the brake pressure is increased proportionately. In Fig. 5 the coefficients of friction for several surfaces are given, as determined by Ralph

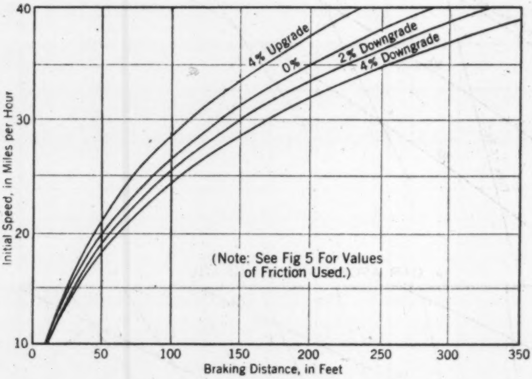

FIG. 4.—COMFORTABLE BRAKING DISTANCE

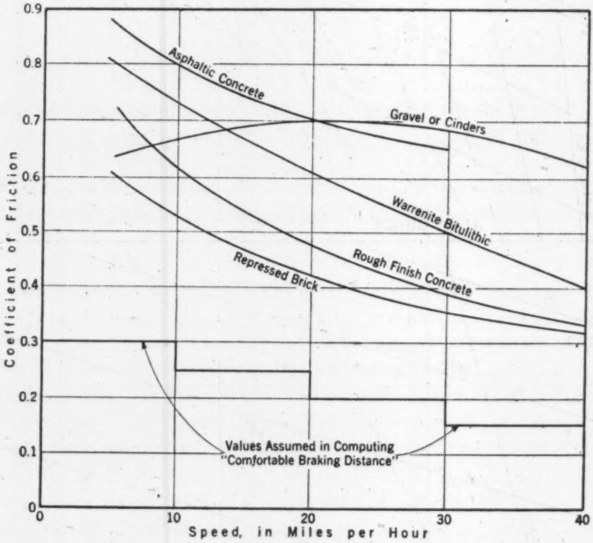

FIG. 5.—COEFFICIENTS OF FRICTION FOR VARIOUS SPEEDS (FULL SKID, STRAIGHT AHEAD, WITH SMOOTH TIRES ON A WET SURFACE)

A. Moyer,[4] Assoc. M. Am. Soc. C. E. Mr. Beakey concluded that a rate of deceleration corresponding to a coefficient of friction of about 0.4 is the maximum without discomfort to passengers. As it was desired to use values that would correspond closely to the usual habits of the average driver, it was assumed that a coefficient of friction of 0.15 at 40 miles per hr would increase to 0.3 at 10 miles per hr. The distances indicated in Fig. 4 checked closely with those observed by Mr. Beakey, which substantiate the assumptions made.

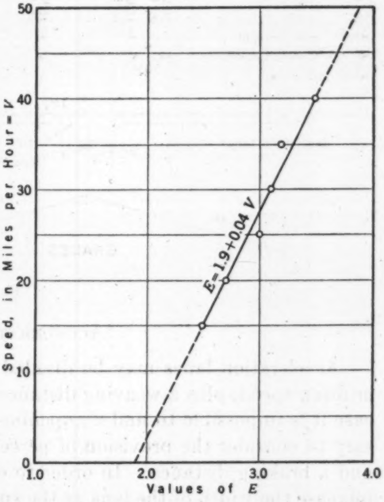

FIG. 6.—AVERAGE DISTANCE, *E*, OF RIGHT FRONT WHEEL FROM EDGE OF 22-FT CONCRETE PAVEMENT, IN FEET

A further refinement of the deceleration lane can be made by funneling. By funneling is meant to provide a decreasing width of lane as the speed decreases. Operators will not drive as fast on narrow as on broad pavement. J. T. Thompson and Norman Hebden[5] determined the average distance of the right front wheel from the edge of the pavement for speeds from 40 miles per hr to 15 miles per hr. Fig. 6 shows results of their observations with an extrapolation sufficient to cover most requirements. In this curve,

$$E = 1.9 + 0.04\,V \ldots\ldots (1)$$

is the average distance, in feet, of the right front wheel from the edge of a 22-ft concrete pavement. Until better information is available, it is suggested that these results be used as a basis for the variation in width of deceleration lanes, provided the minimum is kept at 11 ft.

To illustrate the application of the foregoing fundamentals to the approach of a filling station, attention is directed to Fig. 7. The cruising speed of the highway is assumed to be 50 miles per hr. Entering Fig. 2, it is found that a weaving distance of 265 ft will be required if a 3-ft insulation strip is used. The car is going up a 3% grade as it approaches the filling station, and (see Fig. 3(*a*)) a distance of 550 ft will be required for motor deceleration to a speed of 30 miles per hr, at which speed brakes are assumed to be applied. From Fig. 4 it is found that 120 ft would be required for a comfortable braking distance to a full stop. The 50-ft radius of the turn-in will permit a 15-mile-per-hr speed very comfortably. Therefore, it is not necessary to bring the motorist to a complete stop. From Fig. 4 it is found that the comfortable braking distance from a speed of 15 miles per hr to a complete stop is approximately 20 ft. The distance required for comfortable braking from a speed of 30 miles per hr to one of 15 miles per hr, therefore, is 120 − 20 = 100 ft. In this manner, and with these assumptions, it is found that a total distance of 650 ft is required to bring a car from a cruising speed of 50 miles per hr to a turning speed of 15 miles per hr.

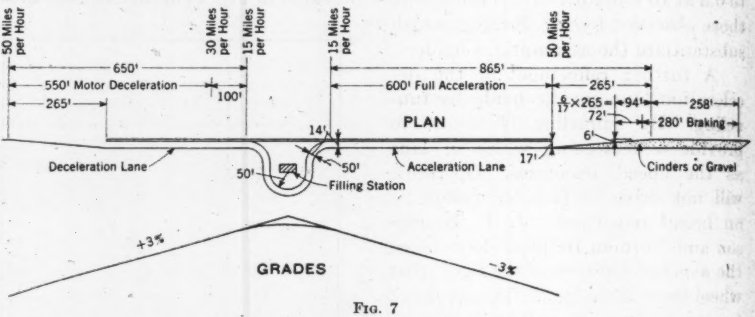

Fig. 7

Acceleration Lanes

Acceleration lanes may be divided into a distance for full acceleration to cruising speed, plus a weaving distance to permit entering the traffic lane. In case it is impossible to find an opening in the highway traffic, it will be necessary to consider the provision of perception distance, brake reaction distance, and a braking distance. In order to encourage acceleration, it is desirable to increase the width of the lane as the speed increases. The use of an insulation strip is advisable to make certain that the drivers cannot enter traffic in less than a distance sufficient to eliminate dangerous speed differentials.

Values of full acceleration distance were determined by Mr. Loutzenheiser.[8] He defined full acceleration as a maximum pickup possible under the control of typical drivers. The model cars tested varied from 1935 to 1937, and tests were made on flat grades. An extension of these results to include grades from 3% upgrade to 3% downgrade is given in Fig. 8. These curves are based upon the mathematical formula derived in the Appendix.

The weaving distance is the same as that for the deceleration lane. (In the treatment of acceleration and deceleration lanes, the weaving distance has been assumed the same whether for cars diverging from, or converging with, the traffic stream. Mathematically, the diverging weaving distance could be slightly smaller, provided that the accelerator was released on leaving the traffic lane, but, since the decrease in speed would be so small, no difference of practical importance would result.) It is further stipulated, however, that the weaving distance should not be less than perception distance plus a distance depending upon the ratio of the width of a car to that of the acceleration lane at the beginning of the weaving distance, as shown in Fig. 1.

Perception distances can be read directly for any speed from Fig. 9(*a*).

---

[8] "Speed-Change Rates of Passenger Vehicles," by Donald W. Loutzenheiser, *Proceedings*, Highway Research Board, National Research Council, Washington, D. C., 1938, p. 92.

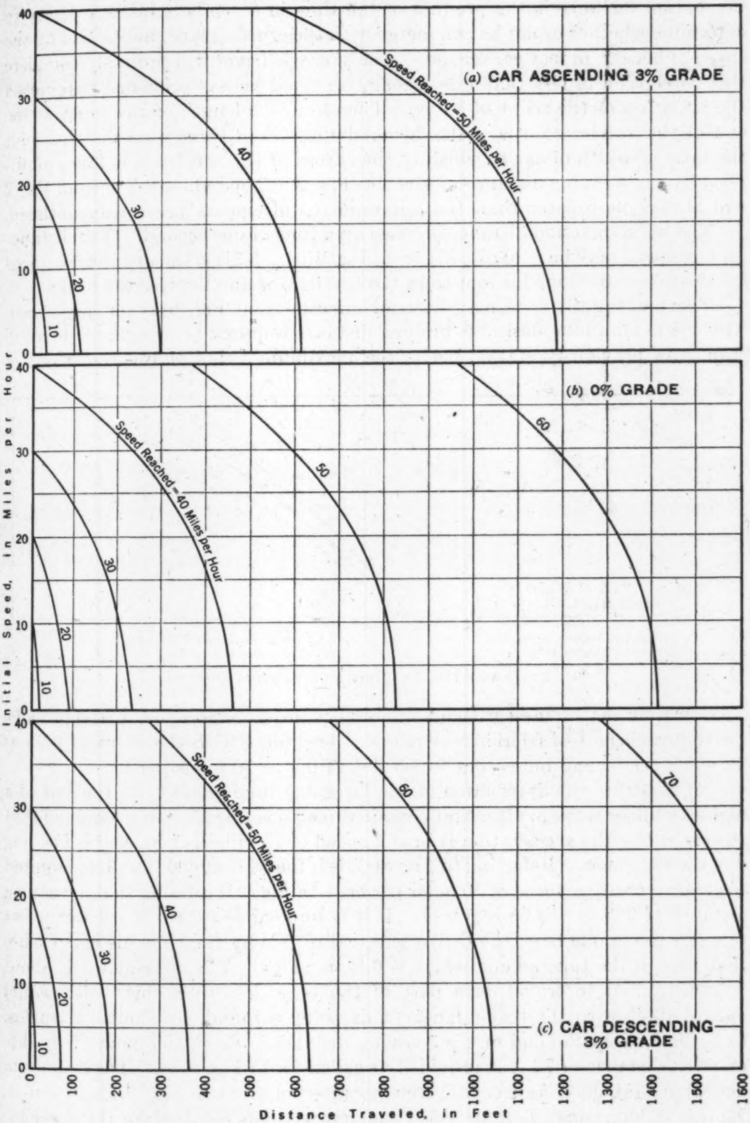

FIG. 8.—ACCELERATION DISTANCES FOR PASSENGER CARS

Perception distance is the product of the time in seconds it takes a driver to determine whether or not he can merge with the cruising lane, multiplied by the speed of his car, in feet per second. The average driver will probably complete this perception in less than one second, provided he has previously appraised the situation at the point of entry. Therefore, the length of the taper at the end of the acceleration lane should not be less than perception distance plus the ratio of width of car to width at the throat of the acceleration lane, multiplied by the weaving distance as given in Fig. 2. The values taken from Fig. 2 will always be greater than the minimum requirements previously outlined.

The brake-reaction distance is based on a time of one second. The distance for any speed may be read directly from Fig. 9(*a*). This is the distance required for the driver to move his foot from the accelerator and depress the brake.

The braking distance may be read directly from Fig. 9(*b*) for any speed. This is the minimum desirable braking distance required to bring a car to a full stop. As previously stated, 0.4 is the maximum value of the coefficient of friction that can be used without discomfort to passengers. A variable value for the coefficient of friction was adopted beginning with the value of 0.25 at 60 miles per hr and increasing to a value of 0.4 at 30 miles per hr.

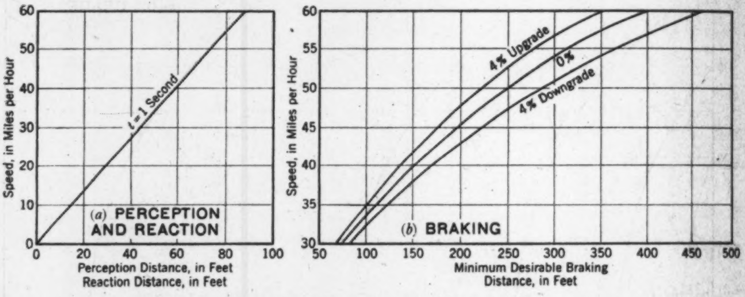

FIG. 9.—PERCEPTION, REACTION, AND BRAKING DISTANCES

To illustrate the application of the foregoing fundamentals to the exit of a highway filling station, attention is again directed to Fig. 7. It is assumed that the car enters the acceleration lane at a speed of 15 miles per hr, and is heading down a 3% grade. Referring to Fig. 8(*c*), it is found that 600 ft will be required to attain a cruising speed of 50 miles per hr. In Fig. 2 it is found that a weaving distance of 265 ft will be required. If it is impossible for the accelerating car to enter the traffic lane, the driver will realize this by the time his car reaches that part of the tapered end which is 6 ft in width. The average car is about 6 ft wide, and to travel on a part of the taper less than this width would mean entry on to the traffic lane. This point is found, by similar triangles, to be 94 ft from the end of the weaving distance. From this point, a brake-reaction distance of 72 ft is provided as called for in Fig. 9(*a*). The minimum desirable braking distance, as given by interpolation in Fig. 9(*b*), is 280 ft. Thus it is determined that an 865-ft concrete apron is required for the acceleration lane. It is found further that an additional 258 ft of the improved shoulder should be provided for emergency stops.

JUSTIFICATION

The provision of adequate acceleration and deceleration facilities at the intersection of a high-speed with a low-speed roadway or turn may be justified by accident experience. Of the accidents on the Schuyler Merritt Parkway, in Connecticut, 71% have been due to internal stream friction. Most of these were further classified as rear-end collisions. Since actual trials indicate that many of the exits and entrances to this highway permit speeds no higher than 20 miles per hr, there remains little doubt as to the location of a sizable percentage of the rear-end collisions, although locations given on accident reports have been too indefinite to be positive in this matter. In cases of this kind, which involve state highway intersections and state-owned roadside parks, there is manifestly a responsibility falling on the state to provide adequate facilities.

The entrances and exits of private property and small business establishments present a problem. It has been estimated that there is a filling station for each 1½ miles of highway. The cost of providing adequate acceleration and deceleration lanes would be several times the value of most of these stations. The problem is even greater when all the eating houses, open-air theaters, etc., are added to the filling stations. Regulation by the state department of traffic control can do much to improve existing conditions on the basis of cooperation between the state and the individual, but the complete solution advocated in this paper appears to be economically justifiable only where the right of access of the abutters is purchased along with the right of way, as has been done in the building of parkways and freeways. It has been predicted that the next decade will bring 25,000 miles of new parkways and freeways, which in itself promises a sizable interest in the problem of speed-change lanes. Once the abutter has no right of access, it is possible to space filling stations so as to leave no doubt of the warrants for the provision of correctly designed acceleration and deceleration lanes.

ACKNOWLEDGMENTS

The writer wishes to express his appreciation to all members of the staff of the Yale Bureau for Street Traffic Research for their encouragement and sound suggestions. Special credit is due Leslie Williams for his painstaking assistance in improving the manuscript.

CONCLUSION

It is concluded that acceleration and deceleration lanes can be reduced to component parts that can be individually analyzed and determined with sufficient accuracy for design purposes. Existing highways have not been provided with adequate acceleration and deceleration lanes. Failure to make such provision has necessitated deceleration to a low speed in the main traffic lanes. As speeds have increased, accident records have disclosed the danger in creating a large differential in speed between traffic on the highway and traffic in the process of leaving or entering it. In designing entrances and exits for an express highway, the principal pitfall to be avoided is insufficient lengths. The motorist will not leave the highway at cruising speed if he knows

it will be necessary to bring himself to a violent stop on a deceleration lane that is much too short. He cannot avoid dangerous differentials in speed if the acceleration lane is too short.

APPENDIX

DERIVATION OF FORMULAS

***Weaving Distance*.—From geometry, "the sum of the squares of the legs is equal to the square of the hypotenuse"; hence (see Fig. 10),**

$$\left(\frac{L}{2}\right)^2 + \left(r - \frac{W}{2}\right)^2 = r^2 \text{..(2a)}$$

or

$$L = \sqrt{W\,(4\,r - W)} \text{..(2b)}$$

Standard texts develop the formula for superelevation:

$$r = \frac{V^2}{15\,(f + e)} \text{....(3)}$$

in which: V = speed in miles per hour; f = coefficient of friction; e = superelevation in feet per foot; and r = radius in feet.

The edge clearance,[5] in feet, should be equal to $1.9 + 0.04\,V$ (see Fig. 6); hence

$$W = a + b + 3.8 + 0.08\,V \text{.(4)}$$

in which: a = width of insulation strip in feet; and b = width of car in feet.

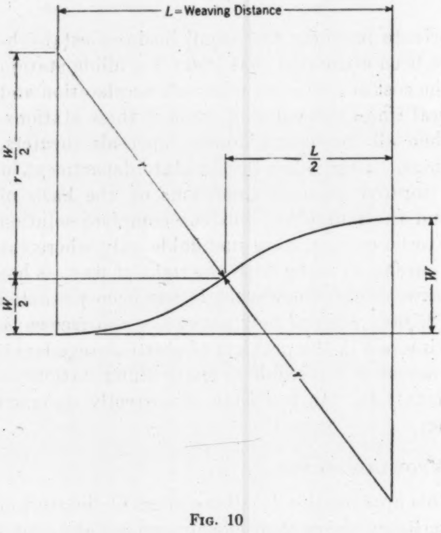

FIG. 10

***Motor Deceleration Formulas*.—From Newton's Second Law of Motion and Fig. 11, the effect of grade on motor deceleration is:**

$$\text{Deceleration} = -\,g\,\frac{G}{100} \text{..................(5)}$$

in which g = acceleration of gravity in feet per second[2] and G = per cent grade. The motor deceleration[2] is as shown in Fig. 12 for flat grades; hence

$$\text{Motor deceleration} = -\,a = \frac{3}{100}\,(v + 15) - g\,\frac{G}{100} \text{.......(6)}$$

Integrating and converting v to miles per hour:

$$\left(V + 10 - g\,\frac{G}{4.5}\right) e^{(3/100)t} = \bar{V} + 10 - g\,\frac{G}{4.5} \text{..........(7)}$$

in which t = time in seconds; $\bar{V}$ = initial speed; and V = final speed. Integrating again, the deceleration distance is

$$s = 50\left[-\left(10 - g\frac{G}{4.5}\right)\log_e\left(\frac{\bar{V} + 10 - g\dfrac{G}{4.5}}{V + 10 - g\dfrac{G}{4.5}}\right) + (\bar{V} - V)\right] \quad (8)$$

in which G changes sign to minus for uphill travel.

Braking Distance.—Let G = per cent grade; F = force in pounds; $\bar{V}$ = initial speed in miles per hour; V = final speed in miles per hour; s = braking distance in feet; W = weight of vehicle in pounds; g = 32.2 ft per sec²; and f = coefficient of friction. From energy conservation:

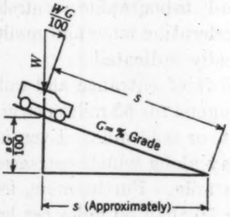

FIG. 11.—EFFECT OF GRADE

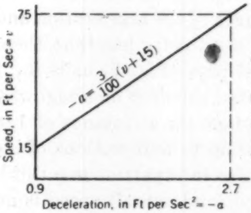

FIG. 12

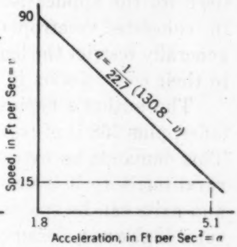

FIG. 13

$$F \times s = \frac{1}{2}\frac{W}{g}(1.47)^2(\bar{V}^2 - V^2) + \frac{WG}{100}s = \frac{W}{g}(fg)s \quad (9)$$

For downhill travel (solving Eq. 9 for s):

$$s = \frac{\bar{V}^2 - V^2}{30f - 0.3G} \quad (10a)$$

and, for uphill travel:

$$s = \frac{\bar{V}^2 - V^2}{30f + 0.3G} \quad (10b)$$

Full Acceleration.—From Newton's Second Law of Motion and Fig. 11, the effect of grade on full acceleration is:

$$\text{Acceleration} = g\frac{G}{100} \quad (11)$$

Full acceleration² is as shown in Fig. 13 for flat grades; hence,

$$\text{Full acceleration} = a = \frac{1}{22.7}(130.8 - v) + \frac{gG}{100} \quad (12)$$

Integrating twice, the acceleration distance is:

$$s = 34.05\left[(87.2 + 0.1513\,gG)\log_e\frac{87.2 - \bar{V} + 0.1513\,gG}{87.2 - V + 0.1513\,gG} - (V - \bar{V})\right] \quad (13)$$

In Eq. 13, G is positive for downhill travel and negative for uphill travel.

DISCUSSION

H. F. Holley,[7] **M. Am. Soc. C. E.** (by letter).—The design of acceleration and deceleration lanes as presented in this paper clarifies a theory that engineers engaged in highway design have been applying in a more or less rule-of-thumb manner for many years.

Acceleration and deceleration lanes are fast becoming the rule rather than the exception in modern highway construction, especially in the design of motorways in metropolitan areas. However, the opportunity rarely presents itself for the application of theory in laying out motorway entrances and exits in congested metropolitan areas. Land values and topographic controls generally restrict the length of the acceleration and deceleration lanes and result in their construction in lengths far less than theoretically indicated.

The author's typical plan (Fig. 7) calls for 1,665 ft of entrance and exit lanes, plus 258 ft of treated shoulder on a highway designed for 50 miles per hr. This demands an extra lane for a distance of 1,923 ft, or 0.36 mile. Even in rural territory it is unusual to find sections of highway along which entrances and exits can be spaced as far apart as one third of a mile. Furthermore, for rural highways, designed (and actual) speed is nearer 70 than 50 miles per hr. Entrance-exit treatment as proposed by Mr. Mitchell on most 60-mile rural highways would call for a continuous extra lane. It was this condition that led to the practice of establishing "service roads" on either side of high-speed rural highways in territory subject to development—first into residential, then small business, and finally into "shoestring" business use.

In the writer's judgment, Mr. Mitchell has been ultraconservative in his requirements for motor deceleration and braking distances. Extensive observations on driver habits in the Los Angeles (Calif.) metropolitan area indicate that deceleration by engine compression is seldom practiced. California drivers tend to approach even a boulevard "stop" intersection under power, and apply their brakes immediately after releasing the throttle. Upon approaching a signalized intersection, the tendency is to speed up in the hope of finding the signal on the "go" upon arrival at the intersection.

TABLE 1.—Braking Distances, in Feet

Agency	Year	Speed in Miles per hr		
		20	30	40
National Safety Council	1935	21	47	84
Aetna Casualty and Surety Company	1935	22	49.5	88
"Traffic Engineer and the Police"; consulting bureau	1938	26	57	101
National Bureau of Standards	1935	28	62	109
Automobile Club of Southern California	1930	22.2	50	89

The "comfortable braking distance," shown graphically in Fig. 4, indicates about 50 ft to stop from a speed of 20 miles per hr, 135 ft from a speed of 30 miles per hr, and 280 ft from a speed of 40 miles per hr. Table 1 shows the braking distances determined from experiments by the agencies listed. It is admitted that these braking distances are more in the nature of emergency braking, rather than "comfortable" braking distances. Also, they do not include "reaction-time distance" which, using the accepted reaction time of 0.75 sec, would add 22, 33, and 44 ft, respectively, to the braking distances shown at 20, 30, and 40 miles per hr.

---

[7] Asst. Chf. Engr., Automobile Club of Southern California, Los Angeles, Calif.

Mr. Mitchell's paper provides an objective toward which designing engineers should strive. However, in metropolitan motorway design the ideal entrance and exit ramp rarely can be achieved.

The Arroyo Seco Parkway, a motorway extending from the heart of metropolitan Los Angeles to the neighboring City of Pasadena, completed in 1940, involved twenty-two vehicular crossings in a distance of 6 miles. It was impossible, due to constriction caused by the Arroyo Seco Channel and other topographic features, to build conventional "clover leafs" at points of vehicular interchange. It was also impossible, due to the large number of intersecting streets, to design entrance and exit lanes of desired length. However, nonstop motorway features were adhered to, the design calling for two 35-ft roadways separated by a planting strip, no intersections at grade, no left turns, and the prohibition of ingress and egress from abutting property. To compensate for the lack of the desired length of the acceleration and deceleration lanes, a "compressed clover leaf" was designed at most interchange crossings. Generally (see Fig. 14), the exit and entrance ramps at intersecting streets are approximately parallel to the motorway; and, due to the fact that the motorway roadway is depressed, the exit ramps are on ascending grades, whereas the

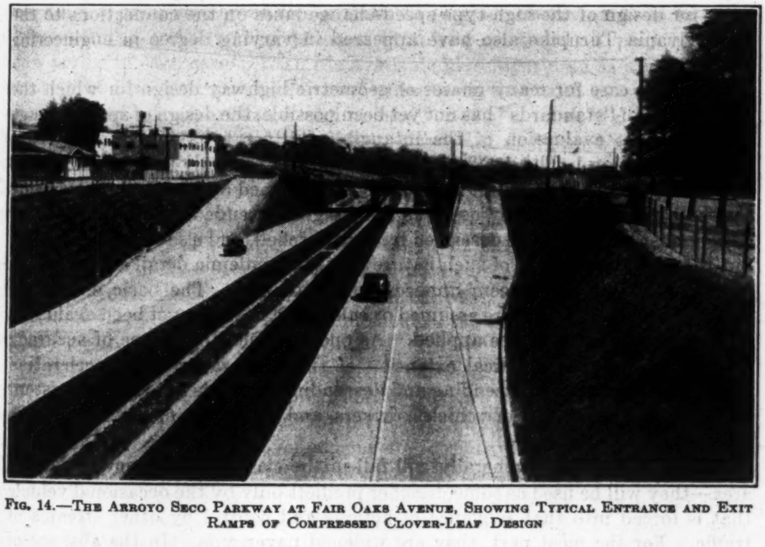

FIG. 14.—THE ARROYO SECO PARKWAY AT FAIR OAKS AVENUE, SHOWING TYPICAL ENTRANCE AND EXIT RAMPS OF COMPRESSED CLOVER-LEAF DESIGN

entrance ramps are on descending grades, permitting relatively fast deceleration and acceleration, with the path of the entering or leaving car roughly parallel to the main roadway. In spite of the fact that entrance and exit lanes are much shorter than indicated as desirable under Mr. Mitchell's theory, traffic using the Arroyo Seco Parkway (which averages about 40,000 vehicles per day) experiences little difficulty in entering or leaving the motorway, and there has been a very favorable accident experience at interchange points.

In the case of an elevated motorway, with intersecting streets crossing under the structure, an unfavorable deceleration and acceleration situation would be encountered at interchange points, and longer exit and entrance lanes should be provided.

Mr. Mitchell is to be commended for reducing to scientific form a matter that highway engineers have been inclined to treat in a haphazard manner.

D. W. Loutzenheiser,[8] Jun. Am. Soc. C. E. (by letter).—The subject of speed-change lanes is an important phase of highway design, to which considerable research and study should be applied. Although the author infers that his paper is the initial attempt to rationalize design of speed-change lanes, it appears to be an academic discussion, somewhat extended in detail, of a design approach made in a paper[9] published elsewhere, in 1940. The details of the bases for design of the high-type speed-change lanes on the connections to the Pennsylvania Turnpike also have appeared in varying degree in engineering publications.

As is the case for many phases of geometric highway design for which the preparation of "standards" has not yet been possible, the design of speed-change lanes involves evaluation of the intangible "driver behaviors" to evolve a practical solution. The result must be simple and perfectly understandable to those using it, but above all it must be so dimensioned and located that drivers can, and will, automatically use it as the designer intended. The approach for design must be of the type described by Mr. Mitchell, and elsewhere previously, but the entire problem is of such nature that the academic detail and precision of values in this paper seem unnecessarily extensive. The basic data upon which the various factors are assumed or calculated have not yet been evaluated to the degree that they are applied. As one example, the degree of accuracy inferred in the mathematical extension of the acceleration and deceleration rates (Figs. 3 and 8) for ascending and descending grades is not at all consistent with the limited number of vehicles, drivers, and conditions of test from which the rates were determined.

Speed-change lanes generally will fall in the class of emergency pavement area—they will be used as some designer predicts only by the occasional vehicle that is forced into that sequence of actions and control by other streams of traffic. For the most part, they are widened pavements. In the absence of other traffic, drivers will enter or leave the outer lane with considerable variance in position and speed, as found necessary at the particular instant. One large field of application of speed-change lanes is at intersections on two-lane and three-lane roads. As shown in Figs. 1 and 7, Mr. Mitchell obviously excludes these cases in order to introduce the insulation strip. The writer feels that in most instances, even along express highways, the flow of traffic will not be facilitated to the extent possible by considering long insulation strips as an essential part of the design. Their chief function is to prevent improper left turns, but as far as use of the speed-change areas is concerned they are better omitted or limited to short lengths. It is stated that the function of the insulation strip is to eliminate points of conflict. The introduction of such strips adds an island point that may be more hazardous than beneficial.

---

[8] Associate Highway Engr., Div. of Design, Public Roads Administration, Washington, D. C.

[9] "A Policy on Intersections at Grade," Am. Assoc. of State Highway Officials, 1940.

In reference to Fig. 6, Mr. Mitchell states that operators will not drive as fast on narrow pavement as on broad pavement, citing data reported by Messrs. Thompson and Hebden as proof.[5] This is questionable usage—conditions other than pavement width usually determine speed of travel on any highway. The important point is that faster traffic generally will drive a greater distance from the edge of pavement than will slower traffic on the same pavement. The placement data quoted[5] were observations on the average position of a "critical vehicle"—that is, placement on a two-lane road as the vehicle was passed by another vehicle. This may or may not be representative of placement on a one-way road, or on roads of other widths; but it does not prove that narrower pavements result in lower speed operations. A study in Missouri[10] reported in 1940 showed that high-speed traffic traveled just as fast on an 18-ft as on a 20-ft pavement, with average speeds of 53 miles per hr, and a top speed of 88 miles per hr in each case. With the available placement data as a basis there seems to be little justification for any variation in the width of speed-change lane, provided it is wider than a minimum of 11 or 12 ft. A desirable width for a one-way lane is 14 ft, barely permitting passage at slow speed past a vehicle stalled on the lane. In the case of the deceleration lane it is fundamentally incorrect to provide narrower widths as the sharp radius curve (50 ft) is approached. The lane width around this curve should be 14 to 17 ft as a minimum.

The evaluation of weaving distance might be clearer if also expressed as a time interval. The speed-distance values calculated from a friction factor of 0.16 approximate that for about a 3-sec interval, which method of presentation is not as suggestive of great refinement in the accuracy of the calculation bases.

A comprehensive study of the speed, placement, driver behavior, and all other pertinent factors in the operation of vehicles on existing speed-change lanes is sorely needed as a basis for proper design of such lanes. Until such data are secured any great refinement for design details based largely on assumptions for the various factors should be considered only as of academic value. Even a short length of added lane will facilitate the flow of vehicles turning sharp curves. Although the benefits of longer lengths of added lane may be anticipated (and doubtless correctly so), it cannot yet be implied or stated that they are proven. It is to be hoped that this paper will focus attention on the need for field data to be used as a basis for proper design of speed-change lanes.

---

[10] "Speed of Motor Vehicles on Missouri Highways," Missouri State Highway Dept., 1940.

HAWLEY S. SIMPSON,[11] M. AM. SOC. C. E. (by letter).—Mr. Mitchell has opened a very interesting subject, and one that has been largely ignored in the past. Entrances and exits to and from high-speed highways have been mainly designed by the "catch-as-catch-can" method. As more express highways in rural districts are built, greater attention must be given to reducing the effect of conflicts caused by vehicles entering and leaving the highway.

With the general principle of the deceleration lane the writer is thoroughly in accord. Regardless of whether traffic is light, or whether it is heavy, vehicles about to leave an express highway may be followed closely by others moving at the same speed. To move the turning vehicle out of high-speed traffic without slowing following vehicles and to reduce the probability of rear-end collisions are the purposes of the deceleration lane. The design proposed by Mr. Mitchell fulfils these requirements quite adequately. The only valid criticism is that it may be too adequate. The author has treated the motorist with greater consideration than the economics of the situation warrants. With the little that is known about habits of drivers it seems quite possible that they would react as favorably to a design that does not involve the rather long distances proposed by Mr. Mitchell. From his own driving experience, the writer sees no reason why such a lane should not be designed to permit deceleration, without braking application, to 40 miles per hr instead of 30 miles per hr and then require a much harder brake application than that proposed by Mr. Mitchell to reduce the speed of the vehicle to a safe turning speed.

The deceleration lane designed by Mr. Mitchell will give the impression of extreme length, and many, if not most, drivers will continue at "cruising" speed for some distance down the deceleration lane. Then they will coast to about 40 miles per hr, and make a much harder brake application than that required by the use of a coefficient of friction of 0.16.

The design of an acceleration lane, however, is in a decidedly different category. Nevertheless, Mr. Mitchell has applied practically the same principles in reverse order. Here the vehicle is assumed to enter the acceleration lane at a relatively low speed and accelerate exactly to cruising speed. The driver reaches this speed at precisely the point where he is expected to begin "weaving" into the cruising lane. At this exact time he must find a gap in traffic sufficient to accommodate his vehicle, and one that will provide clearance space between preceding and following cars, or he must abandon the maneuver and make a hard brake application in the emergency stopping space. There he will await an opening in traffic and enter just as if no acceleration lane had been provided.

Whether such a lane is proper is a moot question. Consider the two extremes of traffic—(1) extremely light, and (2) extremely heavy. In the first situation, there is a high probability that the required opening will be available upon arrival at the weaving section. If this is so, why is an acceleration lane necessary? Would it not be just as feasible and much less expensive to require the vehicle to come to a full stop at a normal right-angle intersection and await an opportunity to enter which, theoretically, would present itself almost immediately?

---

[11] Research Engr., Am. Transit Assn., New York, N. Y.

At the other extreme, when traffic on the main highway is very dense, the probability that the driver, having reached cruising speed, will be able to enter the traffic stream at the exact moment he arrives will be so remote that a very large percentage of the entering vehicles will be forced to use the emergency stopping area. Thus, they will be required to enter the traffic stream exactly as if there had been no acceleration lane; in other words, as if the intersection had been designed as a normal right-angle entrance.

For traffic volumes between these two extremes the condition will partake of the nature of either one or the other of the two cases just described.

Thus, it seems more logical to forego the construction of an acceleration lane, and to require traffic to stop at the entrance to a high-speed highway and await an opportunity to enter without interfering with other vehicles.

From the standpoint of accidents it seems likely that this solution is preferable to the construction of a deceleration lane. A driver in a car moving on to a main highway, and at the same speed as the traffic on it, is in a most difficult position to see and appraise the speed and position of vehicles at his left rear. His chances of being able to enter that traffic at the precise point where there happens to be an opening is so slight as to insure a marked increase in traffic accidents. Construction of such lanes should proceed cautiously until an opportunity has been afforded to learn the outcome more accurately.

Commenting upon the accident experience on the Merritt Parkway in Connecticut under the heading "Justification," Mr. Mitchell states, from rather inconclusive evidence, that: "there remains little doubt as to the location of a sizable percentage of the rear-end collisions * * *." The writer doubts if this conclusion is warranted by the facts and strongly urges a more intensive accident study of highways of this kind before exact conclusions are attempted. Many hours of driving on the Merritt Parkway have led the writer to conclude that there is a substantial potential hazard in the inadequacy of the deceleration lanes, and relatively little hazard at entrance points which, though providing a short length of additional roadway width, partake more nearly of conventional design.

MILTON HARRIS,[12] ASSOC. M. AM. SOC. C. E. (by letter).—The "Design of Acceleration and Deceleration Lanes" has been treated admirably by Mr. Mitchell in segregating the design requirements into their component parts. This approach allows one to weigh the relative importance of each element and to give consideration to the data upon which the design is founded.

Following this line of thought, there seems to be little to criticize in application of the tables and curves if they are assumed to be inherently correct and applicable to this problem. The only exception in application seems to lie in advocating an improved shoulder for braking distance beyond the exit from the acceleration lane. It would seem that a car using the acceleration lane could see parallel moving vehicles and so adjust its speed, while still within the lane, to permit it to mix without stoppage when the exit was reached. This presumes that the insulating strip is a low curb or fin across which a motorist can see. An insulating strip is an excellent device to channelize traffic.

---

[12] Associate Highway Engr., State Div. of Highways, Sacramento, Calif.

One element of design that does not seem to be included in the paper is the relation of volume to lane length and width. This is of particular importance when designing acceleration and deceleration lanes for large turning movements and storage where at least two lanes are required to handle the volume efficiently. The problem grows still more complicated when consideration is given to the necessity of crossing deceleration volumes with the acceleration stream at an intersection and signalization is introduced.

One is led to believe that traffic engineers are prone to accept formulas and experimental data without due regard to their practical application, both from an economic as well as a traffic standpoint. The data presented in this paper in the form of tables and curves have been collected over a period of time under conditions that were hardly similar to those presented. Although it cannot be said that such data are not applicable to this design problem, the fact still remains that much research must be conducted to ascertain if fundamental data are applicable to a variety of conditions.

With an unlimited laboratory at the "front door," it is suggested that new designs for traffic use be subjected to actual test under a variety of conditions before adoption. In the case of acceleration and deceleration lanes, an improved shoulder adjacent to an intersecting road could be used and sandbags placed to simulate the insulating island. The speed, volume, and wheel placement patterns could be collected and analyzed for various lengths of lane under similar conditions, thus proving or disproving the theoretical deductions in so far as that one locality was concerned.

T. F. HICKERSON,[13] M. AM. SOC. C. E. (by letter).—One of the hazardous and annoying features of highway transportation to which even the most careful drivers are subjected is that incident to traffic unexpectedly entering or leaving the highway at speeds different from that of the traffic stream. For the freeway, express highway, parkway, or super-highway of tomorrow, where abutting traffic has no right of access except at widely separated intervals, the foregoing hazards may be greatly minimized if entrance and exit lanes are built in accordance with the general considerations brought out so thoroughly by Mr. Mitchell.

The deceleration equation, Fig. 12, may be simplified perhaps if written as follows:

$$a \text{ (or } -a) = 1.35 + 0.03\,v \quad \ldots\ldots (14)$$

Likewise, the acceleration equation, Fig. 13, might be written

$$a = 5.76 - 0.044\,v \quad \ldots\ldots (15)$$

In changing from v (feet per second) to V (miles per hour) it is a little confusing to the reader to note the ratio 1.47 (the strictly correct value) in Eq. 9, whereas the approximate value of 1.50 is used in Eqs. 7, 8, 12, and 13. Obviously the difference is of no practical significance.

---

[13] Prof. of Applied Math., Univ. of North Carolina, Chapel Hill, N. C.

Since $v = \frac{ds}{dt}$ and $a = \frac{dv}{dt}$; by division, $\frac{v}{a} = \frac{ds}{dv}$; or, $ds = v\,\frac{dv}{a}$. Hence, Eq. 8 may be obtained directly from Eq. 6, by only one integration, instead of from Eq. 7. In a similar manner, Eq. 13 may be derived from Eq. 12 by one integration instead of two, as suggested by the author. These latter comments are trivial and are merely offered for what they may be worth as constructive criticism of a timely and valuable paper.

W. L. WATERS,[14] M. AM. SOC. C. E. (by letter).—Although this paper is very interesting, it is somewhat academic and it is based on assumptions, so that the tables and formulas given may create an unwarranted feeling of confidence in a designer who uses them.

The paper may be criticized for neglecting the practical features of the problem as distinct from the academic ones. In any highway where high speed (say, 40 miles per hr) is permitted on the outside lane, and where the traffic is fairly dense (say, 1,000 cars per hour in that lane), the only safe procedure is for the incoming motorist to come to a full stop and await an opening in the traffic. From the converging acceleration lane good vision of the oncoming traffic is impossible, and any attempt to break into a line of oncoming high-speed traffic at this point is dangerous.

The author's method of designing the deceleration lane is very safe; but the entry of cars into high-speed traffic is always a danger point. For the latter, the most practical and safe plan seems to be to limit the speed in the outside lane, place conspicuous warning signs one-quarter mile ahead of any entrance, and make all incoming traffic come to a full stop.

R. A. MOYER,[15] ASSOC. M. AM. SOC. C. E., AND DONALD T. DAVIDSON,[16] JUN. AM. SOC. C. E. (by letter).—In the paper on the design of acceleration and deceleration lanes, Mr. Mitchell has focused attention on certain relatively new design details which highway engineers are slowly recognizing as worthy of consideration in the design of the modern highway. The planning of details in the method of handling traffic at intersections and entrance and exit lanes will always be a challenge to the highway designer's ingenuity. There are also certain fundamental principles in design involving vehicle behavior with its limitations, and driver behavior with the driver's limitations, which are gradually being recognized by engineers and for which standards of performance are being established. As the results of field tests and related research yield new and more exact information on these subjects, it is to be expected that closer agreement in these standards will result.

In general, the writers are in agreement with the standards that Mr. Mitchell has recommended, and consider them quite reasonable on the basis of the results of tests conducted by the writers in 1941. In this discussion certain refinements in the design of the curves are offered, with comments in regard to certain other elements in the design proposed by the author which appear to be worthy of consideration.

---

[14] Cons. Engr. (Bury & Waters), New York, N. Y.

[15] Research Associate Prof., Highway Eng., Iowa State College, Ames, Iowa.

[16] Research Graduate Asst.-Highway Engr., Eng. Experiment Station, Iowa State College, Ames, Iowa.

The author computed the values for weaving distance in both the deceleration and acceleration lanes on the basis of a reverse curve composed of two symmetrical circular curves. He states (see heading "Deceleration Lanes"): "The assumption of an **S**-path of travel is a theoretical expedient entirely, and there is no doubt that drivers would find a spiral path more natural than a reverse circular path." He further states: "The formula derived on the basis of the **S**-path contains all the variables involved in the natural path." The writers have taken exception to the latter statement because an examination of the author's formulas, and the very fact that no provision is made for the natural spiral path in the formulas, indicates that the important variable C, the rate of change of acceleration, is not considered. The value of C reflects the driver's ability or skill in steering a car along a definite path from a tangent to a curve or from one curve to any other curve with a reasonable degree of accuracy in a given distance or length of time. The use of the reverse circular curve or of the straight-line transition from one lane to the other, as shown in Fig. 1, adds little to the economy of construction or to the appearance of the design. This type of construction is almost certain to provide too abrupt a change in direction and too short a length in the weaving distance because it does not provide a natural path that the driver can follow easily.

To clarify this important phase of design of exit and entrance lanes, values of weaving distance were computed on the basis of a natural path composed of four equal spiral curves transitional throughout using the same speeds and values of W as in Fig. 2. In addition to the mathematical analysis, a series of carefully controlled road tests were run to determine minimum lengths of weaving distances using a test car whose characteristics were well known from previous tests on highway curves.

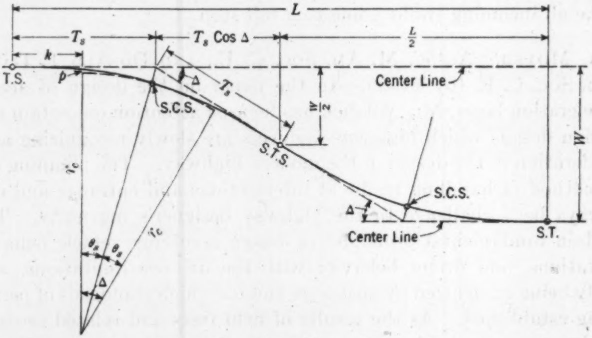

FIG. 15.—REVERSE CURVE COMPOSED OF FOUR EQUAL SPIRALS TRANSITIONAL THROUGHOUT

In the mathematical analysis for the determination of the weaving distance, the standard spiral formulas, as recommended by the Iowa Engineering Experiment Station [4] and by the U. S. Public Roads Administration,[17] were used.

---

[17] "Transition Curves for Highways," by Joseph Barnett, Bureau of Public Roads, U. S. Dept. of Agriculture, U. S. Government Printing Office, Washington, C. D., 1938, pp. 7-26.

The proposed curve layout is shown in Fig. 15, and from this it is evident that the weaving distance L may be computed as follows:

$$L = 2\,[T_s + T_s \cos \Delta] = 2\,[T_s\,(1 + \cos \Delta)] \quad \text{.......... (16)}$$

Since the tangent distance T_s and the length of each spiral L_s are approximately equal,

$$L = 2\,[L_s\,(1 + \cos \Delta)] \quad \text{.......... (17)}$$

The standard formula for length of spiral L_s is

$$L_s = \frac{3.16\,V^3}{C\,r_c} \quad \text{.......... (18)}$$

in which V is the speed in miles per hour, C is the rate of acceleration in feet per second^3, and r_c is the radius of the circular curve in feet. Substituting this value for L_s in Eq. 17,

$$L = 2\left[\frac{3.16\,V^3}{C\,r_c}\,(1 + \cos \Delta)\right] \quad \text{.......... (19)}$$

The standard curve formula for the determination of the radius r_c is

$$r_c = \frac{0.067\,V^2}{f + e} \quad \text{.......... (20)}$$

in which f is the coefficient of friction and e is the superelevation in feet per foot.

Substituting the value for r_c in Eq. 19, and using a value of e equal to zero, will reduce the value of L to

$$L = 2\left[\frac{47.1\,f\,V}{C}\,(1 + \cos \Delta)\right] \quad \text{.......... (21)}$$

For a spiral curve that is transitional throughout, the intersection angle Δ is equal to the sum of the two spiral angles θ_s. Since the standard formula for the spiral angle θ_s is

$$\theta_s = \frac{L_s\,D_c}{200} \quad \text{.......... (22)}$$

in which D_c is the degree of the circular curve, then

$$\Delta = \frac{L_s\,D_c}{100} \quad \text{.......... (23)}$$

The spacing W between the center line of the highway and of the exit or entrance lane can be computed for any value of L by using the formula

$$W = 2\,L_s \sin \Delta \quad \text{.......... (24)}$$

A summary of the computed values for weaving distances L and lane spacings W for speeds from 20 to 60 miles per hr for values of friction f and rates of change of acceleration C in the usual operating range is given in Table 2. The values of coefficient of friction used in these computations ranged from 0.10 to 0.20. A value of $f = 0.20$ is generally accepted as a reasonable design value for speeds of 20 miles per hr or less, and a value of 0.16 is the standard value for speeds from 30 to 60 miles per hr. For speeds greater than 60 miles per hr a value of $f = 0.10$ is preferred. The values of C can be treated in like manner—that is, use a value of $C = 4$ ft per sec^3 for speeds of 20 miles per hr or less, $C = 3$ ft per sec^3 from 30 to 60 miles per hr, and a value of $C = 2$ ft per sec^3 for speeds greater than 60 miles per hr.

TABLE 2.—"WEAVING DISTANCE" VALUES FOR REVERSE CURVES COMPOSED OF FOUR EQUAL SPIRALS, TRANSITIONAL THROUGHOUT

Speed, in miles per hr	f	R_c, in ft	D_c, in degrees	$C = 2$			$C = 3$			$C = 4$

As a result of the mathematical analysis, it was apparent that for any given values of f and C only one value for length of weaving distance L and one value for spacing W was possible if four equal spiral curves, transitional throughout, were used. To determine the length L for any given value of W, changes in the design values of f or C are required. To obtain smaller values of W than those determined using the recommended design values for f and C, a reduction in the value of f is the safest procedure. To obtain larger values of W than those determined using the recommended design values for f and C, a reduction in C is the safest procedure. It should be noted in Table 2 that, with $W = 16.8$ ft for a speed of 20 miles per hr, $f = 0.16$, and $C = 4$, the length L is 149.0 ft; whereas with very nearly the same distance $W = 16.6$ ft at the same speed, $f = 0.10$, and $C = 2$, the length L is 187.5 ft. This increase of 38.5 ft in the length of L is an increase of only 25% and indicates that the changes in weaving distance within the ordinary range in design values of f and C will not vary by more than from 25% to 30%.

On the basis of the foregoing analysis Fig. 16 for weaving distance was prepared using a constant value of $W = 12$ ft and values of a equal to 0, 3, 6, and 9 ft for speeds ranging from 20 to 60 miles per hr. When comparing the values of L in Fig. 16 with similar values in Fig. 2, it will be noted that the latter are approximately 40% less than the former. This difference in the lengths of L is the logical difference between circular reverse curves of the same radius and spiral curves with radii varying from an infinite radius to that used by the author for the same conditions of speed, lane spacing, and values of f.

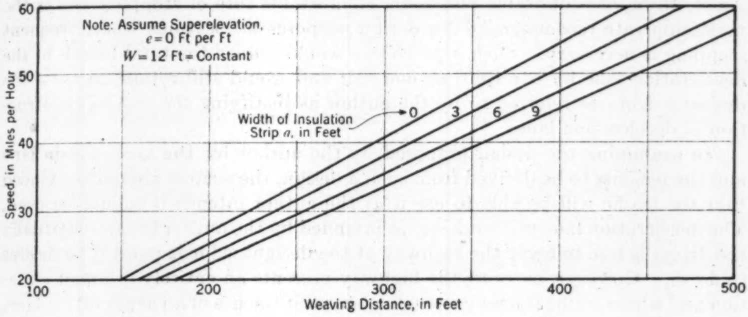

FIG. 16

As a check on the mathematical analysis, road tests were run with a test car of known steering characteristics on curves. This car has been used on many tests on curves and, on the basis of the results of tests by the General Motors Corporation on many different makes and year models of cars,[18] may be considered as an average type of car in respect to steering and handling on curves. The car was equipped with a ball bank indicator that was used to aid the driver in holding to the maximum specified side friction and the maximum curvature at each speed. By holding the side friction to the maximum value of $f = 0.16$ recommended by the author, the minimum lengths in the weaving distance obtained in these tests checked rather closely with the values given in Fig. 2. Since the test values were the minimum lengths that could be obtained without exceeding the value of $f = 0.16$, it follows according to the mathematical analysis for the determination of L using spiral curves that large values of C were developed in these tests. With relatively small intersection angles Δ, accuracy in the steering of the car was not a critical item, which indicates why values of C equal to 6 and 8 ft per sec^3 were possible. For design purposes values of C equal to 3 or not greater than 4 ft per sec^3 are to be preferred and this greatly simplifies the steering of the car from one lane to the other.

The design proposed by the author may be criticized on the basis that the lengths of the deceleration and acceleration lanes are unnecessarily long. The introduction of spirals as the natural path that the cars will follow will further increase these lengths and, where local conditions require it, some modification in the design standards would have to be made. Under these conditions a reduction in the cruising speed or the design speed at the entrance to the exit lanes would be an important consideration. Also, motor deceleration might be used only for speeds greater than 40 or 50 miles per hr for a fixed distance such as one half the weaving distance to be followed by higher rates of stopping by the use of brakes than are recommended by the author. A stopping rate of 8 ft per sec^2, which corresponds to a value of f equal to 0.25, has been established on the basis of extensive tests at Iowa State College, Ames, Iowa, as a desirable maximum comfortable rate of stopping and is the maximum rate recommended for design purposes in locations where frequent stopping is necessary. Such a procedure would reduce the total length of the deceleration lane by one third or one half and would still retain many of the desirable features referred to by the author as justifying the cost of construction of deceleration lanes.

---

[18] "Marking Highway Curves with Safe Speed Indications," by R. A. Moyer and D. S. Berry, *Proceedings*, Highway Research Board, National Research Council Vol. 20, 1940, pp. 399–428.

In examining the design proposed by the author for the acceleration lane and the benefits to be derived from such a design, the writers are not convinced that the traffic will be able to use it as the author intends it should be used. The deceleration lane will work out as intended by the author because normally the driver is free to leave the highway at the designated exit point if he desires to do so. However, entering the highway presents an entirely different situation and where traffic is heavy enough to warrant the use of an acceleration lane, the opportunities to enter the highway freely without interference are likely to be available only for a limited percentage of the traffic entering the highway. This is a phase of traffic behavior that should be investigated to determine the extent to which traffic entering from an acceleration lane can do so freely with varying volumes of traffic on the highway.

Although an acceleration lane designed solely as such has the advantage in reducing delay both for the turning traffic and the through traffic on the highway, the writers contend that an important function of the acceleration lane should be to provide ample space in which the turning traffic can merge safely into the through traffic lane without requiring the turning traffic to stop or the through traffic to reduce speed seriously. To satisfy this requirement a greater length should be provided in which the traffic can merge by reducing the length of the insulation strip and by replacing the cinders or gravel braking section (which traffic would not use) by a paved section of the same length which the traffic would use. Full acceleration to the cruising speed is not necessary when entering the highway and a reduction in the length of the insulation strip to one half the length shown in this section of the acceleration lane should be quite satisfactory, especially under conditions where a reduction in the total length of the acceleration lane recommended by the author is necessary. Observations of traffic for many years have revealed to the writers that traffic which is not legally required to stop by signs or similar devices will stop only as a last resort and for this reason it is questionable if there is any justification for a cinder or gravel braking section. An improvement here would be to cover this section with a distinctive type of low-cost paved surface that could be used either for braking or for merging the turning traffic with through traffic. Such a treatment would provide greater flexibility in the use of the acceleration lane and would reduce delays and traffic interference by an appreciable amount as compared with that possible if the design proposed by the author is used.

There is little doubt but that the proposals made by Mr. Mitchell are in the right direction. The trend in the control of traffic today is to provide a smooth continuous flow of traffic along highways and through intersections in such a way that delays, large speed differentials, and unnecessary stops are eliminated, and so that traffic can leave and enter through highways freely. The savings in the cost of vehicle operation and in time occasioned by the elimination of delays and traffic stops mount rapidly as the volume of traffic increases. Road tests conducted by the writers have revealed that when cars are stopped every other block the gasoline mileage is cut in half, the average speed is reduced by one third, and the tire wear is more than six times as great as when no stops are required. Furthermore, the design of highways to provide a smooth continuous flow of traffic will not only reduce operating costs and save time but, as the author has clearly stated, it should reduce highway accidents.

The author is to be congratulated for having made a careful analysis of the many details in vehicle and driver behavior which are certain to play a more prominent part in the design of highways in the future. It is hoped that his paper will stimulate research in field observations of traffic behavior and in the development of standards of design that will be adopted by highway departments.

STEPHEN E. BUTTERFIELD,[19] ASSOC. M. AM. SOC. C. E. (by letter).—State traffic engineers, engineers dealing with the control of rural and high-speed traffic, and students of rural accident statistics are well aware of the large number of accidents that result directly from the conflict arising between slow-moving, decelerating, or accelerating vehicles and through-moving vehicles, traveling at a constant, high rate of speed. Of equal economic significance is the accompanying congestion, resulting in time losses and lower over-all speeds, which occurs at points of egress from or access to high-speed highways carrying substantial volumes of traffic. It is apparent that many highway designers have not been equally cognizant of the importance of providing a facility that permits a vehicle to diverge safely from, or merge with, the fast through-moving stream of traffic. In many of these cases where highway designers have attempted to provide accelerating and decelerating facilities, it is apparent that insufficient thought has been given to their functional design or to the study of their component parts. The exit and entry ramps to the Merritt Parkway, in Connecticut, and to the Hutchinson River Parkway, in Westchester County, New York, are examples of these earlier and inadequate facilities.

In view of these facts and in view of the vast program of parkway, freeway, and dual highway construction upon which the United States is engaged, Mr. Mitchell's treatise is extremely timely. The author has clearly outlined the essential elements that should be considered in the design of accelerating and decelerating lanes. Although this subject has been studied previously in some detail,[20] Mr. Mitchell has now successfully presented a concise treatment of the component elements in the design of accelerating and decelerating lanes. These elements are treated in a logical sequence and in a strictly analytical manner. Also, the author has carefully assembled and interpreted, in the light of their value to the design of accelerating and decelerating lanes, the available research material applicable to this subject.

---

[19] Traffic Engr., State Highway Dept., Hartford, Conn.

[20] "Accelerating and Decelerating Lanes," by Wortham W. Dibble, Harvard Bureau for Street Traffic Research, June, 1938; also "Accelerating and Decelerating Roadway Areas," by Stephen E. Butterfield, Yale Bureau for Street Traffic Research, June, 1939.

From a review of this paper, it should now be clear to most highway engineers that there is no longer need for making major assumptions or hypotheses in the designing of accelerating and decelerating lanes. Further research on some of the minor controversial matters relating to this subject doubtless will throw much-needed light on certain phases of the problem, such as to what extent motor deceleration should be considered and at what point motor deceleration gives way to brake deceleration.

Mr. Mitchell has presented a sound mathematical approach to the matter of weaving distance, a problem which formerly has been subject to the greatest diversity of opinion. An insulation strip, in the form of a true physical barrier, is of the greatest importance to insure the correct use of the decelerating lane and to insure that the decelerating process occurs entirely off from the through-moving lanes. This insulation strip should form a sufficient barrier so that no motorist will be tempted to ride over it in order to enter the exit ramp. Except for a short distance at its approach end, this insulation strip should not be a low mountable curb. The color scheme of this barrier area, and of the decelerating lane itself, should offer such contrast to the highway proper that the point of divergence will be clear to the approaching motorist.

In his presentation, the author has allowed the motor deceleration distance to overlap the weaving distance, thus permitting a part of the through-pavement area to be used for the act of deceleration. This means, in the example presented, that with a cruising speed of 50 miles per hr, a vehicle under motor deceleration will be traveling at approximately 41 miles per hr at the end of the weaving distance. This is the point at which a vehicle is finally entirely off from the through-moving lanes. Should not the deceleration distance be treated separately from, and introduced at the end of, the weaving distance? This would insure freedom from any possible conflict between the decelerating vehicle and a following through-moving vehicle. This would be consistent with the design of the accelerating lane in which no attempt at merging with the through stream of traffic is made until the full cruising speed has been attained.

In the use of certain values as the cruising speed for the through-moving traffic, one should not lose sight of the fact that the existing cruising speed or the design cruising speed may not be the one that will be adhered to in the not too distant future. Lest the highway under construction become antiquated soon after its completion, it is wise to consider the cruising speed as that average speed to be expected on the projected highway at a time ten or fifteen years in the future.

Some highway designers are still reluctant to admit the necessity of providing accelerating lanes, even though they do admit the very real need of decelerating lanes. It is generally conceded that if either the decelerating lane or the accelerating lane must be sacrificed, it should be the accelerating lane in favor of the decelerating lane. The crux of the argument revolves around whether full security is to be provided to the following through-moving motorist at the point of exit, and yet no security provided to him against a suddenly entering vehicle at a point of entry. Since vehicles are likely to be grouped, even with a light volume of traffic on the through lanes, an entering vehicle may encounter merging conditions not drastically different from those encountered under high volume conditions.

The inability of the motorist of average intelligence and long driving experience to judge accurately his distance from, and the speed of, an approaching vehicle is well known. Because of his inability to judge the speed of an approaching vehicle and because of his normal impatience to delay, is it not far better to remove the possibility of a human error by providing a facility which largely removes the human element? With the provision of grade separations, freedom from access to abutting properties, decelerating lanes, and the other natural attributes of a freeway, a sense of security is afforded the motorist that does not actually exist unless merging lanes are provided which permit vehicles to enter the highway at the cruising speed. It follows naturally that the higher the speed of the through route the greater is the need of accelerating lanes and the greater is the inability of the motorist who is stopped at the entry to the expressway to judge the speed of the approaching vehicles.

So-called accelerating lanes in the form of extra pavement widths have been provided at the entry point to certain parkways located in Eastern United States. The failure of vehicles to use these extra pavement widths as accelerating lanes should not serve as a measure of their value; rather it should serve as an indictment of their inadequate design. When carefully designed, and in accordance with the general principles outlined by Mr. Mitchell, accelerating lanes will be found to be a highly functional and an urgently needed parkway facility.

This paper should be welcomed by all engineers and highway designers confronted with the problem of parkway and expressway design. Mr. Mitchell has so segregated the design elements that it should be a relatively simple matter to adapt the general method to the treatment of any individual problem or to substitute for the submitted data later data derived from further research on the individual elements.

ADOLPHUS MITCHELL,[21] ASSOC. M. AM. SOC. C. E. (by letter).—In preparing the paper on acceleration and deceleration lanes it was recognized that the available data on which the limit of motor deceleration and other constants were based was not sufficient to allow the selection of final values. For this reason, it was hoped that those discussing the paper would do so in a constructive manner and present more conclusive evidence for the determination of these factors. It is gratifying that practically all discussions were kept on this high plane.

In summarizing the discussions submitted, an effort will be made to isolate the controversial elements and to modify the recommendations of the paper where it appears to be justified.

---

[21] Senior Traffic Engr., State Highway and Public Works Comm., Raleigh, N. C.

Deceleration Lanes.—The weaving distance was given particular attention by Messrs. Loutzenheiser and Moyer and Davidson. It is gratifying to note that they all agreed with the writer that his values were acceptable as minimums. Messrs. Moyer and Davidson appear to have gone further into the problem than any one else and in a very scientific manner. They state that "By holding the side friction to a maximum value of $f = 0.16$ recommended by the author, the minimum lengths in the weaving distance obtained in these tests checked rather closely with the values given in Fig. 2." However, on the basis of a spiral shown in Fig. 15, they have arrived at a length somewhat in excess of those given in Fig. 2, and this bears some comment.

In stating that "The assumption of an S-path of travel is a theoretical expedient entirely," and that "there is no doubt that drivers would find a spiral path more natural than a reverse circular path," the writer did not have reference to the spiral employed by Messrs. Moyer and Davidson. This spiral was developed by railroad engineers on the basis of providing for a transition from a tangent to a circular curve in a manner that would increase the centrifugal force acting on the vehicle uniformly from zero at the end of the tangent to that determined by the circular curve at the end of the transition. This would permit the elimination of all "pants friction" provided that the superelevation was increased uniformly from zero at the end of the tangent to that of the circular curve at the end of the transition, on the condition that a constant speed was maintained. In the present problem it will be impracticable to superelevate the pavement in this manner and to assume that the speed will not vary throughout the weaving distance. For these reasons, Messrs. Moyer and Davidson not only failed to present a formula for the "natural path" but also failed to present one resting on a sound theoretical basis. Although the discussion of the weaving distance gives the impression of providing a basis for longer minimum lengths, examination of the throw (p) of the spiral shows this to be purely theoretical (amounts to $p = 0.35$ ft in the problem of Fig. 7, although L is equal to 505 ft, using $f = 0.16$, $W = 17$, $V = 50$, and $C = 3$) and not at all commensurate with the accuracy with which automobiles are steered. Their comparison of Fig. 16 with Fig. 2 is misleading. All curves in Fig. 2, except one, are based on a width of lane varying with the speed as listed under the heading "Deceleration Lanes." The values of Fig. 2 are approximately 70% less than those of Fig. 16 by Messrs. Moyer and Davidson.

Their remarks regarding C in Eq. 18 were not clear since C is a constant, the evaluation of which is not final. They themselves recommend using C as a constant for any given design speed.

Mr. Simpson suggests that motor deceleration be assumed equal to 40 miles per hr, and Messrs. Moyer and Davidson suggest 40 or 50 miles per hr. The writer suggested that "40 miles per hr for a 70-mile-per-hr highway and 30 miles per hr for a 50-mile-per-hr highway" be assumed. Since nearly all of those taking part in the discussion agreed that deceleration lanes determined on this basis are too long, it is suggested that the assumption of motor deceleration to 50 miles per hr be used for a 70-mile-per-hr highway and 40 miles per hr for a 50-mile-per-hr highway.

Most of those discussing the braking distance agreed that a somewhat higher coefficient of friction should be adopted than those shown in Fig. 5. Messrs. Moyer and Davidson suggested a value of $f = 0.25$, on the basis of actual tests. The writer is inclined to agree with them and suggests that this value be used. This would result in the following equation:

$$s = \frac{\bar{V}^2 - V^2}{7.5 \pm 0.3\,G} \quad \text{.......................}(25)$$

There was very little comment on funneling or providing a decreasing width of lane as speed decreases. Apparently no one knows anything about this subject at the present time.

Very little was written about the insulation strip for the deceleration lane. The writer is inclined to shorten this strip to a length determined by the emergency stopping distance so as to provide a more open throat than that theoretically required. The insulation strip is necessary to insure correct use of the deceleration lane, as has been proved by experience. Proper design will eliminate the hazard of introducing an island point.

The changes agreed upon would result in a length of deceleration lane of 465 ft instead of 650 ft for the problem of Fig. 7.

Acceleration Lanes.—It appears that there is no definite agreement of the distance required for full acceleration. Mr. Loutzenheiser does not think the writer was justified in extending the data for level ground to include the effect of gradients. It has been the experience of Ernest E. Wilson, director of the General Motors Proving Ground, that "The hill climbing abilities of a passenger car can be very closely determined from theoretical equations if acceleration data taken on a level road are used in the calculations."

The insulation strip along the acceleration lane was an item of considerable interest. Mr. Loutzenheiser would either shorten it or omit it altogether. Mr. Butterfield thinks it is all right as presented. Messrs. Moyer and Davidson suggest that it be shortened to one half of the length of the acceleration lane. The writer suggests that it be shortened to the point where it is possible for entering traffic to attain the average speed of the adjacent highway.

There was considerable diversity of opinion as to the braking section provided at the end of the lane. Mr. Harris does not think it is necessary, and Messrs. Moyer and Davidson would use a low-cost paved surface. Since this section amounts to no more than improved shoulder, the writer is inclined to agree with Messrs. Moyer and Davidson.

Messrs. Simpson and Moyer and Davidson would construct deceleration lanes only, whereas the others appeared to think that the acceleration lane had some merit, particularly Messrs. Harris and Butterfield. After studying the various comments on the subject, the writer still fails to understand why acceleration lanes are not important for dual-lane highways. Where traffic is heavy, it is even more important than where it is light, because it would be necessary to use signals to enable traffic to enter. The only problem seems to be that of persuading traffic to move from the outside to the inside lane in order to allow traffic to enter from the acceleration lane (signs, signals, markings, and devices are available for this purpose). Since it is relatively easy to enter a traffic stream when approximating the speed of the automobiles thereon, it would require a smaller distance between vehicles on the highway in order to enter it than would be the case when an automobile had to enter at a very low speed as would be the case at a T-intersection. The operation of "stop" lights would introduce delays on the highway that engineers have come to recognize as equivalent to a monetary loss. The cost of such delays should be estimated to determine if they would justify the construction of the acceleration lane.

Messrs. Loutzenheiser, Harris, and Waters mentioned the need for additional data on acceleration and deceleration lanes, some of which were furnished by Messrs. Moyer and Davidson. Data are needed on the form of the "natural path," the maximum permissible differential in the speed of cars on the highway with that of merging traffic, and other factors involved in the design of acceleration and deceleration lanes.

Conclusion.—Mr. Holley's example of the Fair Oaks Avenue crossing of Arroyo Seco Parkway was most interesting; however, its value was greatly reduced by his failure to give speeds, grades, and dimensions. It is significant that he states, "Mr. Mitchell's paper provides an objective toward which designing engineers should strive."

Mr. Loutzenheiser appears to believe that the writer's paper is "an academic discussion, somewhat extended in detail, of a design approach made in a paper[9] published elsewhere, in 1940." The writer's paper was written in 1939 and submitted to Yale University, at New Haven, Conn., in 1940, through the Yale Bureau for Street Traffic Research, in partial fulfilment of the requirements for a certificate in street traffic control. There is a marked lack of similarity between the two treatments.

The writer is indebted to Professor Hickerson for checking the development of the equations used.

CRACK PREVENTION PROGRAM, HIWASSEE DAM

BY O. LAURGAARD,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. DOUGLAS MCHENRY, REGINALD H. THOMSON, W. R. WAUGH, AND O. LAURGAARD.

SYNOPSIS

As completed, Hiwassee Dam, a Tennessee Valley Authority (TVA) structure in western North Carolina, with a height of 322 ft from the lowest rock foundation to the roadway, was the highest overflow gravity dam. Its concrete, manufactured from the local graywacke rock, had to be placed largely during the warm summer months. To insure that the dam would be impervious to the passage of water and its surface would be weather-resistant, it was important that the mass should be free from major cracks. This required a concrete with a gradual temperature rise, one that would harden slowly, and one that would permit considerable expansion before its ultimate strength was reached.

To achieve these results the program included: (1) Use of low-heat cement; (2) a low cement content; (3) thin casting lifts; (4) long exposure periods; (5) artificial cooling for mixing water; (6) washing, rinsing, and cooling the aggregate; (7) artificial cooling of the concrete in place; (8) cleanup of horizontal joints between lifts; (9) the use of steel reinforcement; (10) diagonal keyways on bulkhead joints; and (11) curing and winter protection.

This paper shows how the program progressed and how cracking has been practically eliminated by rigid control and inspection. Actually, a saving in cement resulted, which more than offset the additional cost of the crack prevention program.

INTRODUCTION

Hiwassee Dam (Fig. 1) is one of the important units in the comprehensive development of the Tennessee Valley. It is situated in the very westerly corner of North Carolina, adjacent to Georgia and Tennessee, on the Hiwassee River, which flows about 50 miles westerly and slightly north into the Ten-

---

NOTE.—Published in March, 1941, *Proceedings*.

[1] Care, Bethlehem Alameda Shipyard, Alameda, Calif. (formerly Construction Engr., Hiwassee Dam).

nessee River. This overflow structure has its spillway at El. 1,503.5 above mean sea level.[2] Average monthly temperatures ranged from a summer high of about 85° F during the working shift from 6:00 a.m. to 3:00 p.m., to a winter low of about 26° F for the shift from 3:00 p.m. to 12:00 midnight.

From the beginning of operations it was an important objective to produce a monolithic structure—one that would conform closely to the design requirements, would be impervious to the passage of water under high pressure, and would resist weathering. A strict program of concrete control therefore was necessary, on account of (1) the material of which the aggregate (including the sand) was composed; (2) the difficulty of controlling the river during construction without using separate by-pass channels or tunnels; and (3) the rather warm climate, especially in the summer time.

FIG. 1.—GENERAL VIEW, HIWASSEE DAM, LOOKING UPSTREAM FROM THE SOUTHWEST

Special consultants were appointed by the TVA to review conditions and submit a report. Two of these consultants, R. W. Carlson, Assoc. M. Am. Soc. C. E., and R. E. Davis, M. Am. Soc. C. E., held several conferences with engineers of the Authority and submitted a program. Quoting from their report: "To obtain water tightness the structure should not only be free from major cracks, but the concrete mix should be plastic, workable and free from water gain, and the workmanship should be such as to insure the bonding of each lift to the lift below"; and again "To insure against devastating action of weathering and erosion, the exposed faces should be of high strength concrete at later ages." The consultants summarized their conclusions and recommendations to achieve the required results in a report of April, 1938.

---

[2] For a general description of the project, see papers by Cecil E. Pearce, Assoc. M. Am. Soc. C. E., on "Design of Hiwassee Dam," in *Civil Engineering*, covering "Basic Considerations," June, 1940, p. 340, and "Engineering Details," July, 1940, p. 433.

By following the suggested program, Hiwassee Dam has been constructed relatively free from cracks, and capable of withstanding weathering for a long time. These results have been accomplished by careful inspection and testing of the cement, by rigid control of the concrete, by selection of proper equipment for manufacturing aggregate, mixing, placing and curing of concrete, and by cooperation between engineering and construction forces. Practically all of the work has been done by the Authority's forces.

Until recently, cracking of mass concrete was regarded as inevitable. As concrete control has developed, certain contributing factors for cracking have been eliminated and thus the mass has been greatly improved. For the recommended program submitted by the consultants, supplemented by such additional features as were believed desirable and worthy by the engineers of the Authority, a number of provisions to reduce or eliminate cracks in Hiwassee Dam were adopted: (1) The use of low-heat cement; (2) a low cement content; (3) thin casting lifts; (4) long exposure periods; (5) artificial cooling of the mixing water; (6) washing, rinsing, and cooling of the aggregate; (7) artificial cooling of the concrete in place; (8) cleanup of horizontal joints between lifts; (9) the use of steel reinforcement; (10) diagonal keyways on bulkhead joints; and (11) curing and winter protection.

None of these methods is novel or original, but the combination of all of them on one job is believed to be unique. After two years of concrete placement, there appear to be no cracks on the upstream face, none of any consequence on the downstream face, and only one small crack that can be dignified by that name in the galleries. Although a few small cracks did appear on the contraction joint faces between blocks during construction, these were unavoidable because of large differences in elevation between the tops of adjacent blocks (caused by closure procedure) at a time of great variations in temperature.

ROUTINE CONCRETE CONTROL AND PROCEDURE

Low-heat cement was furnished by five manufacturers from six different mills, with acceptance tests by the Authority. Rigid control was exercised in the manufacture of aggregate including sand, and in the mixing and placing of concrete. Frequent screen analyses served as a basis for controlling the aggregate grading. Tests were made during the first few months of concreting to determine the effect of grinding in the mixers, which were used to correct the combined aggregate grading of the material going into the mixers and to obtain a desirable grading in the fresh-mixed concrete. All concrete aggregates except sand were thoroughly washed to remove extraneous material including fines and thus aid to maintaining a reasonably constant combined aggregate grading. Rapid moisture tests on all aggregates at the mixing plant served to control the water-cement ratio. Similarly, vigilant inspection of concrete placing in the forms assured thorough compaction and proper placement.

Other measures to insure uniformly high quality included particular attention to the cleanup of old concrete surfaces and adequate curing of all concrete. Routine tests of specimens made from daily samples served as a check on the compressive strength, and other desirable properties, of the concrete. Special tests on mixer grinding, bleeding, workability, and strength relationship for variable water-cement ratios produced additional valuable information. Pertinent data for all the concrete mixes and test specimens are given in Table 1.

USE OF LOW-HEAT CEMENT

Contracts with several cement companies had been awarded for modified cement when it was concluded to use low-heat cement. Therefore, it was necessary to pay a premium of from 5 to 10 cents per bbl for the new material. To comply with the specifications this material was called "modified cement for summer use at Hiwassee Dam," although in reality similar specifications governed the low-heat cement used at Marshall Ford Dam and elsewhere under the United States Bureau of Reclamation. Specifications for "summer cement" were similar to the modified or "Type B" cement, except that the tricalcium aluminate (C_3A) was limited to a maximum of 7%, tricalcium silicate (C_3S) to a maximum of 35%, dicalcium silicate (C_2S) to 40% minimum and 65% maximum, and tetracalcium alumino ferrite (C_4AF) to a maximum of 20%. The "summer cement" specifications also required the fineness to be between 1,700 and 2,200 sq cm per g as against 1,600 to 2,200 for "Type B" cement.

Strength requirements are also somewhat lower for the "summer" than for the "Type B" cement. While exact data are not available to compare concrete strengths for the two types of cement, relative results for Norris and Hiwassee concretes are shown in Table 2. Although the greater strength shown on the Norris Dam concrete is due to some extent to the lower water-cement ratio (W/C), it is also known that the type of aggregate was responsible for some additional strength.

TABLE 2.—COMPARISON OF CONCRETE STRENGTHS, IN LB PER SQ IN.

Age at test	Face concrete, Norris[a]	Face concrete, Hiwassee[b]	Mass concrete, Hiwassee[c]
7 days	3,617	1,723	900
14 days	4,646	2,750	1,438
28 days	5,500	4,254	2,509
90 days	7,332	6,168	4,078
6 months	7,768	6,560	4,569
1 year	8,609	7,218	4,718

[a] 1.2 bbl "Type B" (modified) cement per cu yd at *W/C* ratio of 0.57 by weight.

[b] 1.15 bbl "summer" cement, at *W/C* ratio of 0.58 by weight. [c] 0.8 bbl "summer" cement, at *W/C* ratio of 0.8 by weight.

For concrete using low-heat cement it was expected that the stripping of forms in the winter time would have a deterimental effect on slowing up the work, but as a matter of fact no serious difficulty arose. The principal consideration favoring low-heat cement was the reduction in temperature rise during the heat of hydration and, consequently, all other things being equal, the corresponding reduction in cracking due to temperature changes. The advantages of insuring the continuity of the structure outweighed the obvious objections of the slight additional cost of cement, the requirement of longer curing, the reduction in early strength, and possibly the necessity for more protection against damage in winter.

LOW CEMENT CONTENT OF CONCRETE

The concrete for Hiwassee Dam and spillway was composed of the two types listed in Table 2. The consultants believed that concrete must contain sufficient cement to provide strength and to insure impermeability, but at the same time that the lower its cement content, the less the tendency would be to crack. In general, dams with a larger percentage of cement have exhibited a greater than average degree of cracking and, in many cases, excessive leakage. On the other hand, some older dams, for which the cement content was less than 0.75 bbl per cu yd, were comparatively free from major cracks and yet were exceedingly watertight. With the recent tendency toward better cement, better gradations of aggregate, the use of drier mixes placed by vibration, and better control in all respects, it seemed reasonable to expect that a low cement constant would minimize cracking.

At Hiwassee Dam the aggregate was considered suitable for the use with lean mixes. Although more water was required for a satisfactory consistency than with other aggregates, the experiments before concreting showed that a mix containing 0.75 bbl per cu yd was plastic and workable and showed almost no water gain. The consultants recommended that a W/C ratio of not more than 0.85 should be used for mass concrete and that the cement content be not more than 0.8 nor less than 0.75 bbl per cu yd. They also recommended that within a distance of, say, 8 ft from exposed faces, the W/C ratio should be approximately 0.6 and the cement content about 1.10 bbl per cu yd. With the W/C ratio of 0.6, using low-heat cement, a strength of 2,500 lb per sq in. was expected at the end of 28 days and a strength of 5,000 lb per sq in. at the end of a year.

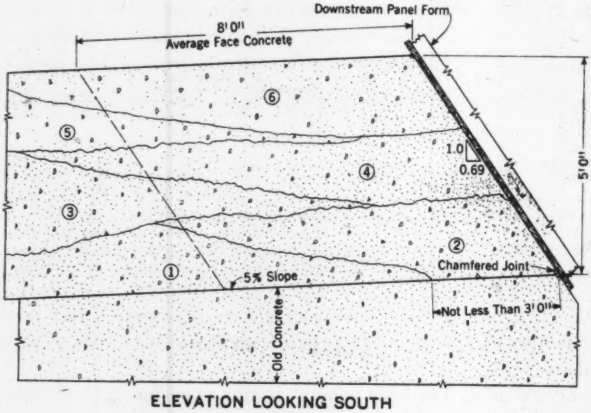

Fig. 2.—Sequence of Pours (Circled Numerals) for Concrete on Downstream Face of Dam

After due consideration, the cement content for the mass concrete was set at 0.80 bbl per cu yd, and for the face concrete at 1.15 bbl with W/C ratios of 0.80 and 0.58, respectively. Near both faces of the dam the concrete was placed in sequence between the mass concrete and the face concrete (Fig. 2) so that no well-defined joint existed between the two types. For the reinforced sections, concretes with maximum aggregates of 3 in. and of $1\frac{1}{2}$ in. were used with a cement content of 1.33 and 1.50 bbl per cu yd, respectively, and a W/C ratio of 0.58. For mass concrete a slump of one inch or less was maintained; for face concrete, $1\frac{1}{2}$ to 2 in.; and for both types of reinforced concrete, 2 to 3 in. Typical data for one class of concrete obtained from 17-in. drilled cores are given in Table 3. The dam was constructed using blocks between vertical expansion joints which were, in general, 50 ft apart (less in the spillway section). Numbering started with block 0 at the north (right) abutment, extending to block 8 next to the spillway; blocks 9 to 15 in the spillway section; block 16 near the power house and so on to the extreme south bank at block 27.

LOW-CASTING LIFTS

By careful control the dam was built up slowly over its full length by reasonably thin lifts and with long exposure periods to enable the "heat of hydration" to be dissipated before the lift was covered with another pour. The program involved 5-ft casting lifts with exposure periods of not less than five days, or equivalent to a one-foot height of concrete placed per day. It was believed that the additional time required for pouring thin lifts would not materially increase the cost.

Exceptions, however, were made to the general rule, particularly during the beginning of concrete placement on foundation rock or the resuming of concrete operations on old concrete; in such cases 2½-ft pours were standard practice. In general, 2½-ft pours were placed until approximately 60% of the foundation rock of each block was covered, except that on the steep foundation rock on the abutments practically the entire foundation was covered by using 2½-ft pours (Fig. 3). Further exceptions were made in some locations; for instance, in blocks 4 and 5 on the north abutment and blocks 23, 24, and 25 on the south abutment, marked changes in the regularity of the foundations formed abrupt slopes or humps. Where humps were found it was necessary to pour a rather large number of 2½-ft lifts before the top of the hump was covered. In order to permit the concrete to harden as long a period as possible and thus cool to about the temperature of the adjoining rock, exposure periods of four and five days were also adopted for 2½-ft pours. This program resulted in a successful treatment of these irregularities. Only one crack was observed as a result of the humps. This occurred in block 4 at a very sharp break in the foundation rock and where the concrete had to be relatively thin over the rock and exposed for almost a year.

From Table 4 it may be noted that, from the lowest area in the foundation in block 11 (El. 1,215.5) to the roadway elevation at the top of the dam (El.

1,237.6), a maximum difference in elevation of 322 ft is recorded and a total of sixty-nine pours was required giving an average of 4.66 ft. Sixty three of these were 5 ft high; two were 2½-ft pours on the rock foundation; and four 2½-ft pours were made on intermediate old concrete surfaces. In block 8 with an approximate height of 270 ft, a total of twenty six 2½-ft pours was made, giving an average of 3.91 ft per pour. Similar data are given for all the blocks with totals for the whole dam.

(*b*) Vibrating Completed

FIG. 3.—SHALLOW CONCRETE LIFTS (2½ FT) ON FOUNDATION ROCK

The small number of cracks is due in part to the care used in casting the concrete on the foundation in 2½-ft lifts. The considerable expense involved on account of practically doubling the cleanup cost seemed to be justifiable. Although the exposure time was permitted at two and a half days for the 2½-ft lifts, usually two 2½-ft pours were cast per week. Studies cited subsequently show the advantages of casting thin lifts with long exposure on foundation rock, thus reducing temperature rise.

LOW CASTING TEMPERATURES

It was known that the casting temperature of the concrete would be rather high, especially during the summer, unless something was done to reduce it artificially. Two expedients were adopted, (1) using refrigeration of the mixing water and (2) rinsing and cooling of the aggregate. The first was the more important. Water batches were taken from the insulated mixing plant surge tank that was supplied by an insulated pipe line from the refrigeration plant. An insulated overflow line returned the excess water to a tank at the refrigeration plant from which it was fed by gravity to sprinkler pipes discharging over the outside of the water cooler coils, thus securing second cooling contact. The water dripped off the cooler coils and ran into the pump sump ready for circulation. Approximately 50 gal per min of river water was cooled for concrete mixing from a usual temperature of about 80° F to as low as 35° F.

The construction of the refrigeration plant was begun in August, 1938, and was completed and put into service on September 2, but was shut down on

October 23, 1938, due to cold weather. In Table 5 are given various temperature data. During winter operations, the mixing water was heated by steam, its temperature being raised from approximately 40° F to 130° F. During a cold spell, the temperatures of the water ran as high as 180° F.

Washing, Rinsing, and Cooling the Aggregate

To control the grading, rinsing screens were installed to wash all aggregate except sand. In this process the aggregate was thoroughly wetted and subsequently cooled by a blast of cold air while it was dropping from the rinsing screens to the conveyer belt. This had the effect of cooling it approximately 3°. The effective reduction in concrete placing temperature by refrigerating the mixing water was about 6°. For a 5-ft lift during an exposure of five days the effective reduction in maximum temperatures due to refrigeration of the mixing water was calculated at about 3°, and due to the washing and cooling of the aggregate about 1°. The placing temperature of the concrete in the summer months averaged about 70° F, and for the winter months every effort was made to secure a temperature between 45° F and 50° F. In view of the small reductions in maximum temperature due to refrigerating the mixing water, it seems that better results might be obtained by installing an effective system of cooling for the aggregate and other ingredients.

Artificially Cooling the Concrete in Place

In general, resort was made to artificial cooling of the concrete in place (1) to reduce temperature cracking that might occur on high exposed contraction joint faces; (2) where the exposure period on the usual 5-ft pours was reduced on account of the exigency of the schedule; (3) to equalize the temperatures between the concrete on the foundation and the adjoining rock as quickly as possible; and (4) to reduce the temperature of concrete in closed recesses to bring it as quickly as possible to that of the adjoining concrete. In block 19 (Fig. 4) about 15 gal per min of river water flowing through each of three loops composed of one-inch iron pipes were used to artificially cool a 5-ft lift of concrete in place. Better results were obtained when the water was of low temperature. The difference in temperature between inflowing and outflowing water ranged from 4° to as high as 10° F. The flow as a rule was regulated daily and the cooling at each level was continued for fifteen days or more.

In Table 6 are given applicable data on artificial cooling. The cofferdam bulkheads in blocks 17 and 18 were poured with slightly thicker lifts than usual so cooling pipes were laid and water circulated in three lifts. This served to (1) expedite the pouring of concrete in those two temporary spillway blocks, (2) eliminate cracking because these bulkheads were designed as integral parts of the dam structure, and (3) offset the constant danger from destructive floods. The concrete in the assembly recesses around the ring seal gates was heavily reinforced and artificially cooled. Thus the maximum time was saved in the pouring schedule by equalizing the temperatures of the green with the older concrete; and high temperatures were prevented in parts of the gate castings when other parts were relatively cool, thus preventing warping in the castings and the gate. The first two 5-ft lifts of closure blocks 10–12–14 (spillway section) were artificially cooled in order to eliminate the necessity of making these pours in 2½-ft lifts. As a large structural steel gate was utilized in the closure, a program of pouring in 2½-ft lifts would have been awkward. The concrete in block 11 was cooled to prevent cracks due to irregularities in the foundation and in the shape of the block itself. Nearly all of the concrete in block 3 was cooled so that a more rapid pouring schedule might be adopted; this block contained the transfer track and, therefore, was not poured until many of the blocks in the dam and the adjoining blocks had almost reached the

[a] Cooling pipes were laid on top of one lift and covered by the next. Lift numbers refer to covering lifts. Numbering of 5-ft lifts started with No. 1 just below roadway level and extended downward to No. 68 at maximum depth. [b] Approximately.

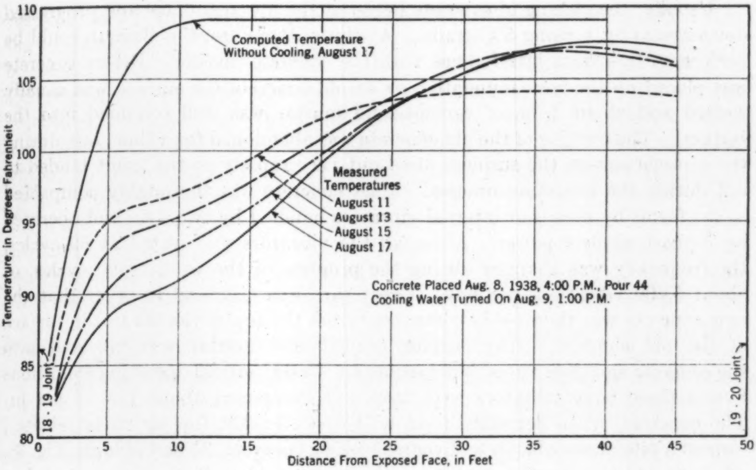

Fig. 5.—Temperature Distribution Parallel to Axis of Dam; Block 19, Bottom of Pour 44, El. 1,320.7

ultimate top elevation of the dam. Therefore, it was poured, utilizing 5-ft lifts with two pours weekly and artificial cooling.

The curves in Fig. 5 show the temperature distribution parallel to the axis of the dam, at the bottom of pour 44 in block 19, both with and without artificial cooling by the circulation of water. It is apparent that the artificial cooling of the concrete after placing was justified.

Cleaning Horizontal Construction Joints Between Lifts

Great care was exercised in preparing old concrete surfaces and foundation rock before pouring in order to secure a good bond, and thus prevent cracking and percolation along the joint with the resulting high uplift pressure. For the first three months a wet sandblast only was used, but on account of the high cost, due partly to the large number of 2½-ft lifts, other methods were attempted.

The method which was finally adopted consisted of an initial "green cut," with a jet of air and water, of the entire surface from 6 to 8 hr after the concrete had been poured in the summer, and from 8 to 20 hr in the winter; and then a final cleanup over the entire area with air and water, which also included a wet sandblast cut of that area from the upstream face of the dam to a line approximately 5 ft below the 8-in. formed drains, with special sandblasting treatments of large areas of laitance. The cutting with a high velocity jet of air and water was performed with an air pressure of about 50 lb and a water pressure of about 100 lb. The final cleanup usually came just prior to resuming concrete placement in the block. It was essential that the initial and final cleanup be followed by a thorough washing and a clean-off by air to remove loose material and water. The cleanup on the job as a whole was excellent.

Usually, the placing of concrete began at the upstream face and progressed downstream on a rising 5% grade. At times, therefore, the cleanup could be performed free from interference with the concrete placing. Before concrete was placed on the rock foundation or on old concrete the surface was usually wetted and about ¾ in. of cement-sand mortar was well broomed into the surface. The wetting of the old concrete was abandoned for a time, but during the summer season the surfaces dried out very rapidly so the grout tended to roll during the brooming process. Mass concrete was thoroughly compacted in the forms by means of internal vibrators handled by two men and operated by 3-phase electric power. Although the vibrators were rated at 60 cycles, the frequency was changed during the progress of the work to 90 cycles, or about 5,400 vibrations per min. Great care was exercised in order that the new concrete was thoroughly compacted from the top of the lift to the surface of the old concrete. Any surplus cement-sand mortar was vibrated into the concrete and thus a good bond secured. Under normal operating conditions five of these large vibrators were used and compacted about 125 yd per hr. The concrete, when deposited from a 7½-cu-yd bucket (by air valve release), formed a pile of very harsh and coarse looking concrete, 3½ or 4 ft high (Fig. 3), which would be vibrated down to a thickness of 1½ or 2 ft. Care was taken that the concrete be not dumped from an elevation higher than 15 ft above the casting grade.

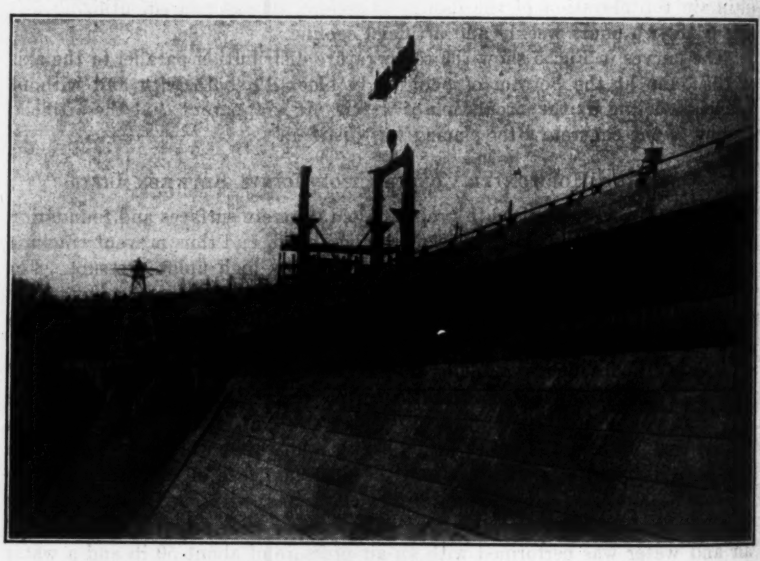

FIG. 6.—DOWNSTREAM FACE, SOUTH ABUTMENT, SHOWING HORIZONTAL CHAMFERED JOINTS, AND CRANE ASSEMBLY ON TOP

To improve the appearance of the dam, to break the usual monotony of a bare concrete face to such great height, and to eliminate any conspicuous appearance of cracks at the joints between pours, a system of horizontal and vertical chamfered joints at lift and block lines was inaugurated. This gives the appearance of a dam with blocks 50 ft wide by 5 ft high (see Fig. 6). The horizontal chamfered joints were not placed on the downstream surface of the spillway section, but they were placed on the upstream face, as well as on the adjacent abutments, above the drawdown level (El. 1,415). The vertical chamfered joints on the abutments were 3¾ in. wide and 1¼ in. deep as compared with 2 in. by 0.75 in. for the spillway. The horizontal chamfered fillets were 3¾ in. by 1¼ in. On blocks where a large number of 2½-ft pours were scheduled, 5-ft pours were cast for a distance of approximately 20 or 30 ft from the downstream face and then the surface was sloped down to make a 2½-ft pour through the balance of the block. The distances of 20 and 30 ft from the downstream faces were staggered so as to eliminate the possibility of a vertical crack forming parallel to the axis of the dam. As far as is known cracking was obviated by this procedure.

To prevent the percolation of water along the contraction joints from the upstream face, vertical 6-in. drains were constructed, with water stops of stainless steel sheets extending through the drains and 12 in. on both sides into the concrete.[2] These extended from the rock foundation to the top of the dam. Additional strips of stainless steel sheets 8 in. wide and 3 ft long were welded to the stainless steel water stops on each side of the contraction joint, and extended 4 in. into the top of each lift, thus bonding the two pours and preventing the seepage of water along the horizontal pour joints with resultant cracking.

Except for the closure blocks 10, 12, and 14 and for some slight adjustments in blocks 17 and 18 due to their use as a temporary spillway and to complications during the construction of the penstock, concrete was poured on a 5% grade (Fig. 2) sloping upward from the upstream face toward the downstream face. No joints or breaks in these lifts were permitted except when they were unavoidable on account of breakdowns in the plant or on account of a flood, as in the case of a closure block. Only six of these inside joints were made in the total number of 1,341 pours in the dam. Under no consideration were these

TABLE 7.—INTERRUPTIONS IN CONCRETE POURING

Date	Shift	Duration	Block No.	Cause
8-4-38	Night	5 hr	23	Excessive rain flooded out freshly poured concrete causing abandonment of form
12-20-38	Night	34½ hr	7	Conveyer pulley shaft broke at head house

12-14-38	Day	20½ hr	14	Head pulley and shaft broken on conveyer belt to mixing plant

[a] Did not complete half lift.

joints permitted closer than 20 ft from either face of the dam; and where the exposure period was in excess of approximately 6 hr, the surfaces were cleaned up and covered with grout the same as a new pour. It is certain that no longitudinal crack appeared in the dam as a result of these joints. Irregularities in pouring are listed in Table 7.

STEEL REINFORCEMENT TO PREVENT CRACKING

Careful inspection of the 1,827.6 lin ft of galleries in the dam has disclosed very few cracks. This is due to several contributing circumstances, one of which is the placing of heavy steel reinforcement, from 1-in. to $1\frac{1}{4}$-in. square bars, in a horizontal position 5 in. above the roof of the gallery (Fig. 7). No doubt other contributing conditions included the use of low-heat cement; the low cement content of mass concrete that was placed all around the inspection galleries regardless of its close proximity to the upstream face of the dam; the long periods of exposure between pours; the pre-cooling of the mixing water in warm weather; and the use of flat roof with corner fillets on a 12-in. radius rather than a full arch.

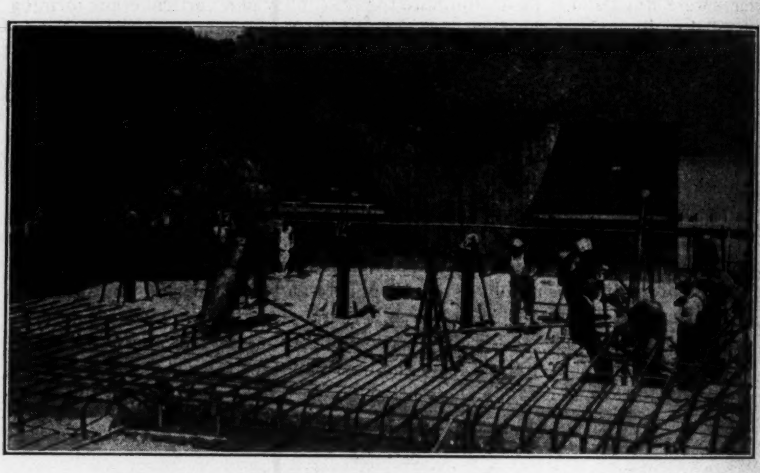

FIG. 7.—TYPICAL REINFORCEMENT OVER ROOF OF INSPECTION GALLERY

Steel reinforcement was also used in the recesses provided for the placement of the ring seal gates in order to prevent cracking in the comparatively thin walls of concrete between the gates and the contraction joints and to bind the concrete firmly to the regulating conduits and the ring seal gate castings. A few cracks were found in the bulkhead faces of blocks 4, 6, 7, 15, 19, and 20, and several of these cracks extended through more than one lift. The first crack was discovered (September 23, 1938) on the 19–20 contraction joint face of block 20. This was caused, no doubt, by a rather large height differential between the two blocks (about 30 ft), and by a rather sudden drop in temperature from a low of 60° at night to a low of approximately 40°. Two cracks were found on the bulkhead face of block 19, which also were caused by the excessive difference (maximum 130 ft) between the top of blocks 18 and 19.

It was anticipated that the high face in block 19 would be subject to some cracking. Therefore, sixteen 5-ft lifts were cooled by pipes for a total height of 80 ft. Two cracks occurred in this bulkhead face, the largest being 0.1 in. It was interesting to note that this crack terminated after it penetrated the cooled portion of the block.

The largest crack occurred in block 15 on the 14–15 contraction joint about November 28, 1938. This crack was influenced, no doubt, by the large ring seal gate recess in the center of block 15, but the 60-ft difference in height between the tops of blocks 14 and 15, coupled with a sudden drop in the minimum air temperatures, probably caused it. This crack reached a maximum opening of ⅛ in. and extended to El. 1,298 and also across the top of the lift parallel to the axis and into the ring seal gate recess. As it was more nearly of structural significance than any other crack, it was carefully explored and full data obtained as to the location, depth, and width inside the concrete. An attempt was made to stop this crack from projecting into the pours that would be made above El. 1,298. Another crack was discovered in block 4, which was caused by the existence of a hump in the rock under the concrete, a considerable height differential, and a long exposure of the block.

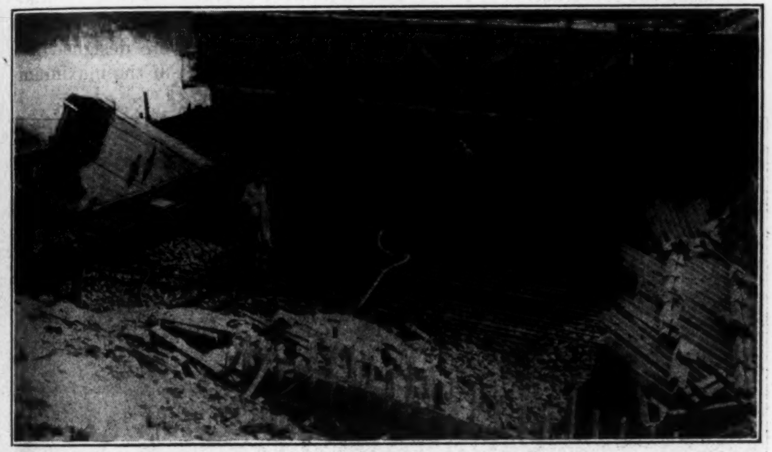

Fig. 8.—Mat of Steel Reinforcement Placed in Block 4 to Prevent Upward Extension of Crack

The crack in block 15 occurred on the side of the bulkhead wall, where it was possible to observe it from time to time. It was decided to place heavy mats of reinforcing steel on the top of the lift and across the block in an attempt to keep these cracks from extending upward. In general, it may be stated that the mat in block 15 was composed of 1¼-in. square bars placed 9 in. center to center, both vertically and horizontally, in cross sectional areas parallel to the axis, and $\frac{3}{4}$-in. spacer bars 9 in. vertically and 2 ft 6 in. horizontally. A mat for block 4 was similar (Fig. 8). These mats proved very effective, as it was possible to observe that the crack in block 15 did not extend beyond the top of the block at El. 1,298 where the steel was placed.

In addition, a decision was made to treat cracks wider than 0.03 in. by covering them with tar impregnated canvas to prevent the entrance of mortar and foreign matter. Horizontal holes were then drilled into the concrete of the bulkhead wall to intersect the crack about a foot from the surface, and pipes were laid for grouting these cracks at a later date.

DIAGONAL KEYWAYS ON BULKHEAD JOINTS

During the construction of Norris Dam a number of cracks on the bulkhead walls extended to the downstream face of the dam following the vertical keyways. To overcome this tendency, diagonal keyways were designed for Hiwassee Dam on the bulkhead walls following the direction of the maximum stresses (practically parallel to the downstream face, see Fig. 9). As a rule, the metal forms used for these keyways were tacked securely to the face of the bulkhead panels to keep them attached during the stripping operations.

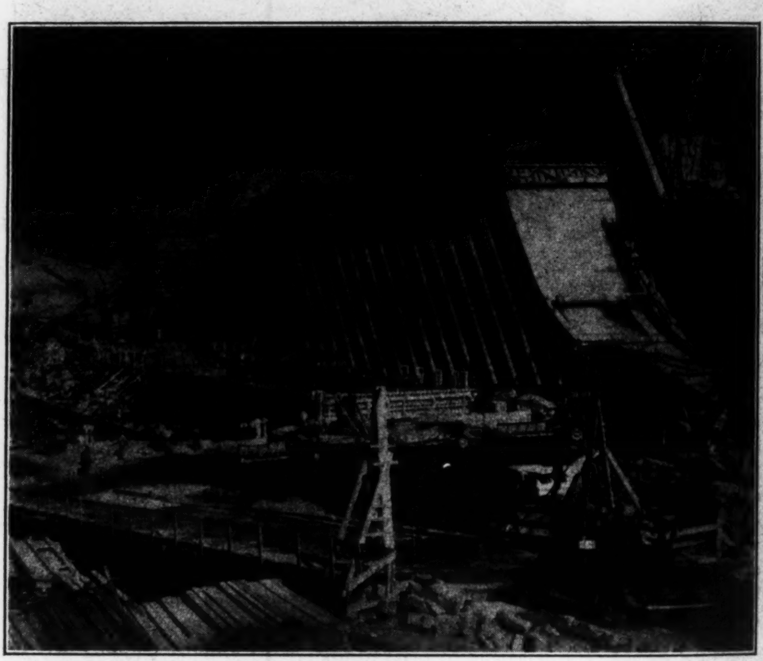

FIG. 9.—DIAGONAL KEYS ON BULKHEAD WALL OF BLOCK 15 (SPILLWAY SECTION)

The keys have a trapezoidal cross section, 6 in. deep and 4 ft wide at the bottom with 12 in. for each chamfered slope.[3] They were constructed of 14-gage and 16-gage steel plate, and on an inclination of $7\frac{5}{32}$ in. horizontally to 12 in. vertically. It is difficult to form any positive conclusion as to the effectiveness of these keyways to prevent cracking on the downsteam face because there were so few cracks at Hiwassee Dam and none of the cracks on the bulkhead faces extended to the downstream face. On the contraction joints, however, it was noticed that fine cracks would follow the keyways, but in almost all instances cracks that extended through several lifts crossed the keyways.

CURING AND WINTER PROTECTION

A program of curing was adopted for Hiwassee Dam at the outset. It consisted of wetting the top of the blocks and the sides for a period of twenty-one days. This did not include the bulkhead walls nor was it done as a rule when the air temperature was 40° F or lower. For a time, sprinklers were used on top of the blocks, and then hand sprinkling. Iron pipes with small holes about 6 in. center to center were fastened to the panel forms to spray both upstream and downstream faces of the dam.

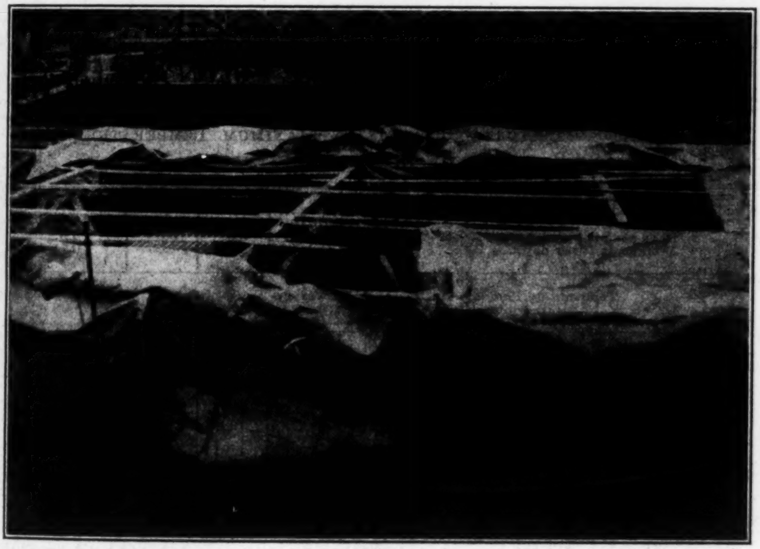

FIG. 10.—TO PROTECT CONCRETE IN FREEZING WEATHER A TARPAULIN COVER WAS SUPPORTED ON HORSES, WITH STEAM COILS UNDERNEATH

Efficient curing by sprinkling with water for long periods undoubtedly produced a continuous gain in strength; and this prevented major cracking as well as fine checks or hair cracks. These hair cracks, when subjected to sudden and wide variations in temperature, might develop into real cracks. It is believed, therefore, that an adequate program of curing did materially assist in the crack prevention program.

---

[3] "Design of Hiwassee Dam—Engineering Details," by Cecil E. Pearce, *Civil Engineering*, July, 1940, p. 435.

Due to the slower hardening process of low-heat cement, it was necessary to install rather elaborate equipment for winter protection not only for the aggregate but also for the mixing and placing of concrete. The gates in the aggregate reclaiming tunnel were surrounded with steam pipes and the tunnel itself was heated by steam. The rinsing screens were protected by wooden housing built around the entire equipment and heated by electricity. The Mixer Building was heated, also the aggregate in the bins, by means of steam coils. The mixing water tank was provided with steam coils. After the concrete had been mixed and delivered to the forms, it was protected from freezing by coverings of heavy tarpaulins or canvas (Fig. 10) and by the use of large steam coils placed sufficiently above the concrete to prevent its damage due to drying out. Much cold weather was experienced, but no serious damage was done to the dam or spillway structure.

TEMPERATURE STUDIES

An attempt has been made to determine by what amount the maximum temperature in the dam has been reduced by the various expedients adopted. From temperature observations it was ascertained that the maximum temperature rise in the dam was 40°. Calculations based on observations at Hiwassee Dam, Norris Dam, and elsewhere, seem to indicate that the use of low-heat cement, low cement content (0.8 bbl per cu yd), low casting lifts (2½ ft) with three and a half days exposure, artificial cooling of mixing water, aggregate,

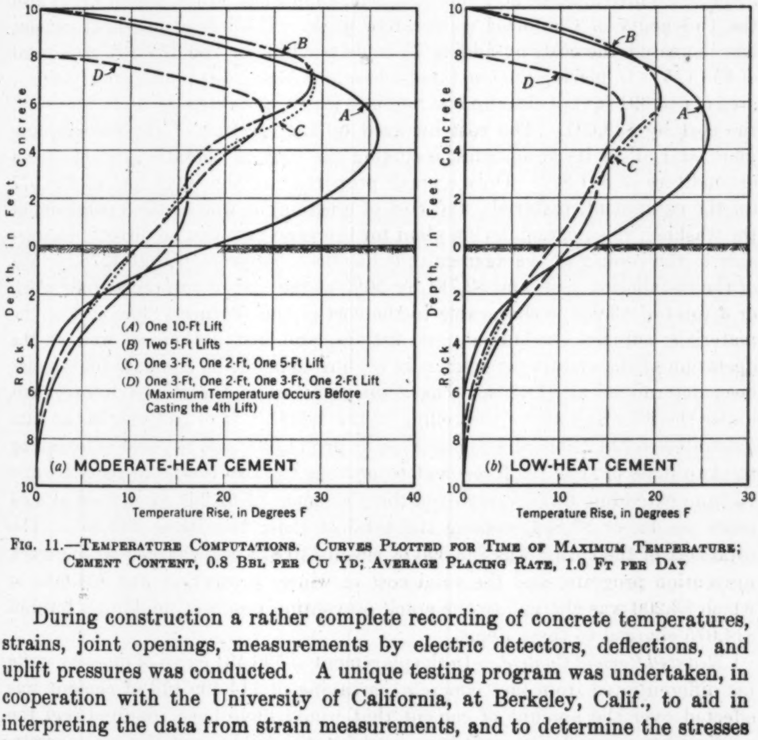
and concrete in place have reduced the maximum temperature approximately 31° below that which could have been expected had "Type B" (modified cement) been used, with a cement content of one barrel per cubic yard, and 5-ft lifts and five-day exposure periods. Of course, this would apply only to those parts of the dam constructed in the 2½-ft lifts and using artificial cooling of the mass. Table 8 shows estimated changes in the maximum temperature rise due to the placing rate and type of cement used; it gives temperatures for concrete, poured at Hiwassee Dam, containing 0.8 bbl of cement per cubic yard, based on preliminary estimates of heat generation for low-heat cement. The cement actually used generated more heat than was estimated. In addition, Figs. 5 and 11 show temperature variations, both recorded and computed.



(a) MODERATE-HEAT CEMENT (b) LOW-HEAT CEMENT

FIG. 11.—TEMPERATURE COMPUTATIONS. CURVES PLOTTED FOR TIME OF MAXIMUM TEMPERATURE; CEMENT CONTENT, 0.8 BBL PER CU YD; AVERAGE PLACING RATE, 1.0 FT PER DAY

During construction a rather complete recording of concrete temperatures, strains, joint openings, measurements by electric detectors, deflections, and uplift pressures was conducted. A unique testing program was undertaken, in cooperation with the University of California, at Berkeley, Calif., to aid in interpreting the data from strain measurements, and to determine the stresses by laboratory methods rather than by mathematical analyses. The entire scientific program was directed by the TVA materials engineering organization, except the experiments at the university. This scientific program was not necessary at Hiwassee Dam in order to prosecute the crack prevention program. That is, when the results were finally interpreted by the experiments and calculations, it was too late to apply them; but they may be of service to other engineers and on other large projects.

Cost of Program

A comparison of the cost of the program of crack prevention at Hiwassee Dam, with a program that would have used a predicted cement content of one barrel per cubic yard and without all of the crack prevention features, has been made. In reviewing the cost, the additional life of the structure, which has no doubt been increased because of the relative absence of cracks, should also be considered and credited, especially when the crack prevention program has actually resulted in a saving.

Additional Costs.—To conduct the scientific program cost $29,000, which includes all instruments, equipment, special shop work, labor, salaries, and also the University of California cooperative work. The use of low-heat cement has increased the cost, by adding 7½ cents per bbl for 766,375 bbl, or a total of $58,115. In placing the two hundred and fifty-one 2½-ft pours, an additional area of 643,691 sq ft of cleanup was required which, at 6 cents per sq ft, increased the cost by $38,621. The cost incurred by the erection of the refrigerating plant and all of its accessories, including the cost of operation, involved an expenditure of $41,820. Only a small proportion of the total cost of $48,677 for the equipment, materials, and cost of erection, as well as the operation, of the washing, rinsing, and drying plant for the aggregate can be directly chargeable to the cooling of the aggregate; it has been determined that $278, or 3% of the installation cost, and $2,781, or 50% of the cost of compressed air used, or a total of $3,059 is chargeable to the cost of this feature. The cost of the materials, supplies, including pipe, fittings, and installation, as well as the operation of the system for artificially cooling some of the concrete blocks, has been determined as $11,864. The additional cost of the steel reinforcement under the floor and above the ceiling of the 1,828 lin ft of galleries in the dam amounted to 238,210 lb at 4.64 cents per lb, or $11,033; and the cost of installing the two mats of steel reinforcement to prevent the two cracks in blocks 4 and 15 from extending upward involved the placement of 52,201 lb of steel at 4.64 cents per lb, or $3,814, making the total of these two items $14,857. The total cost of the curing was $43,500 of which $10,875 was charged to the crack prevention program, and the total cost of winter protection was $31,600, of which $3,200 was charged to the crack prevention program, making a total of $14,075 charged to these items.

Reduced Cement Content.—In the placement of 596,431 cu yd of mass concrete (as differentiated from face concrete), a saving of 114,499 bbl of cement was effected over the amount of cement that would have been required had the predicted one barrel of cement been used for each cubic yard of mass concrete. When a check was made by deducting 0.20 bbl of cement per cubic yard for the 596,451 yd of mass concrete, a saving of 119,290 bbl was obtained. In calculating the saving in cement, however, the lower number (114,499 bbl) was used; at $2.14 per bbl, which is the cost at the mixing plant, a total saving of $245,028 is indicated.

The cost of the crack prevention program may be summarized as follows: Additional cost of—

Scientific program	$ 29,000
Use of low-heat cement	58,115
Thin casting lifts	38,621
Low casting temperatures	41,820
Cooling the aggregate	3,059
Artificially cooling the concrete in place	11,064
Use of steel reinforcement	14,867
Curing and winter protection	14,075
Total additional cost of crack prevention (794,439 cu yd at 26½ cents)	$210,621
Reduction in cost for saving in cement (114,499 bbl at $2.14)	245,028
Surplus or saving	$ 34,407

ACKNOWLEDGMENTS

During construction I. L. Tyler, M. Am. Soc. C. E., Douglas H. McHenry, and W. R. Waugh, Assoc. M. Am. Soc. C. E., have had charge of the Materials Engineering Section in the order named under the immediate direction of the writer. These men supervised the work in the concrete laboratory, the technical control of the aggregate manufacture, and the concrete mixing and placing; conducted the scientific program; and directed much of the work on the crack prevention program. The results achieved are largely due to their efforts.

Hiwassee Dam was designed and built by the TVA under the general direction of: A. E. Morgan as chief engineer and Carl A. Bock as assistant chief engineer until May 1, 1938, and since that date, Theodore B. Parker, chief engineer; B. W. Steele until November 20, 1936, as chief design engineer; Barton M. Jones as acting chief design engineer from November 20, 1936, to January 16, 1939; H. A. Hageman since that date as chief design engineer; Theodore B. Parker to July 1, 1938, and A. L. Pauls, since that date, as chief construction engineer; C. E. Blee, project engineer at the dam; and the writer as construction engineer. All the foregoing are members of the Society. Lex Phifer was acting construction superintendent to January 1, 1938; from that date to March 8, 1940, J. E. Walters was construction superintendent, and since the last date E. C. McClenagan was acting construction superintendent.

DISCUSSION

Douglas McHenry,[4] **Esq.** (by letter).—The author has presented a straightforward objective account of the procedures which were successfully used to control cracking during the construction of a large concrete dam. It might be well to emphasize the thought that Hiwassee, like every other major dam, represents a particular case in respect to both design and construction, and that the control methods which were satisfactory in this case may be insufficient or uneconomical elsewhere. On this account the paper would not have lost in value or interest had it included more discussion of the reasoning which led to the adoption of certain procedures and the rejection of others, together with a final evaluation of the effectiveness of the various items listed in the cost schedule.

On future projects where cracking control is required, the Hiwassee experience may well serve as a guide, but scarcely as a model to be followed exactly. The list of factors to be considered in conducting a control program may reach rather formidable dimensions. It will include such items as properties, topography, and structure of the foundation, properties of the materials of construction, details of design, river diversion scheme, climate, and (not the least important) the personnel of the design and construction groups. All of these items can, and should, be taken into account. Many of the details can be accorded only qualitative consideration, and must be handled in accordance with common sense and experience. Many cannot be covered by advance specifications because the conditions requiring treatment are often unpredictable.

A successful crack control program must combine (very much after the fashion of a successful program of foundation treatment) a rigid general specification, based upon preliminary study, with flexible detail specifications which may be adapted to various unpredictable conditions.

The writer was in close contact with the Hiwassee program from the time of its inception until the completion of the dam, and gained a definite impression that the relative values of the different phases of the program were about proportional to their relative costs, with the exception of the item "low casting temperatures." It appears, now that the job is completed, that the expenditure for cooling the mixing water would have been better justified had it been increased sufficiently to permit the use of slush ice in the mixers (as at Friant Dam, in California); or, if it had been distributed among the other phases of the program. The advantage gained by pre-cooling is dissipated to some extent during the period of exposure between lifts; so pre-cooling will be most effective with a rapid placing schedule.

The evidence favoring some type of low-heat cement for massive concrete construction is now established rather definitely. Former fears regarding construction difficulties due to its slower rate of hardening have been largely dispelled, and experience has shown that it need cost little or no more than modified cement. Superficial temperature studies may be deceptive in regard to the effect of type of cement. Under certain construction conditions it is possible that low-heat cement will produce a greater temperature rise than modified cement. The advantage lies chiefly in the slower early rate of heat generation (especially advantageous with artificial cooling), the more favorable shape of the temperature gradients, and the greater extensibility of the concrete.

---

[4] Engr., U. S. Bureau of Reclamation, Denver, Colo. (formerly Engr., TVA).

The decision to use thin lifts on the foundation and on old concrete surfaces was based upon theoretical studies of temperature distribution, and the resulting stresses. Such studies were necessarily incomplete because of the present lack of a satisfactory means of relating strains and stresses during the early life of concrete. It is gratifying that field performance indicated that this phase of the control program was fully justified.

The cost item of $11,064 for cooling the concrete in place artificially represents, in the writer's opinion, one of the most worth-while items of expenditure in the program. Among other things, it has indicated the complete feasibility of applying embedded-pipe cooling to local regions where a degree of volume constancy is required, either to prevent cracking or for other reasons. It is of interest to compare the cost of the adopted control methods with the cost of an alternative scheme, probably equally effective, involving artificial cooling of the entire dam. With complete cooling the items of thin casting lifts, low casting temperatures, cooling the aggregate, and local artificial cooling might have been eliminated, but all others would have been largely, if not wholly, retained. The minimum cost of a complete embedded-pipe cooling system may be taken as $0.144 per cu yd of concrete (the cost for Grand Coulee Dam), or $115,000 for the entire structure. The total cost under this scheme would have been $231,000, compared with the actual cost of $210,621. The difference is scarcely great enough to be significant as an indication of the relative economies of the two schemes because of insufficient data on their relative merits. In this particular case, grouting the contraction joints before putting the structure into service was not considered necessary. In cases where early grouting is essential, complete artificial cooling is definitely required.

The author's balancing of saving in cement against the cost of the control program to indicate a net saving is most interesting. This balance apparently carries an inference that the dam as actually constructed, with a low interior cement content and relatively free from cracks, is equal in quality to the same structure with higher strength interior concrete and a normal amount of cracking. The writer is inclined to concur in this view, but recognizes it as an excellent subject for speculation.

The inclusion of the $29,000 item for the scientific program is likewise of interest; this inclusion acknowledges a debt to the similar research investigations of the past that are to a large extent responsible for the success and economy of the Hiwassee control program.

REGINALD H. THOMSON,[5] HON. M. AM. SOC. C. E. (by letter).—This is a paper of unusual excellence because it gives a clear and concise report on the numerous different operations that had as their common objective the prevention of cracks and the construction of the most durable wearing surfaces in the Hiwassee Dam. Furthermore, a financial statement on the program is submitted, and the reader is afforded an opportunity of appraising this phase of concrete dam construction on a dollars-and-cents basis. Although he differs with the author on some matters, the writer would nonetheless express his appreciation of this distinctly superior paper. The fact that the total cost of the dam is nowhere given renders percentage studies based upon total cost impossible.

---

[5] Cons. Engr., Seattle, Wash.

During recent years the building of concrete dams has become a matter of increasing care and concern to those charged with the responsibility of their construction and maintenance. For this there is good reason, since some of the older dams have failed to possess either the watertightness or "permanence" so confidently and enthusiastically attributed to them when they were first built. Dams are expensive structures at best, and heavy maintenance and repair bills following heavy initial investments are always unsatisfactory. Particularly are they so when unexpected.

The engineers furnishing the ten or eleven formulas, under which this construction was to be completed, showed by their provisions that they fully realized that water was one of the greatest of solvents, that in passing through cracks either in concrete or granite it dissolved and carried away some of the substance, and in so doing not only enlarged the crack but weakened the structure. The rules for the distribution of the cement throughout the structure showed an intelligent comprehension of the relation of heat in the newly made blocks of concrete to their expansion and contraction in the process of curing.

There was also a definite comprehension of the fact that either rock or masonry exposed to weather is subject to elements provided by nature for the destruction of masonry by the aid of water in connection with heat and cold. It was also finally detected and falteringly admitted that water is a destructive agent in the concrete mix itself, and that its proportionate quantity must be regulated carefully.

Engineers finally came to a realization that excessive mixing water was the cause of many troubles. Dams and other structures built with sloppy mixes were leaking, weathering, and eroding, whereas older dams of the "dry-tamped" period were not. With flawless logic it was reasoned that a marked return toward former practice would largely restore the former qualities. It also was observed that concrete mixtures with more cement in them resisted weathering and the penetration of water better than the leaner mixes. Methods of mixing so as to combine the aggregate into a somewhat unified body were studied also.

Out of the accumulated experiences has come a very marked improvement in modern dam construction that permits a central mass of concrete of reasonably low cement content, a water content as low as possible, and an aggregate gradation of maximum density. Having established these values for the particular project, thenceforth it is demanded to maintain them and secure uniformity in batching, mixing, placement, and curing. The final result comes from the minute attention given to the adopted formula—or to its misuse.

The tables in this paper, beginning with Table 1, constitute valuable data for the student of concrete behavior. Here are given the weights of seven different batch mixes, and the weights of cement, sand, and large aggregates of four different sizes, together with the pounds of water used. This is followed by records of compressive strength achieved by the various field mixes running up to one year. This provides a field for specific investigation for inquisitors through many years to come.

Table 2, comparing concrete to certain composition in the Norris Dam with concrete of different composition in the Hiwassee Dam, shows the persistence of study and forward look on the part of the Hiwassee constructer. Table 5 gives the temperatures prevailing when the various masses were deposited. Certainly, the care and watchfulness taken in securing and recording the facts given in these tables mark a class of construction personnel far ahead of the ordinary, and, through such careful work and intelligent study of results, concrete so made should enjoy the word "permanent." How much of the special work done under this $210,621 contract is at this date specifically unusual it is difficult to affirm definitely.

The use of low lifts (approximately 5 ft) with long hours given for each lift to enable the concrete to adjust its chemical combination and return to quite nearly normal temperature, using a minimum of cooling pipes throughout, as against the common practice of 10-ft lifts with an abundance of cooling pipes, is a process that can be commented upon only with data furnished from structures of similar size, and this comparison the writer is not able to make.

It is true that the three casting lifts are charged with only $38,621 of the total increased cost, and that at 6¢ per sq ft for the cost of cleaning up, and with no knowledge as to the price paid per hour, the 6¢ cost carries little information for a separate job. On such works as the writer has been engaged upon, time of completion of the structure has been of great value. Here, with 5-ft casting lifts, five days (or one day per ft) is given for curing of concrete. This was done to avoid cumulative heat and resultant expansion. Since all this work was done on a cost-plus arrangement, and since the writer is ignorant as to the terms of the agreement, he cannot give any opinion as to the probable final cost compared with the cost that would have followed with 10-ft lifts and standard cooling pipes.

The report on diagonal keyways is very interesting and indicates that the usual belief that stresses occur normally at right angles to the face of a structure is reasonably correct.

The paper refers to tests made during the first few months of concreting to determine the effect of grinding in the mixers, which tests were used to correct the combined aggregate grading of the material going into the mixers, and to obtain a desirable grading in the fresh mixed concrete. This process is one which the writer does not quite comprehend. Was it to determine the number of revolutions to be made in the mixing drum, or was the rock aggregate so soft that the reduction made in the size in the mixers had to be accounted for? This is a refinement to which the writer is not accustomed.

Engineers who follow contractors' methods of "getting things done," rather than laboratory methods, will no doubt question the value or the worth of the $210,621 cost added to the possible lesser cost that might have been incurred with less attention to details.

One can only "guess at" or roughly estimate the probable cost of the dam, except by listing the quantities of materials used in its construction, but cannot place the probable cost at less than, say, $12,000,000. Now, an insurance cost of $210,621 placed upon a $12,000,000 structure, to insure longer life, is a very small sum. Personally, the writer feels that the need of refacing the face and spillway of this dam has been postponed by this care for such a number of years that it will make this sum a ridiculously small one to have been incurred in order to produce the added life.

It is understood that there is a committee of engineers in the employ of the federal government which is now examining every known dam in the United States, and preparing a report in which all salient points relating to construction will be set out. When that has been published, many theories will no doubt be dissolved, and a better light given by which to design; but the tables given in this paper will continue to be of value.

W. R. WAUGH,[6] ASSOC. M. AM. SOC. C. E. (by letter).—In recent years more and more study has been given to the problem of temperature cracking in mass concrete. An analysis of the causes surrounding the occurrence of a crack usually has suggested a possibility of eliminating the recurrence of a crack under similar conditions by controlling the circumstances that were known to have caused the original crack. A diligent record, made during construction, of the location and circumstances of occurrence of cracks, is invaluable as an aid in studying the causes, and suggesting means, of controlling cracking. At Norris Dam such a record was made as a part of a program of special-instruments investigation which included the measurement of concrete temperatures at selected points in the dam. Much of the experience gained from a study of these data, along with knowledge gained from the experience of other agencies, was translated into the special program adopted for Hiwassee Dam. The success of the program is attested by the small number of cracks that developed.

As indicated by the author, some cracks did occur and careful records were made of locations and circumstances of occurrence. These indicate the need for continued study of causes and improvements in the technique of prevention. Refinements in the construction program offer a means of eliminating circumstances under which cracking is likely to occur. The elimination of large differentials in height between adjacent blocks is one means of avoiding circumstances that are conducive to cracking. High contraction-joint faces exposed for long periods nearly always result in cracking; however, the construction program can usually be arranged economically to eliminate most of these high exposed faces. In some instances it is necessary to leave certain blocks low for stream diversion during construction. When such a situation arises, special measures can be taken to control the conditions of temperature in the adjacent blocks with the high exposed faces so that cracking will not occur. The mass was cooled artificially in a circumstance of this nature at Hiwassee Dam, with success.

---

[6] Materials Engr., TVA, Hiwassee Dam, N. C.

In the closing paragraphs of the paper under the heading "Cost of Program: Reduced Cement Content"), the author has presented a summary in which he purports to show that an actual saving in total cost of the structure was achieved as a result of the program. In several respects the writer cannot agree with the author's method of computing what he calls "Additional Cost," and there also arises a question as to the validity of the credit claimed for a saving in cement.

Considering first the summary of additional cost and using the author's nomenclature and explanation under the heading "Additional Cost," the estimate in Table 9, Col. 3, is submitted as the writer's estimate of additional cost. Comparing these values with the author's summary (Col. 2, Table 9), it will be noted that three items (Nos. 1, 5, and 8, Table 9) have been omitted and one item (No. 7) changed. First, the cost of the scientific program (No. 1) has been omitted because this program was conducted to gain additional knowledge concerning stress, strain, contraction joint openings, foundation uplift pressures, and interior temperatures during construction and with the structure in service. It is true that some of the thermometer installations aided in the control of artificial cooling in one block, and this was a benefit to the program; but largely the scientific program did not benefit the crack prevention program directly and, therefore, should not be charged against it. Second, some small benefit, no doubt, was gained from the cooling of the aggregate (No. 5, Table 9) after the rinsing process was completed due to evaporation of free water. The rinsing process, however, had an entirely different function, and the benefit which did accrue was small and purely incidental; and, therefore, this charge should not be made. Third, the charge for "curing and winter protection" (No. 8, Table 9) should be omitted because these are normal functions of the concreting program that would have been

TABLE 9.—Comparative Cost Estimates, Crack Prevention Program, in Dollars

No.	Description (1)	Author (2)	Writer (3)

10	Reduction in cost for saving in cement	245,028	123,000
11	Surplus or saving	34,407	....
12	Increase in cost of project	....	30,434

conducted regardless of whether or not any special measures for controlling temperature cracking had been adopted. Fourth, as to the "use of steel reinforcement" (No. 7), only that which was used in the special mats intended for the purpose of preventing the extension of two cracks which had already occurred should be charged to the program, because the steel in the roof of the galleries would normally have been used in any event.

In proof that an actual reduction in cost to the structure resulted from the program, the author has taken a credit for cement saved. The cement content of 0.80 bbl per cu yd for interior (mass) concrete was a natural outcome of having selected a maximum allowable water-cement ratio which resulted in this cement requirement since for the desired consistency the water requirement was a rather definite quantity. In assuming what he calls "the predicted one barrel of cement" per cubic yard as a basis for the saving computed, the author has used a value that is subject to question since this prediction was made during the very early investigations and before a maximum allowable water-cement ratio was selected. The saving he has computed, therefore, is subject to question. The value of using the lowest possible cement content commensurate with desired properties of the hardened concrete both from the standpoint of pure economy and the reduction in tendency to crack is beyond question, but in this case the manner of computing the saving is questioned. At Norris Dam a cement content of 0.90 bbl per cu yd for the interior concrete was adopted. Using this value in computing the credit for cement saved would seem more logical. Thus the credit would be about half of that used by the author, or roughly $123,000 (No. 10, Table 9). Applying this credit against the suggested "Additional Cost" (No. 9), an estimated increase in cost to the structure of $30,434 would result.

It does not seem logical that a program so valuable to the finished structure could be conducted without cost. This would seem contrary to the old adage that, "You can't eat your cake and have it too." Even if the program had cost the project all of the $153,434 proposed as the "Additional Cost" (which is probably not true) and if no credit was taken for cement saved (which would indeed be an extreme viewpoint), the value to the structure in reduced maintenance and increased life should be much more than the additional amount expended on the program. In the preliminary planning the improved quality of the structure was the consideration that prompted the adoption of the program. It was anticipated that the program would cost something, but it was fully appreciated that the improvement in quality of the structure would be worth far more than the additional cost incurred.

O. LAURGAARD,[7] M. AM. SOC. C. E. (by letter).—In addition to the formal written discussions of this paper, certain phases have been discussed in conversation and by correspondence with other engineers. The writer was pleased with the favorable comments by all the discussers, because they are familiar with the subject and qualified to express their opinions. In general, he agrees with most of them, but in some instances questions will be answered, the text clarified, or explanations made.

---

[7] Care, Bethlehem Alameda Shipyard, Alameda, Calif.

The contribution by Mr. McHenry is interesting and valuable to the general discussion regarding flexible detail specifications for a successful crack prevention program; the use of low-heat cement and temperature studies; the use of thin concrete lifts during construction, based upon theoretical studies of temperature distribution and resulting stresses; the comparative value of the item of low casting temperatures; the relative value of cooling the concrete, in place, artificially by embedded water pipes; and the balancing of the saving in cement against the cost of the crack prevention program.

The writer agrees with Mr. McHenry that the paper would have lost none of its value or interest had it included more of the discussion or reasoning that led to the adoption of certain procedures and the rejection of others, together with a final valuation of the effectiveness of the various items listed in the cost schedule; but such data are so numerous and formidable (as expressed subsequently by Mr. McHenry) that time and space would not permit the inclusion of all of them. The items enumerated in the second paragraph of Mr. McHenry's discussion were considered by the engineers of the TVA in connection with the crack prevention program as adopted.

Although it may be admitted that the pre-cooling of the mixing water was not as effective as had been hoped, the writer cannot agree with Mr. McHenry that this item was not as justifiable in proportion to cost as the other items. From Table 5 it may be seen that for the five months from May to September, inclusive, in 1939, for shift 1, the air had an average temperature of 80.2°, the cement 100°, the river water 74.4°, the cooled mixing water 42.4°, and the concrete placing temperature 72.2°. It will be noted that for June, 1939, for a five-day period when the water was not artificially cooled for the same shift, the average temperatures were: Air 83°, cement 107°, river water 75°, and the concrete casting temperature 81°. Thus it will be noted that the casting temperature of the concrete for June, 1939, was reduced about 9°. In the paper it was stated (see heading "Washing, Rinsing, and Cooling the Aggregate") that "The effective reduction in concrete placing temperature by refrigerating the mixing water was about 6°." Of course, it must be admitted that, if a temperature of 32° had been maintained for the pre-cooled water, the casting temperature would have been reduced another 2°, which would have been justifiable. The pre-cooling of the mixing water at Hiwassee Dam was an afterthought and was not effective until September, 1938. An old refrigerating plant that was available was installed so the minimum temperature for the mixing water was set at 35° or 36° to prevent the freezing of the pipes. In the case of a slow placing schedule, something less than 1 ft per day as was adopted for Hiwassee Dam, the advantage gained by pre-cooling may be lost to a limited extent.

The writer agrees with Mr. McHenry in regard to cooling the concrete in place artificially. He advocated the placement of cooling pipes and the circulation of cool water through the concrete of the dam before construction was begun, but this plan was not adopted by those in higher authority. The embedment of cooling pipes in local regions to reduce cracking, maintain uniform volume, and for other purposes resulted, and was fully justified by the results obtained.

The comparison of costs, as made by Mr. McHenry, between complete artificial cooling of the concrete in the dam and the combined cost of thin casting lifts, low casting temperatures, cooling the aggregate, and local cooling, is interesting. The estimates made by the writer for plant and operation and for embedding cooling pipes were about 17¢ to 18¢ per cu yd, which is higher than the cost of 14.4¢ at Grand Coulee Dam, primarily on account of the smaller yardage and the remoteness of the work. Pre-cooling the mixing water in conjunction with artificial cooling of the concrete in place would be much more effective because the low casting temperature would reduce the temperature during the early setting stage, and the circulation of cool water would prevent the dissipation of this pre-cooling during the long exposure period.

The discussion by Mr. Thomson is of great interest and of especial value concerning: The increasing care and concern to those in charge of concrete dams; the heavy maintenance and repairs of poorly constructed dams; the distribution of cement in the dam and its relation to heat, contraction, and expansion; the destructive effect of water and exposure; the danger of excessive use of water; the use of thin casting lifts; the use of diagonal keyways; and the writer's interpretation of the tables submitted with the paper.

To answer the inquiry of Mr. Thomson concerning the use of 10-ft lifts with complete artificial cooling, several assumptions must be made. If the costs of thin casting lifts, low casting temperatures, cooling the aggregate, and artificially cooling the concrete in place are eliminated in the tabulation of the cost of the crack prevention program, and the other four items retained, then savings could be made in addition to the cleanup of the pours. If the cleanup should be made at the same cost as at Hiwassee Dam (6¢ per sq ft) and the cost of circulating cooling water is placed at 17¢ per cu yd (as estimated in this discussion), then the cost of the crack prevention program using 10-ft lifts would be about 21¢ per cu yd compared with 26.5¢ at Hiwassee Dam. In the judgment of the writer the use of 10-ft lifts with the foregoing program would not be as effective for crack prevention as that used at Hiwassee Dam; and in addition other factors should be considered also.

Mr. Thomson refers to tests made to determine the effect of grinding in the mixers, and desires to know the purpose of the tests. They were made to determine the grading of the aggregate in the concrete after the mixing, in order that the engineers could make the necessary changes and adjustments to the grading of the aggregate as it was fed into the mixers. It was discovered early that the graywacke rock was inclined to break down in the mixers and produce an excess of fine material. The grinding of the aggregate in the mixers, including the tests made and conclusions drawn, is important and could easily be made the subject of a paper, so time and space will not permit complete discussion in great detail. The writer feels, however, that a brief résumé may be of interest. The rock and sand seemed to break down to a minimum size, between 200-mesh and 325-mesh, but there was practically no aggregate of a smaller size. During the summer of 1938 a large number of small "grab" samples (from 100 to 125 lb) were taken from the concrete at the mixer discharge, which were wet-screened to give an average grading from the mixer, and were compared with the average theoretical grading going into the mixer. The tests indicated a large increase in the – 100-mesh material, so this size was reduced from 16% to 12% in the finished sand by wet classifying. These small tests showed increases in the – 100 fines from 100% to 200%. The tests also showed an increase of the material between 28-mesh and 100-mesh during the mixing, which suggested a reduction of the quantity of sand. It may be noted in passing that no precedent was available as a guide to determine the most desirable grading or to make adjustments to compensate for the grinding. It was found that other aggregate material, which was believed to be stable, showed considerable change due to grinding, but not perhaps to the same extent as the graywacke.

In order to obtain more reliable data than those from the small "grab" samples, it was decided to analyze some full 2½-cu-yd batches. In the test batches it was necessary to omit the cement because the time for wet-screening a batch of that size was about a week for several men. In place of the cement, – 100-mesh classifier fines were substituted by absolute volume in order to simulate as nearly as possible the mixing action when cement was used. Six 2½-cu-yd batches were analyzed, three of which were charged and mixed for 2½ min in the regular manner and three of which were charged on what was designated a "split batch" charging, and mixed for a total of 2½ min. The "split batch" cycle was charged in two parts: First, the water, cement (or – 100-mesh fine substitution), sand, and two smaller sizes of rock were charged into the mixer and mixed for 1¼ min; and second, the coarse rock and cobbles were charged, and mixing continued for another 1¼ min. The objective, of course, was to reduce the amount of grinding, since the grinding, it was assumed, was largely a result of "ball mill" action with the coarse aggregate grinding the sand. This method of charging and mixing was adopted for "face" concrete after July 17, 1939. Changes in grading of the coarse aggregate—particularly cobbles, coarse rock, and medium rock—were small. The amount of material larger than 4-mesh changed only slightly after mixing, and a comparison of these amounts (see Table 10) indicates that very little material is lost from the coarse aggregate into the sand classification. The results for the full batch tests altered the conclusions reached from the small "grab" samples. The large tests showed an average increase of about 50% for the – 100 classification.

Mr. Thomson raises a question as to the cost of the dam. The approximate costs kept at the dam are $13,285,000, to which should be added $2,379,000, representing other general accounts, and $1,150,000 for land acquisition, making a total of $16,814,000. If it were possible to separate, physically, the power house, penstocks, and power equipment from the dam, the $13,285,000 could be broken down further into these items: Dam, $10,226,000; power house, substation, turbine, generator, and miscellaneous power-house equipment, $2,001,000; reservoir relocations, $765,000; and reservoir clearing, $295,000. Mr. Thomson fixed the cost of the dam at $12,000,000, whereas the dam and power house cost $12,226,000; therefore the expenditure of $210,621, or 1.72%, as a factor for crack prevention and longer life seems reasonable.

Mr. Waugh takes exception to the writer's claim for reduction in the cost of the crack prevention program by the saving in cement. He also deducts the cost of the scientific program, $29,000; the cost of cooling the aggregate, $3,059; the cost of curing and winter protection, $14,075; and a part of the cost of steel reinforcement, $11,053, from the estimated cost of $210,621 for the entire program. The net result of the deductions by Mr. Waugh is to show an increased cost of $30,434 for the program, whereas the writer showed a saving of $34,407. These items will be taken up briefly in the foregoing order, which is the same as that used by Mr. Waugh.

TABLE 10.—COMPARISON OF AGGREGATE GRADING FOR MASS CONCRETE BEFORE AND AFTER MIXING[a]

(Expressed as a Percentage Change Based on Volume of Material Before Mixing)

Test No.	Standard Screen Size						
% passing: % retained:	.... 4-mesh	4 8	8 14	14 28	28 48	48 100	100 Pan
			(*a*) REGULAR CHARGING				
6	−1.0	−26.8	−11.5	−12.2	0	+41.9	+78.1
2	−3.0	− 6.8	−12.2	− 7.9	+41.2	+13.9	+47.2
1	−5.0	−20.0	−12.5	− 7.7	+27.6	+61.9	+58.2
			(*b*) SPLIT CHARGING				
3	+2.0	−31.0	−11.5	− 7.3	+11.1	+23.7	+22.6
4	0	−29.7	−10.4	−10.5	+19.5	+25.0	+25.0
5	0	−27.4	−12.2	−12.8	+10.8	+ 5.7	+67.7

[a] Minus (−) indicates that the quantity after mixing is less than it was before mixing; plus (+) indicates that the quantity after mixing is greater than it was before mixing.

In the paper, the writer used the phrase "predicted cement content of one barrel per cubic yard" advisedly and after careful consideration. In other words, it seemed that there was no hope of using less than 1.00 bbl of cement for the interior mass concrete and 1.25 bbl for the face, using modified cement (Type B) and graywacke rock and sand. During the early period of the Hiwassee project, before the type of cement or cement content had been decided upon, 1.05 bbl of cement per cubic yard for the mass concrete in the interior of the dam was generally considered, especially using sand manufactured from graywacke rock. Consideration was even given to the importation of quartz sand from Georgia because of the breaking down of the graywacke sand. Exhaustive tests were made in the laboratory to determine the suitability of the various types of available aggregate, with the result that it was determined to use both graywacke rock and sand. Engineers of the design department and others in authority advocated 1.05 bbl of cement for the interior mass concrete of the dam. At several conferences the writer advocated 1.0 bbl per cu yd of modified cement (same as Norris Dam) for the mass concrete, but it was not adopted.

It was only after the consultants (Messrs. Carlson and Davis) had recommended[8] low-heat cement and low cement content that any cement content less than 1.0 bbl per cu yd was considered (to the knowledge of the writer). In their report they suggested that the desired results would be most nearly obtained as follows:

---

[8] "Problems Pertaining to the Concrete for Hiwassee Dam," Report by Roy W. Carlson and Raymond E. Davis, Cons. Engrs., to Carl A. Bock, Asst. Chf. Engr., April 11, 1938, pp. 2 and 7.

(1) By using a low-heat cement;

(2) By using for the interior of the mass a concrete of low cement content, and for the exposed faces a concrete of normal cement content;

(3) By a controlled placing schedule, using thin lifts immediately above foundations and immediately above surfaces of concrete that had been placed for a considerable period; and

(4) By maintaining low casting temperatures.

In their report they further stated:

> "A trial mix containing 0.75 bbl. per cu. yd. has been shown to be very plastic and workable and to exhibit almost no water gain. * * * preliminary investigations would seem to indicate that a cement content of 0.75 bbl. per cu. yd. might be employed with a water-cement ratio of not greater than 0.85, * * *. It is recommended that for the mass of the dam there be employed a concrete for which the water-cement ratio is about, but not more than, 0.85 and for which the cement content is not more than 0.8 nor less than 0.75 bbl. per cu. yd."

Table 11, from the official records of TVA, is submitted to show the cement content of the dams designed and constructed previous to the Hiwassee Dam.

TABLE 11.—CEMENT CONTENT OF TVA DAMS

Description	Pickwick	Wheeler	Guntersville	Norris	Chickamauga	Hiwassee
Volume (cubic yards)	626,919	612,857	286,312	968,119	489,169	783,154
Cement Content:						
Barrels	693,956	774,054	369,442	1,061,190	642,783	741,127
Barrels per cubic yard	1.105	1.260	1.290	1.096	1.310	0.946

The amount of saving by the reduction in cement used can be obtained by three methods: First, by the actual number of barrels of cement used for the 596,431 cu yd of interior mass concrete, compared with the predicted one barrel per cubic yard, which gives 114,499 bbl at $2.14, or $245,028; second, by applying the saving of 0.20 bbl per cu yd for the 596,431 cu yd, which gives 119,290 bbl of cement at $2.14, or $255,280; and third, by taking the total yardage of concrete at Hiwassee Dam of 794,439 cu yd and applying the difference between the average cement content at Hiwassee Dam and the average at Norris Dam (as shown in Table 11) at 0.15 bbl per cu yd, which gives 119,166 bbl at $2.14, or $255,015. After all, the amount of saving in cement is a matter of judgment. The writer believes the lowest sum ($245,028), which was used in the paper, to be fair. Mr. Waugh states that "At Norris Dam a cement content of 0.90 bbl per cu yd for the interior concrete was adopted." According to the record, that is correct, but the adopted content was not realized in practice. It is found from the record that, during the first two months of concreting at Norris Dam, 1.10 bbl was used; then the content was changed to 0.95 bbl and later adopted to 0.90 bbl. Evidently the actual average of placement was in excess of 1.00 bbl because the average of all mass concrete interior and face (for 871,763 cu yd) was about 1.061 bbl per cu yd and the average for 968,119 cu yd was 1.096 bbl.

The discussion by Mr. Waugh, of studies of temperature cracking in mass concrete, is valuable.

Mr. Waugh admits that some benefit was received during construction from the scientific program, and the writer admits that the benefit did not equal the total cost of $29,000, but the clearest explanation is made by Mr. McHenry when he states

> "The inclusion of the $29,000 item for the scientific program is likewise of interest; this inclusion acknowledges a debt to the similar research investigations of the past that are to a large extent responsible for the success and economy of the Hiwassee control program."

Mr. Waugh admits a small benefit from the cooling of the aggregate, but the charge (explained in detail in the paper) also is small. On the other hand, the reduction in casting temperature of the concrete amounted to about one degree The design of the inspection tunnels (being flat on the top and bottom with chamfered corners and heavy horizontal steel reinforcement above the roof and below the invert), and the placement of interior mass concrete around the exterior of the tunnels, produced a job practically free from cracks; so the inclusion of the cost of the steel reinforcement in the crack prevention program seems reasonable. Only that part of $74,600 (the cost of the curing and winter protection, which could be attributed to the slow setting tendency of low-heat cement), or $14,075 as explained in the paper, was charged to the crack prevention program. All of the items of cost were obtained from the records of the cost engineer, and the final figures reflect his judgment, and that of several others familiar with the work.

The writer desires to express his appreciation to those participating in the discussion of this paper.

FORMULAS FOR THE TRANSPORTATION OF BED LOAD

BY H. A. EINSTEIN,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JOE W. JOHNSON, A. A. KALINSKE, O. G. HAYWOOD, JR., SAMUEL SHULITS, JOHN S. MCNOWN, AND H. A. EINSTEIN.

SYNOPSIS

A method for the representation of bed-load data is given in this paper. The method is based on the conception that bed-load transportation is the movement of bed particles, as governed by the laws of probability. By means of this method an equation is obtained, which describes a great number of experiments in channels with uniform beds. A group of experiments conducted on sand mixtures provides material for describing another application of the method.

INTRODUCTION

In the past the problem of bed-load transportation has been studied mostly by empirical methods. More recently, there has been a tendency to base transportation formulas on the new theories of turbulence.[2, 3] It is the writer's belief that an approach to the problem of transportation can be made by a combination of the empirical and rational methods and that the results can be expressed by dimensionless plots.

Before proceeding with the development of these formulas, it is necessary to discuss briefly two important considerations: (1) The difficulty or impossibility of defining, accurately, the so-called "critical" values; and (2) the possibility of correlating bed-load movement with local fluctuations in water velocity along the bed.

(1) Attempts have been made in the past to derive an expression for the "initial movement" that is governed by certain definable "critical" conditions to be used as the first step toward the solution of the transportation problem.

NOTE.—Published in March, 1941, *Proceedings*.

[2] "Anwendung der Aehnlichkeitsmechanik und der Turbulenzforschung auf die Geschiebebewegung," by A. Shields, *Mitteilungen der Preussischen Versuchsanstalt für Wasserbau und Schiffbau*, Heft 26, Berlin, 1936.

[3] "An Analysis of Sediment Transportation in the Light of Fluid Turbulence," by Hunter Rouse, Assoc. M. Am. Soc. C. E., SCS, Sedimentation Div., SCS-TP-25, Washington, D. C., July, 1939 (mimeographed).

In interpreting the results of many experiments on bed-load movement, and in comparing them with those obtained by other experimenters, the writer has concluded that a distinct condition for the beginning of transportation does not seem to exist. It is just as impossible to determine the limit of initial movement as to determine the maximum possible flood of a river. Just as the engineer is able to predict the probable maximum flood of a river to be expected within a given range of years, however, so is he able to define the hydraulic conditions in a stream that will produce any given small rate of movement, which might be called the limit. This value can be chosen without any restriction. It is difficult to believe that the hydraulic conditions that will produce such movement could have any special meaning in the problem of transportation as a whole. Therefore, the writer will not use the conception of critical tractive force, or any other critical value, when the term "critical" pertains to the flow where transportation begins.

(2) In general, transportation of bed load has been described as follows:[4] A particle of the bed moves when the pushing force or lifting force of the water overcomes the weight of the particle. This push or "lift" is expressed in terms of the average flow. The usual conception is that transportation begins when the velocity increases enough to overcome the weight, and that, with further increasing velocity of the water, the rate of transportation will also increase, following a certain law that is found empirically. To prove that this conception is misleading, assume that the force acting on a particle could be described by means of the average flow alone. If the velocity of the water is increased gradually to a point at which the first particle would just be moving, the force acting on all the other particles of the same kind and size would move those too. Therefore, in a uniform bed where all particles have the same size and shape, all would start moving together; they would be unable to settle again because at all points the water velocity is just sufficient to start movement. If this were true, there could be no law governing the rate of transportation, but only a critical velocity. At all undercritical velocities, there would be no transportation, whereas, at all supercritical velocities, the rate of transportation would be limited only by the number of particles available. Therefore, it cannot be presumed that the rate of bed-load transportation is a function of the average flow. Instead it is proposed to express it in terms of the fluctuations of the water velocity near the bed.

Results of previous studies[5] describing the movement of a bed-load particle by means of statistical methods are to be used in an attempt to coordinate the rate of transportation with the fluctuations of the water velocity near the bed. The results of these studies can be summarized as follows:

(*a*) These flume studies dealt with the movement of rather coarse particles along a bed consisting of the same kind of grains. Being coarser than 1 in. these particles always remained near the bed, rolling, sliding and, sometimes, in saltation according to the normal description of bed-load movement. It was found that the moving bed load and the bed on which it was moving formed a unit, inasmuch as there was a steady and intensive exchange of particles between the two. Thus it is concluded that all the particles of the bed, down to a certain depth, take equal part in the movement, alternatively moving and returning into the bed.

---

[4] "The Force Required to Move Particles on a Stream Bed," by William W. Rubey, *Professional Paper No. 189-E,* U. S. Geological Survey, Washington, D. C., 1938.

[5] "Der Geschiebetrieb als Wahrscheinlichkeitsproblem," von H. A. Einstein, *Mitteilung der Versuchsanstalt für Wasserbau an der Eidgenössische technische Hochschule in Zürich*, Verlag Rascher & Co., Zürich 1937.

(*b*) Bed-load movement is to be considered as the motion of bed particles in quick steps with comparatively long intermediate periods of rest. Thus bed-load movement is a slow downstream motion of a certain top-layer of the bed.

(*c*) The average step of a certain particle seems always to be the same even if the hydraulic conditions or the composition of the bed changes; and

(*d*) Different rates of transportation are produced by a change in average time between two steps and by a change in the thickness of the moving layer.

These concepts permit the development of a formula in general terms. The rate of transportation will be described by means of this average "step."

NOTATION

The letter symbols in this paper are defined where they first appear and are assembled for convenience of reference in Appendix I.

DERIVATIONS

This paper will treat only the bed-load movement of uniform sediment and mixtures acting like uniform sediment. In both cases it is possible to describe the sediment by a representative diameter D and its density ρ_s. The expression "acting like uniform material" means that both bed material and moving material have the same composition and, therefore, the same representative diameters. It is possible in this case to describe transportation at a certain point of the bed by one symbol; namely, the rate of transportation q_s. Two special cases of transportation, both of which have been observed and described in engineering literature, may be excluded from treatment in this paper: (1) Bed material moving in suspension; and (2) bed-load movements, in which the composition of the bed is essentially different from the composition of the transported material.

A bed-load formula is an equation linking the rate of bed-load transportation with properties of the grain and of the flow causing the movement. A formula of this kind can be derived by expressing in an equation the fact that all particles passing the unit width of a section as bed load are just on the way to perform one of these steps of the constant length $L = \lambda_0 D$. Fig. 1 shows the cross section and the rectangular area with the length L and with unit width, where all particles start the steps that together form the rate of transportation q_s. Eq. 1 expresses the condition that the total volume passing the unit width of the section per second (q_s divided by the specific gravity of the particles, both under water)

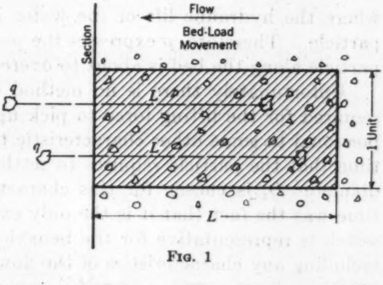

FIG. 1

equals the total volume of all the particles starting a step during a second in the aforementioned rectangular area. This volume is obtained by multiplying the number of particles in the surface of the area by the probability that a particle in the bed surface will start moving during a given instant and with the volume of a given particle. Eq. 1 follows:

$$\frac{q_s}{(\rho_s - \rho_f)\, g} = \frac{L}{A_1 D^2}\, p_s\, A_2\, D^3 = \frac{A_2}{A_1}\, \lambda_0\, p_s\, D^2 \qquad (1)$$

in which: q_s = the rate of transportation, in weight (under water), per unit of width, per second; ρ_s and ρ_f = density of particle and fluid, respectively; g = acceleration due to gravity; D = representative diameter of the particles; A_1 and A_2 = dimensionless ratios such that $A_1 D^2$ = the area that the grain covers in the bed and $A_2 D^3$ = the volume of the particle; p_s = the probability that a particle will start moving in any given second; and λ_0 = the dimensionless measure for the length of the single step.[5] It must be kept in mind, however, that λ_0 may or may not be a constant; that is, it has not been proved to be constant.

If A and D are transposed to the left side of Eq. 1, that side will include all terms pertaining to the grain, whereas the right side $\lambda_0\, p_s$ is still an unknown function of the flow—that is:

$$\frac{q_s}{(\rho_s - \rho_f)\, g\, D^2}\, \frac{A_1}{A_2} = \lambda_0\, p_s \qquad (2)$$

In this equation A_1, A_2, and λ_0 are dimensionless, but p_s has the dimension sec^{-1}. In order to make the right side of Eq. 2 dimensionless, p_s must be multiplied by a given time. The most reasonable time to use is the average time, t, required for the water to remove one particle from the bed. If $p = t\, p_s$, then p is dimensionless and gives the number of steps that start from any given place during the time it takes to remove one particle. The maximum value of p is 1, and indicates that at all times and at all points particle by particle starts to move. The minimum value of p is zero; therefore, p expresses the probability that a step is about to begin at a given place. These steps start everywhere on the bed. Therefore, p can be interpreted as the probable part of the bed area in which steps are starting. A step is started only at a point where the hydraulic lift of the water is able to overcome the weight of the particle. Therefore, p expresses the probability that the hydraulic lift on any particle along the bed is about to overcome the weight of the particle.

Unfortunately there is no method of expressing or measuring the time t required for the lifting force to pick up a particle. It is assumed to be proportional to some other characteristic time of the particle in the water. The time that the particle requires to settle in water, a distance equal to its own diameter D, is chosen for this characteristic. The reason for choosing this time was the fact that it is the only expression with the dimension of a time, which is representative for the behavior of the particle in the liquid without including any characteristics of the flow. This time can be expressed as

$$\frac{D}{v_f} = \frac{1}{F} \sqrt{\frac{D\, \rho_f}{g\, (\rho_s - \rho_f)}} \qquad (3)$$

in which: v_f = the velocity of a particle settling in water; and F = a parameter for settling velocity. In Eq. 3, $F = 0.816$ for particles greater than 1 mm, settling in water of normal temperature. Fig. 2 shows the values of F for smaller grain sizes. Characteristics of the materials in Fig. 2 are: Kinematic viscosity $\nu = \frac{\mu}{\rho_f}$ equals, for water, 0.012, and, for air, 0.16, cm² per sec; and specific densities, $\frac{\rho_s - \rho_f}{\rho_f}$, are as follows—

Material	Specific density
Barite in water	3.22
Gravel in water	1.65
Coal in water	0.25
Gravel in air	2,210.0

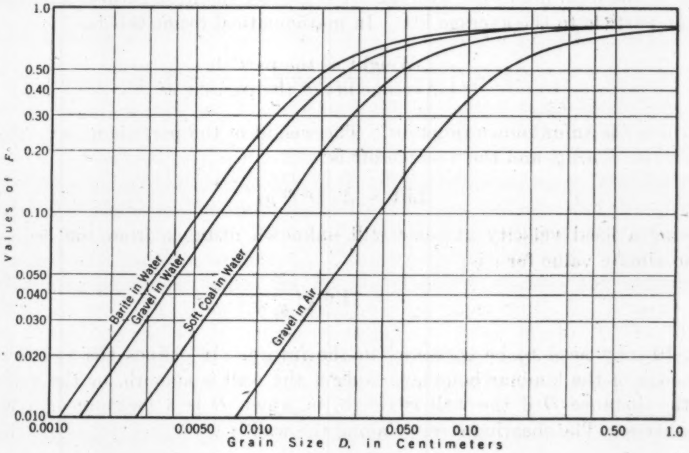

FIG. 2.—PARAMETER F FOR DETERMINING THE SETTLING VELOCITY OF VARIOUS MATERIALS

In Fig. 2 the following equation for the settling velocity derived by William W. Rubey[6] has been used for the determination of F:

$$v_f = \sqrt{\frac{2}{3} g \frac{\rho_s - \rho_f}{\rho_f} D + \frac{36\,\mu^2}{\rho_f^2 D^2}} - \frac{6\,\mu}{\rho_f D} = F \sqrt{D\, g \frac{\rho_s - \rho_f}{\rho_f}} \ldots\ldots (4)$$

In this formula all terms are measured in centimeter-gram-second units. Hence, F will be

$$F = \sqrt{\frac{2}{3} + \frac{36\,\mu^2}{g\, D^3 \rho_f (\rho_s - \rho_f)}} - \sqrt{\frac{36\,\mu^2}{g\, D^3 \rho_f (\rho_s - \rho_f)}} \ldots\ldots\ldots (5)$$

---

[6] "Settling Velocities of Gravel, Sand, and Silt," by William W. Rubey, *American Journal of Science*, Vol. 25, No. 148, April, 1933.

The time t required to remove a particle from its place in the bed then will be

$$t = \frac{A_3}{F}\sqrt{\frac{D\,\rho_f}{g\,(\rho_s - \rho_f)}} = \frac{p}{p_s} \qquad (6)$$

in which A_3 is still an unknown constant. Eq. 1 can now be changed to the form

$$p = \frac{A_1\,A_3}{\lambda_0\,A_2}\left[\frac{1}{F}\,\frac{q_s}{(\rho_s - \rho_f)\,g}\sqrt{\frac{\rho_f}{\rho_s - \rho_f}}\,\frac{1}{g^{0.5}\,D^{1.5}}\right] \qquad (7)$$

In an attempt to express p as the probability of the local hydraulic lift[4] to overcome the weight of the particle, p refers to the part of the bed in which locally (at a certain moment) the lifting force is greater than the weight of the particle. It can be stated that p refers to the part of the bed in which the ratio of the local lift to the average lift is greater than the ratio of the weight of the particle to the average lift. In mathematical terms this is

$$p = f\left(\frac{\text{Weight of the particle}}{\text{Average lift of the particle}}\right) \qquad (8)$$

in which f is an unknown function. The weight of the particle under water is $A_2\,D^3\,(\rho_s - \rho_f)\,g$, and the average lift is

$$\text{Lift} = A_4\,D^2\,v^2\,\rho_f \qquad (9)$$

v being a local velocity at some still unknown distance from the bed. An approximate value for v is:

$$v = 11.6\sqrt{\frac{\tau}{\rho_f}} \qquad (10)$$

Eq. 10 may need to be corrected in the future. It defines the velocity[3] at the edge of the laminar boundary layer if the wall is smooth, or the velocity at the distance D if the wall is rough, in which D is a measure of average roughness. The shearing stress τ along the wall is

$$\tau = S\,R\,\rho_f\,g \qquad (11)$$

in which S is the slope and R is the hydraulic radius; therefore

$$v = 11.6\,\sqrt{S\,R\,g} \qquad (12)$$

Eq. 8 can now be written

$$p = f\left[\frac{A_2\,D^3\,(\rho_s - \rho_f)\,g}{(A_4\,D^2\,\rho_f)\,(135\,S\,R\,g)}\right] = f\left[\frac{A_2}{135\,A_4} \times \frac{(\rho_s - \rho_f)\,D}{\rho_f\,S\,R}\right] \qquad (13)$$

By assuming that Eq. 10 gives the correct value for the velocity, Eqs. 7 and 13 can be combined and a new transportation formula formed:

$$A\left\{\frac{1}{F}\left[\frac{q_s}{(\rho_s - \rho_f)\,g}\right]\sqrt{\frac{\rho_f}{\rho_s - \rho_f}}\,\frac{1}{g^{0.5}\,D^{1.5}}\right\} = f\left[B\left(\frac{\rho_s - \rho_f}{\rho_f}\,\frac{D}{S\,R}\right)\right] = p. \qquad (14)$$

in which

$$A = \frac{A_1 A_3}{\lambda_0 A_2} \qquad (15a)$$

and

$$B = \frac{A_2}{135\, A_4} \qquad (15b)$$

are constants which, however, may vary with different shapes of the particles. Whether λ_0 and A_4 really are constant under all conditions must be determined later. Introducing

$$\phi = \frac{1}{F} \frac{q_s}{(\rho_s - \rho_f)\, g} \sqrt{\frac{\rho_f}{\rho_s - \rho_f}} \frac{1}{g^{0.5}\, D^{1.5}} \qquad (16a)$$

and

$$\psi = \frac{\rho_s - \rho_f}{\rho_f} \frac{D}{S\, R} \qquad (16b)$$

Eq. 14 can be written in the short form:

$$A\, \phi = f(B\, \psi) = p \qquad (17)$$

The function f as well as the two constants A and B must be determined empirically. Data from a great number of measurements using various materials have been analyzed, and values of ψ and ϕ computed. A semilogarithmic plot of these values is shown in Fig. 3(*a*). The grain sizes range from 0.315 to 28.65 mm in diameter, the water depth from 18 to 1,100 mm, and the specific gravity of the particles from 1.25 to 4.22. All these experiments are performed in flumes with uniform sediment. The experiments marked "Zürich" are described briefly in a paper by E. Meyer-Peter[7] whereas the remaining experiments are taken from the generally known paper by G. K. Gilbert.[8] It seems that all these points follow, reasonably, a single curve. It should be noted that from these data not a single experiment has been omitted even when the measurement appeared questionable. It might be mentioned also that the hydraulic radius R is computed by a method[9] that eliminates the effect of side-wall friction and gives results comparable to a channel of infinite width (see Appendix II).

In Fig. 3(*a*) all the points with values of ϕ less than 0.4 seem to follow the straight line, curve (1), the equation of which is

$$0.465\, \phi = e^{-0.391\, \psi} \qquad (18)$$

If Eq. 18 is assumed to represent the law of transportation:

$$\left.\begin{aligned} A &= 0.465 \\ B &= 0.391 \\ f(x) &= e^{-x} \end{aligned}\right\} \qquad (19)$$

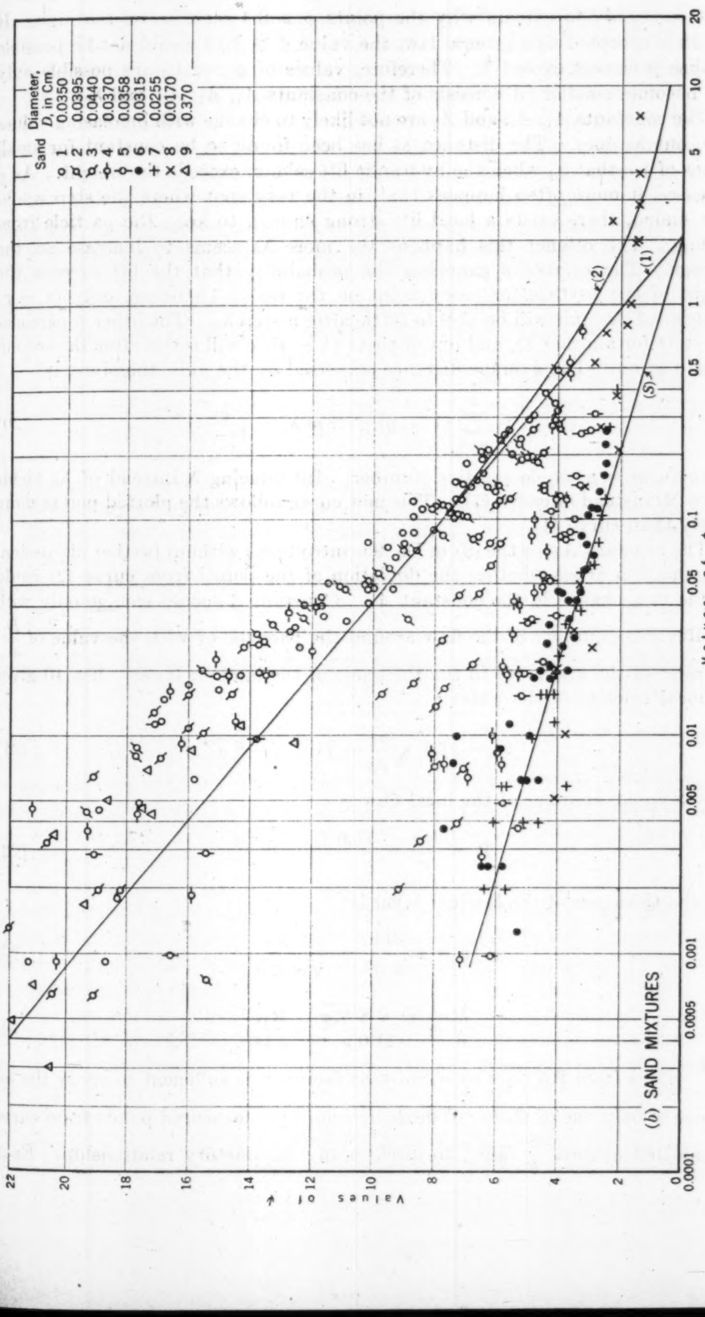

FIG. 3.—BED-LOAD EXPERIMENTS SHOWING THE RELATION BETWEEN φ AND ψ

it remains only to explain why the points $\phi > 0.4$ seem to be too high. If Eq. 18 is accepted as a general law, the value $\phi > 2.15$ would not be possible because p cannot exceed 1. Therefore, values of $\phi > 2.15$ are possible only if A becomes smaller (A consists of the constants A_1, A_2, A_3, and λ_0).

The constants A_1, A_2, and A_3 are not likely to change with increasing values of p, but λ_0 does. The distance λ_0 has been found to be constant for small values of p—that is, when the hydraulic lift seldom exceeds the weight. As p increases, it more often happens that, in the very spot where the step would have ended, there exists a local lift strong enough to keep the particle from settling. The oftener this happens the more λ_0 seems to increase on the average. The symbol p expresses the probability that the lift exceeds the weight of the particle for every point on the bed. Therefore, only $(1 - p)$ particles of the unit will be able to settle after a step λ_0. The other p particles will start for another λ_0, and out of these $(1 - p)\ p$ will settle after the second λ_0, and so on. The average distance traversed by the unit, therefore, is:

$$\lambda = \sum_{m=0}^{\infty} (1 - p)\, p^{m-1}\, m\, \lambda_0 = \frac{\lambda_0}{1 - p} \quad \text{..............} \quad (20)$$

in which m = a whole positive number. Introducing λ instead of λ_0 yields curve (2) instead of curve (1). This new curve follows the plotted points more closely than curve (1).

The constant A_4 for the lift in Eq. 9 is introduced without further discussion. The question arises whether the deviation of the points from curve (2) could be due to a change in the constant A_4. Constant A_4 could change only with the Reynolds number of the flow around the particle, or with the value of $\frac{D}{\delta}$, the ratio of the grain size to the thickness of the laminar layer. Eq. 10 gives the local velocity of the water:

$$v = 11.6 \sqrt{\frac{\tau_0}{\rho_f}} = 11.6 \sqrt{S R g} \quad \text{...............} \quad (21)$$

The Reynolds number of the local flow is

$$\mathbf{R} = \frac{D v}{\nu} = \frac{11.6\, D \sqrt{S R g}}{\nu} \quad \text{..................} \quad (22)$$

and the thickness of the laminar layer is

$$\delta = \nu \frac{D v}{\tau_0/\rho_f} = \frac{11.6\, \nu}{\sqrt{S R g}} \quad \text{..................} \quad (23)$$

or

$$\frac{D}{\delta} = \frac{D \sqrt{S R g}}{11.6\, \nu} = \frac{\mathbf{R_D}}{134} \quad \text{...............} \quad (24)$$

As $\frac{D}{\delta}$ differs from $\mathbf{R_D}$ only by a constant factor, it is sufficient to study the influence of only one of them. The deviation of the measured points from curve (2) plotted against $\frac{D}{\delta}$ failed to disclose any satisfactory relationship. Each grain size appears to follow a separate curve; therefore, it appears much more probable that A_4 is a constant, but that the exponential law for p does not extend down to $\psi = 0$. Another explanation for the deviation of the points may be that part of the grains have been transported in suspension. In this case those experiments would be outside the field of application of Eq. 17. More experiments, however, will be required in this range to determine the exact shape of the curve. It may be emphasized that in most American rivers the bed load is largely transported under conditions pertaining to this part of the curve, and, therefore, further study in this direction is most urgent.

The title of this paper was chosen specifically to avoid the impression that any attempt was being made to discover "the law of bed-load transportation," because it is the writer's belief that such universal law does not exist in a simple mathematical form. Just as it is necessary to distinguish between friction in smooth and rough pipes or channels, so it is necessary to distinguish between different kinds of transportation. Nevertheless, the distinction between friction along rough, wavy, and smooth walls was only possible on the discovery of the general method of plotting the friction factor against Reynolds' number. An attempt is made in this paper to determine a corresponding method of presenting transportation data by introducing the quantities ψ and ϕ, both of which are derived by pure speculation, using only generally known facts.

As an example, the method is used to discuss the results of experiments with sand mixtures, conducted at the U. S. Waterways Experiment Station, at Vicksburg, Miss.[10] Fig. 3(*b*) gives the results of these experiments as a ϕ-ψ graph. The method described in Appendix II has been used to determine the effective hydraulic radius. Curves (1) and (2) are transferred from Fig. 3(*a*), and all the various sand mixtures have been assigned different symbols.

The first problem was to determine the effective diameter of the mixtures—that is, the value of D that would represent the mixture in the formulas. Experience gained in previous studies has convinced the writer that the most usable value for this effective diameter is the grain size of which 35% to 45% of the material is finer. This value is readily obtained from the cumulative size-frequency curve of the mixture. The 40% value was used for Fig. 3(*b*), although it is realized that the use of a 35% value would tend to bring the high points closer to curves (1) and (2).

The distribution of the points in Fig. 3(*b*) is very interesting to note. At first glance one observes that the points for sands 1, 2, and 9 distinctly follow curves (1) and (2). Sands 3, 4, and 5 follow the curves in the upper part only. Sands 6, 7, and 8 fall below the curves at all points, but a distinct grouping of points along a line curve (*S*) is noticed.

The two curves, (2) and (*S*), seem to represent limits of maximum and minimum transportation for a given value of ψ. In searching for an explanation of this the three following questions naturally arise: (1) Is there any relationship between the position of the points and friction loss? (2) Is there any relationship between the position of the points and the condition of the bed?

---

[10] "Studies of River Bed Materials and Their Movement, with Special Reference to the Lower Mississippi River," *Paper No. 17*, U. S. Waterways Experiment Station, Vicksburg, Miss., January, 1935.

(3) Would a similar distribution be possible also in experiments with uniform material, or is it characteristic only of mixtures?

With regard to question (1), it was found that Manning's n, without exception, increased suddenly when the points leave curves (1) and (2). This means that the bed becomes rougher than the original material as soon as the rate of transportation decreases below that shown by curves (1) and (2). The reverse is also true—that is, the rate of transportation will decrease as soon as the roughness of the bed increases.

The reason for this increased roughness is of interest. As a rule, riffles begin to form precisely at the place where the points depart from curve (1). If riffles are the reason for the increase in Manning's n, this value must always increase when riffles are formed. Sand 1 does not show this increase and sand 2 only very slightly—although these sands develop general riffles like all the other mixtures. Therefore, the riffles are not the reason for the increased roughness, but merely happen to develop simultaneously. This answers question (2) in the negative.

Question (3) suggests that perhaps some kind of sorting of the grains is the reason for the deviation from curve (1) and for the increase of roughness at the same time. It is the writer's belief that this is true, but unfortunately it is not subject to direct proof. This sorting would be caused by the lack of material in the upper end of the flume. If the sand is fed in at a smaller rate than the stream is able to transport it, the bed starts to build some kind of a protective layer of coarse grains on the surface and buries all the finer grains beneath. The average grain size in this coarse layer is much greater than the average grain size in the bed, and scour is either reduced or completely prevented. For this reason, it is impossible, during an experiment, to detect a lack of feeding merely by watching the position of the bed. Curve (1) gives the results obtained when the highest quantity of sand is fed in that can be transported without deposition, and curve (S) gives the smallest amount that will be transported without scour on the protecting layer. If D is the effective diameter of the original bed material, it is reasonable to believe that these two limits coincide for uniform material and that curve (S) falls more and more below curve (1) as the material decreases in uniformity.

These are merely some suggested methods of studying bed-load transportation. It would be very easy to determine, by experiment, the validity of such reasoning. If the interpretations are correct, it should be possible to determine all points between the two limiting curves by merely changing the rate of sand feed. It would also be very instructive to conduct a similar group of experiments in the opposite sequence—that is, by beginning with high discharges and progressively decreasing the discharge and load. If the explanation is correct, one will probably not return to the same curve obtained with increasing flow. This would also answer question (3). This ϕ-ψ method is offered as a new procedure for studying bed-load problems. It may be possible to refine the method by introducing corrections for the velocity v, and various constants; but as a whole it seems to be satisfactory in its present form.

SUMMARY

In concluding it may be stated that the treatment of transportation problems by means of statistical methods, made possible by the use of large-scale experiments, led to the proposed method of representation:

Two dimensionless functions ψ and ϕ have been developed theoretically, ψ as the ratio of the forces acting on the particle, and ϕ including the rate of transportation and the size and settling velocity of the particle. The interrelation between these two functions expresses the law of transportation, and at the same time expresses the statistical distribution p of the velocity of the liquid close to the laminar boundary layer. The transportation law is derived by use of a great many experiments with uniform sediment, and is then used in discussing published results of experiments with sand mixtures.

ACKNOWLEDGMENTS

The writer is greatly indebted to Prof. E. Meyer-Peter of Zürich, Switzerland, for having permitted the use of valuable data, even though the results of the original work have not as yet been published in full.

APPENDIX I

NOTATION

The following notation conforms essentially with American Standard Symbols for Hydraulics compiled by a Committee of the American Standards Association[11] with Society representation, and approved by the Association in 1929:

A = a dimensionless constant, defined in Eq. 15*a*:
    $A_1 D^2$ = the area that the grain covers in the bed; and
    $A_2 D^3$ = the volume of the grain;
    A_3 = a dimensionless unknown constant in Eq. 6;
    A_4 = a dimensionless unknown constant in Eq. 13, the expression for the hydraulic lift of a particle;
    A_b = the area with reference to the bed;
    A_m = the area with reference to part m of a cross section;
    A_w = the area with reference to the wall;
B = a dimensionless constant, defined in Eq. 15*b*;
b = surface width of a stream;
D = diameter; the representative diameter of a particle;
d = depth; depth from the water surface to a particle;
e = base of Napierian logarithms;
F = a factor defined by Eq. 5;
f = function of; see also f_m in Eq. 25:
    f_b = function for friction along the bed;
    f_w = function for friction along the wall;

---

[11] ASA-Z10b-1929.

g = acceleration due to gravity;

L = length of the steps taken successively by particles in a river bed = $\lambda_0 D$, the average of all the steps taken by a single particle;

m = a whole number;

N = a number of units;

n = Manning's roughness coefficient:

- n_b = roughness of the river bed;
- n_m = roughness of part m of the perimeter;
- n_w = roughness of the side-wall;

P = wetted perimeter:

- P_b = wetted perimeter along the bed;
- P_m = wetted perimeter of part m of the circumference;
- P_w = part of the wetted perimeter along the wall;

p = probability that, at a given point in the bed, the lifting force required to overcome the weight of the particle has been generated:

- p_s = the probability of a particle starting movement at a given second;

q = rate of flow or discharge per unit width:

- q_b = discharge pertaining to the unit width of bed;
- q_s = the rate of transportation, in weight (under water), per unit of width, per second;

R = hydraulic radius:

- R_b = hydraulic radius pertaining to the bed;
- R_m = hydraulic radius pertaining to the part m of the cross section;
- R_w = hydraulic radius pertaining to the wall;

$\mathbf{R_D}$ = Reynolds' number of the grain D;

S = hydraulic slope;

t = time required for the water to build up sufficient force to pick up a particle;

V = average velocity in the cross section of a stream;

v = filament velocity at a given point in the cross section and at an unknown distance from the bed:

- v_f = settling velocity;

δ = thickness of the laminar layer (see Eq. 23);

λ = average distance traveled by a unit of bed load:

- λ_0 = the dimensionless measure of a single step taken by a particle;

μ = absolute viscosity of a fluid;

ν = kinematic viscosity = $\frac{\mu}{\rho_f}$;

ρ = density:

- ρ_f = fluid density;
- ρ_s = density of a particle;

τ = shearing stress;

ϕ = a function defined by Eq. 16*a*;

ψ = a function defined by Eq. 16*b*.

APPENDIX II

METHOD OF CALCULATING THE HYDRAULIC RADIUS IN A CROSS SECTION WITH DIFFERENT ROUGHNESSES

Water flowing through a certain profile continuously transforms its potential energy into heat by means of friction.[9] This friction, along smooth or rough walls, follows certain laws. Formulas expressing these laws contain the velocity of the water V, slope of the energy grade line S, acceleration of gravity g, roughness of the wall, length of wetted perimeter P, and the cross-section area A. The latter two are commonly combined into the hydraulic radius $R = \frac{A}{P}$. Some of these variables enter the equation explicitly, and others, like g and the roughness, are sometimes hidden in other constants.

In this connection only turbulent flow is of interest. A thin layer of laminar flow exists along the wall, which may or may not be able to hide the irregularities of the wall. In both cases most of the energy of the flow is destroyed by transformation into turbulence—that is, by an irregular deflection of the different flow filaments, caused by instabilities of the laminar layer (smooth wall) or by roughnesses extending out of the layer (rough wall). The filaments (which have been flowing only in the direction of the general flow) are deflected without gaining energy. Therefore, the average velocity in the direction of the flow of the newly established eddy is smaller than the average of the velocities of all the particles composing the eddy prior to its formation. The slow-moving eddy is pulled into the fast flow and accelerated again by other particles by use of part of their flow energy. At the same time, eddy energy is destroyed by laminar friction and the entire process begins over again.

In order to discuss the distribution of friction over a cross section in mathematical terms, two assumptions are necessary. The first assumption is that the entire cross section can be divided into units that will correspond to similar units of the wetted perimeter so that the potential energy of the area unit is transferred into eddy energy along the corresponding surface unit, and these eddies are accelerated and destroyed again in the former area unit. It is evident that the ratio of all area units to the corresponding surface unit will be the same in a cross section with uniform roughness. If the average velocity is assumed to be the same for all units of a simple cross section, every friction formula applicable to the entire section will also be applicable to each unit.

The second assumption is that the same friction formula will be applicable to a certain unit, even though the roughness of other parts of the cross section is changed. This second assumption enables one to make computations on any cross section with composite roughness, as, for instance, a flume with smooth side-walls and granular bed, a river with rough banks or partly sandy and partly rocky bed, etc. The procedure is as follows: For each part (P_m) of the wetted perimeter having a certain roughness, one can find the corresponding area, A_m, to be combined into a variable hydraulic radius $R_m = \frac{A_m}{P_m}$. The roughness in this unit may be described by the factor n_m. The slope S and the average velocity V are constant for all units. If there are N units, it is possible to establish $N + 2$ equations; that is, N equations of the form—

$$V = f_m(S, g, n_m, \text{ and } R_m) \ldots\ldots\ldots\ldots\ldots (25)$$

one equation of the form—

$$A = \sum_{m=1}^{N} A_m \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

which shows that all the area units add up to the total area, and one equation of the form—

$$P = \sum_{m=1}^{N} P_m \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

which shows that all the wetted-perimeter units add up to the total wetted perimeter.

Consider, as an example, a flume experiment in which the section is divided into two units—bed and side-walls. In this case four equations may be stated. The roughness of the side-walls will be obtained from preliminary experiments. The function f_w and the constant n_w are known. The values of P_w, P_b, V, and S will be measured in each individual experiment. Eq. 27 is meaningless, in this case, because all values of P_m are measured. Eqs. 25 and 26 enable the investigator to compute A_w, A_b, and n_b, if he assumes the function f_b suitable for the character of the bed.

This method can be checked very easily by applying it to a flume with different roughness in the side-wall and a stable bottom. If it is possible to find two roughness factors n that will satisfy measurements having different water depths, the method is satisfactory. The writer has checked the method several times and always has found it to be correct within the accuracy of the measurement. As an example, this procedure is well illustrated when both bed and side-wall friction can be expressed by means of Manning's formula:

$$V = \frac{1.486}{n} S^{0.5} R^{0.67} \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

As previously stated, V, S, width b, and depth d are measured, and n_w is known; therefore, it is possible to determine R_w directly by using Manning's formula for the wall:

$$R_w = \left(\frac{n_w}{1.486} \frac{V}{S^{0.5}} \right)^{1.5} \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

The area with reference to the wall is

$$A_w = 2\, d\, R_w \ldots\ldots\ldots\ldots\ldots\ldots\ldots (30a)$$

the area with reference to the bed is

$$A_b = d\,(b - 2\,R_w) \qquad \text{(30}b\text{)}$$

and the corresponding hydraulic radius is

$$R_b = \frac{A_b}{b} = d\left(1 - 2\,\frac{R_w}{b}\right) \qquad (31)$$

By using the radius R_b, the roughness factor n_b is then obtained, thus,

$$n_b = \frac{1.486}{V}\,S^{0.5}\,R_b{}^{0.67} \qquad (32)$$

and the discharge corresponding to the unit width of the bed is

$$q_b = V\,R_b \qquad (33)$$

The values R_b, q_b, and n_b have been used in the paper for the evaluation of ψ for all experiments.

To consider a numerical example,[12] let $b = 2.416$ ft; $d = 0.276$ ft; $q = 1.000$ cu ft per sec; and $S = 0.0010$. For turbulent flow[13] the average value of Manning's n, applied to the side-walls, is 0.0097. From this information the following computations can be made: $A = b\,d = 0.667$ sq ft; $V = \frac{q}{A} = 1.50$ ft per sec; $R_w = \left(\frac{n_w}{1.486}\,\frac{V}{S^{0.5}}\right)^{1.5} = \left(\frac{0.0097}{1.486} \times \frac{1.50}{0.0316}\right)^{1.5} = 0.172$ ft; $R_b = d\left(1 - 2\,\frac{R_w}{b}\right) = 0.276\left(1 - 2\,\frac{0.172}{2.416}\right) = 0.237$ ft; $n_b = \frac{1.486}{V}\,S^{0.5}\,R_b{}^{0.67} = \frac{1.486}{1.50}\,0.0316 \times 0.384 = 0.012$; and $q_b = V\,R_b = 1.50 \times 0.237 = 0.356$ cu ft per sec per ft of width.

Values R_b, n_b, and q_b do not contain the influence of the side-wall and, therefore, can be used in any formula for bed-load transportation, the results being expressed for a channel of infinite width.

DISCUSSION

Joe W. Johnson,[14] Assoc. Am. Soc. C. E. (by letter).—Compliments are due the author on his approach to the problem of bed-load transportation, especially in his dimensionless expressions and the absence of any "critical" term whose value, in general, is difficult to determine accurately.

In connection with investigations[15,16] by the Soil Conservation Service on the transportation of sediment in natural streams, most of the published and unpublished data from the United States and Europe on the transportation of bed load in laboratory flumes have been assembled. For these various data, computations have been made and the results tabulated in a consistent system of units as follows:

(1) Discharge (cu cm per sec)
(2) Flume width (cm)
(3) Mean water depth (cm)
(4) Water-surface slope
(5) Water temperature (°C)
(6) Mean velocity (cm per sec)
(7) Bottom velocity (cm per sec)
(8) Hydraulic radius of bed (cm)
(9) Friction velocity (cm per sec)
(10) Reynolds' number
(11) Manning's n for the bed ($ft^{1/6}$)
(12) Unit discharge (cu cm per sec per cm)
(13) Rate of bed movement (g per sec per cm)
(14) Duration of run (minutes), and
(15) Bed condition.

Items 1 to 7, inclusive, and 13 to 15, inclusive, are observed factors and have merely been converted from the various units of observation to the foregoing units. The hydraulic radius of the bed (item 8) has been calculated by the author's method of eliminating the effects of the flume side-walls. The other derived terms—that is, friction velocity, Reynolds' number, Manning's n, and unit discharge—are calculated by using the hydraulic radius of the bed.

An off-hand assumption might be that there is available a set of data reduced to a consistent system of units and applying to channels of infinite width. With the effect of flume width eliminated it would appear possible to obtain a relation between the rate of transportation or bed roughness and certain physical and hydraulic factors. However, it is scarcely possible to obtain such a relationship because of certain important factors inherent in the apparatus used in each separate set of experiments. These factors vary from experiment to experiment, and unfortunately cannot be reduced to a definite value as in the case of side-wall effect.

In studying the summary of the various bed-load data, several objections to the experimental apparatus and procedure are apparent and appear to account for the limiting value of the data. The most important objections are: (*a*) Variations in the type and manner of sand feed; (*b*) short flumes; and (*c*) short periods of sand collection. The author has already referred briefly to the problem of sand feed and has stressed its importance. The use of short flumes has the twofold disadvantage that: (1) It is extremely difficult to obtain an accurate measurement of the slope; and (2) the distribution of velocity and flow conditions do not become stabilized in such short reaches. Of interest in respect to this latter factor are certain experiments conducted in the United States, as well as in Europe, with a bed of movable material placed in a recess only a few feet in length located near the center of a flume in which the remainder of the bed is fixed at a different roughness than the sand bed. In such cases the vertical velocity distribution measured above the movable bed is not the distribution resulting from flow over the movable bed but more closely approximates the distribution for the relatively smooth bed upstream. No relation between velocity distribution and bed movement or roughness could be expected in such cases.

[15] "Studying Sediment Loads in Natural Streams," by Gilbert C. Dobson and Joe W. Johnson, *Civil Engineering*, February, 1940, pp. 93–96.

[16] "A Distinction Between Bed Load and Suspended Load in Natural Streams," by H. A. Einstein A. G. Anderson, and J. W. Johnson, *Transactions*, Am. Geophysical Union, 1940, Pt. 2, pp. 628–633.

The duration of run is of importance in giving information on the relative value of various experiments. In most of the past experiments where short collection periods were used, a considerable scattering of data is noticeable. The author previously[17] has stressed the importance of using relatively long collection periods in studying the rates of bed-load transportation in order to eliminate the short-period fluctuations that are characteristic of most bed-load movement. Also, with short runs the bed condition may not have time to become so adjusted that a calculated roughness factor is indicative of conditions that would prevail after a longer period of operation.

Data from laboratories in the United States as well as in Europe all appear to be limited in value by one or more of the aforementioned factors. The distinct limitations of the various data became evident to the writer when an attempt was made to use certain data to obtain information on the correct value of the grain diameter to use in the author's ψ-functions and ϕ-functions when mixtures are considered. (The author has used the grain diameter at the 40% value in discussing the movement of United States Waterways Experiment Station mixtures, but admits that the 35% value would have tended to cause better agreement.) Mr. Gilbert's data[8] on the transportation of synthetic mixtures, for instance, should be of value in providing such information, but unfortunately he neglected to observe the depth of flow in these particular experiments. In this case, as well as in many others, extremely important observations have not been recorded because the experimenter apparently failed to realize their importance, or was confining his attention to some other phase of the problem. All pertinent data should be recorded whether or not the observer can see any immediate use of certain observations.

It is strongly urged, therefore, that, before future extensive flume experiments on bed-load transportation are undertaken (with the possible exception of experiments intended for demonstration or qualitative information), the experimenter "take stock" of the limitations of past studies and design his experiments to eliminate most of these objections. Little progress in the technique and range of conditions of laboratory bed-load investigations appears, in general, to have been made since the classic experiments of Mr.

[17] "Calibrating the Bed-Load Trap as Used in the Rhine," by H. A. Einstein, *Schweizerische Bauzeitung*, Vol. 110, No. 14; also, see *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 1293.

Gilbert.[8] Bed-load experiments are both expensive and time consuming and future experiments to improve on those made in the past should be directed to give more accurate data throughout a wider range of conditions, especially in the range $\phi > 10$ where transportation in large streams is perhaps most likely to occur.

A. A. Kalinske,[18] Assoc. M. Am. Soc. C. E. (by letter).—Any attempt to rationalize the problem of bed-load transportation by using known basic physical phenomena is most welcome, especially if the expressions developed are correlated with experimental data. Although the author's work in this direction is most enlightening, there are present certain ambiguities and some indefinite statements and assumptions that make the writer question the physical picture of bed-load transportation as presented, and the generality of the final expressions. If these questionings are due to misinterpretations on the part of the writer, it is hoped that the author will attempt to clear up these points.

One confusing item to the writer is in regard to exactly what the author considers as being bed load. In the "Introduction" he states that bed-load movement is confined to those bed particles moving in quick steps and with long rest periods. Does this only include particles that slide and roll or does it also include those that jump up? If a particle rolls along fairly continuously, or with only short rest periods, is it excluded from the author's definition? Under "Derivations" the author states definitely that his treatment excludes "Bed material moving in suspension." However, in his derivations he considers the lifting of particles off the bed and the effect of the turbulence on the particles. What the line of demarcation is between bed load and suspended load is nowhere definitely stated. In a previous paper[19] the author with A. G. Anderson, Jun. Am. Soc. C. E., and J. W. Johnson, Assoc. M. Am. Soc. C. E., gives a definition for bed load as follows: "Bed-load is that part of the total sediment-load composed of all particles greater than a limiting size whether moving on the bed or in suspension, and includes all bed-material in movement." Does this definition apply to the analyses in the present paper? Would it not be better to define or differentiate between various types of sediment transportation by consideration of the different forces causing the movement instead of considering its visual appearance? It seems that this is what must be done if a physically correct analysis is to be made of any type of sediment movement.

The writer cannot agree that the concept of critical tractive force has no meaning in bed-load transportation. Naturally, for any given size of material, there is no single value of the tractive force below which not a single particle moves, and above which all particles of that size do move. First of all, the tractive force is not a constant value but tends to fluctuate about some average value. Second, the dragging and pushing forces tending to move the bed particles depend on the position a particle happens to assume and how much influence its neighbors exert. Nevertheless, statistically a value of the tractive force can be defined such that below it any movement will be practically negligible. To use the author's terminology it is possible to define a tractive force such that the probability of movement of any particular particle is very remote indeed for any practical considerations. Certainly the fine work of A. Shields[2] in regard to the critical tractive force for different sizes and types of particles indicates that this concept has physical meaning and practical usefulness.

[18] Asst. Prof., Univ. of Iowa, Iowa Inst. for Hydr. Research, Iowa City, Iowa.

[19] "A Distinction Between Bed-Load and Suspended Load in Natural Streams," by H. A. Einstein, A. G. Anderson, and J. W. Johnson, *Transactions*, Am. Geophysical Union, 1940, Pt. II, p. 628.

The transportation of sediment by the process of saltation, so clearly described and analyzed by R. A. Bagnold[20] for the movement of desert sand by wind, also occurs to a certain extent in water. The physical processes causing such movement are closely related and even similar to those for bed load. In fact, experimentally, separate determination of bed load and saltation load is almost impossible. The author's description and analysis of the movement of bed load seem very much similar to movement by saltation, particularly his statements regarding step movement and the lifting process. Mr. Bagnold differentiates between bed load and saltation load by calling the former those particles which creep, slide, and roll along the bed without any appreciable rise from the bed. For desert sand this differentiation is fairly definite, since the particles moving by saltation rise an appreciable distance above the sand surface, many times as high as 4 ft to 6 ft. In ordinary rivers it is doubtful if the rise of particles off the bed in the process of movement by saltation is more than perhaps a fraction of an inch or a few inches at the most. Therefore, any distinction between bed load and saltation load in rivers and canals becomes difficult.

Physically, the bed load might be considered as those particles which do not have sufficient lift exerted on them to raise them off the bed; instead they can only roll or slide. It appears that saltation occurs when the forces causing the rolling and sliding become large enough to exert a "lift" on the particles and thus raise a particle up into the flowing fluid. The raised particles immediately drop down since there is no force to support them in the fluid. Actually, of course, turbulence is present and upward velocity components tend to keep the raised particles up longer than they otherwise would stay. However, it is not considered that transportation by suspension comes into the picture unless vertical velocity components are present that are larger than the fall velocity of the particles a sufficiently large proportion of the time. Mr. Bagnold definitely concluded that the turbulence in the air had a negligible effect in transporting the sand of the size he was considering. In fact, from his description of the process of saltation, this type of movement can occur without the presence of turbulence if a sufficiently high drag and forward velocity could be developed without inducing turbulence. Naturally, this is not possible with air or ordinary liquids. In regard to this particular point, Mr. Shields[2] showed experimentally that bed-load movement takes place at a Reynolds number when the viscous boundary layer still covers the particles. All this leads to the conclusion that bed-load movement, in the sense considered by Mr. Shields, and movement by saltation can be brought about by forces that do not necessarily arise due to the presence of turbulence. Of course, if turbulence is present, particle movement by these methods may be profoundly affected.

---

[20] "Transport of Sand by Wind," by R. A. Bagnold, *Geographical Journal*, Vol. 89, 1937, p. 409.

In the writer's opinion, this is the intrinsic difference between bed-load and saltation-load movement and transportation by suspension; the latter type of movement is due entirely to turbulence.

In his classic experiments and observations, Mr. Bagnold defines a so-called "threshold" wind velocity and also relates the total sand movement to the mean flow conditions. This definitely contradicts the author's statements relating to critical conditions and the possibility of defining bed-load transportation as a function of mean flow.

In the "Introduction" the author lists four axiomatic statements on which he bases all of his analyses. According to him these statements are the results of previous studies; however, since the results referred to are published in a paper not readily available to American engineers in general, it would have been better to give a little more background material and present the basis for these fundamental statements. For instance, the concept of an "average step" certainly needs further elaboration.

In the "Derivations" the factor p is defined as giving "* * * the number of steps that start from any given place during the time it takes to remove one particle." Exactly what is meant by "place" and the "time to remove one particle"? Is "place" the area covered by one particle? In order to make p, in Eq. 2 dimensionless the author introduces, very arbitrarily, a time t, which he chooses to call the time required for a particle to settle a distance equal to its own diameter. This particular t certainly could have been defined in many other ways. Therefore, it appears that at this point in particular the author departed from a theoretical analysis of the physical processes and stepped over into the realm of abstract dimensional analysis.

In the "Derivations" the author refers to bed-load movement as being due solely to the "lift" on a particle. The lifting forces that act on a particle resting on the bed are certain definite hydrodynamic forces caused by the flow over the particle. However, bed-load movement is not due entirely to such lifting forces; impact and pushing forces are certainly also present. Of course, all such other forces are also probably proportional to $D^2 v^2 \rho_f$ as given by the author for the lift forces, although at low velocities the liquid viscosity may be of importance. Eq. 10 is not correct for the velocity at the distance from the wall of the particle diameter. J. Nikuradse's velocity equation for sand-roughened pipes gives for the value of v at the edge of the protuberances the value $8.5 \sqrt{\frac{\tau}{\rho_f}}$.

The data presented by the author seem to be functionally related in the manner indicated, particularly for the smaller sediment loads. However, for the larger sediment loads it is extremely doubtful if the measurements included solely bed load in the sense that the writer interprets bed load. In regard to the sand mixtures, such mixtures cannot be described completely by any mean effective diameter unless the size-frequency curve is of the same type and shape for all such mixtures.

The writer agrees with the author that there is no single, universal law which will describe bed-load transportation. The reason for this is that different sets of forces come into play for different stages of movement. For small ratios of sediment size to laminar boundary layer thickness, the forces causing movement are certainly different from conditions when the laminar layer is no longer present. As shown by Paul Nemenyi,[21] if any analysis or correlation of experimental data is to be really useful for extrapolation, the entire "picture" must be kept in mind. The complete picture of bed-load transportation is probably divided into a number of phases, each having a slightly different set of predominating forces. The various phases are probably separated by critical regions. The transition from pure rolling and sliding to combined rolling, sliding, and "jumping" or saltation is such a critical region. The coming into play of the vertical velocity component of the turbulence is another such critical region. All these various phases of sediment transportation will become immensely clarified if some parameter can be found against which data can be plotted for all the phases of sediment transportation, from the simple rolling and sliding of the particles, when the grains are still covered by a laminar boundary layer, to when the major part of the material is being moved in true suspension. Mr. Shields made a start in this direction by use of the parameter $v_f\, D/\nu$, in which v_f is the friction velocity, $\sqrt{\frac{\tau}{\rho_f}}$; D is the particle diameter; and ν is the kinematic viscosity. Perhaps the parameter $\frac{v_s}{v_f}$ (in which v_s is the settling velocity) may serve this all-important function. This particular parameter is a function of the Reynolds and Froude numbers of an individual particle.

This paper should certainly serve the very important function of stimulating thought in regard to the problems of sediment transportation, and particularly so-called bed-load movement, along directions different from those followed by engineers in the past years. The paper should also show definitely that the innumerable, purely empirical bed-load equations now scattered throughout the literature are probably of limited application and certainly should not be used blindly for conditions widely different from those for which the data used in developing the equation were obtained. Eq. 18 certainly seems quite generalized; nevertheless, the limitations of its applicability should be carefully noted. The important question about this equation is in regard to what exactly was taken or considered as "bed load" in the experiments on which it is based. This point should be more definitely clarified both for Mr. Gilbert's data[8] and that obtained by the author in Zürich.

O. G. HAYWOOD, JR.,[22] JUN. AM. SOC. C. E. (by letter).—An interesting analytical derivation of a bed-load formula is presented in this paper, which has the decided advantage that all of the arbitrary constants introduced have a definite physical meaning. However, proceeding backward from his final empirical expression to the evaluation of some of these constants leads to results sufficiently doubtful to reflect upon its validity.

[21] "The Different Approaches to the Study of Propulsion of Granular Materials and the Value of Their Coordination," by Paul Nemenyi, *Transactions*, Am. Geophysical Union, 1940, Pt. II, p. 633.

[22] Capt., Corps of Engrs., U. S. Army, 27th Engr. Battalion, Fort Buchanan, Puerto Rico.

From Eqs. 15*a* and 19, $A = 0.465$. The order of magnitude of constants A_1 and A_2 may be estimated by assuming spherical grains, thus giving $A_1 = \frac{\pi}{4}$ and $A_2 = \frac{\pi}{6}$. The general magnitude of λ_0, if it is a constant as assumed, may be estimated from observations of bed-load movement. For a grain of 1 mm diameter, a travel distance in a single step of 10 cm is not an unreasonable estimate, or $\lambda_0 = 100$. Then $A_3 = \frac{0.465 \times 100 \times \frac{\pi}{6}}{\frac{\pi}{4}} = 31$; and, from Eq. 6, $t = \frac{31}{0.75}\sqrt{\frac{0.1 \times 1}{980 \times 1.65}} = 0.32$ sec, which appears to be an absurdly high value for the time to remove one particle of 1 mm diameter from the bed. From the definitions of t, p, and p_s, t is evidently that almost instantaneous transition period when a particle passes from a state of rest to a state of motion, and which the writer would consider more properly of the order of a few thousandths of a second.

A similar analysis of the other equation constant, $B = \frac{A_2}{135\, A_4} = 0.391$, leads to equally disturbing results. Again assuming spherical grains in order to approximate the values of the constants, $A_2 = \frac{\pi}{6}$ and A_4 then computes to be 0.01. Thus, the coefficient of lift is 0.01 and constant for all conditions satisfying the author's basic equations. It must be noted, however, that Eq. 9 is identical to the generally accepted equation for the drag on a particle. Moreover, numerous experiments have shown that the coefficient for drag varies decidedly with the turbulence around the particle (Reynolds' number), and that the coefficient has a minimum value of the order of 0.15. It is evident that the lift must exceed the weight of the particle before it will be lifted from the bed. It appears decidedly unlikely that particles could withstand a dragging force of at least fifteen times their weight before moving. In other words, if the coefficient of lift is that indicated by the author's results, the particles composing the bed would all be shoved along the bed long before the lift forces could become of sufficient magnitude to be effective, and the derivation based on this lift equation fails.

Returning to a more general view of the paper, the writer does not concur in the statement in item 2(*c*) of the "Introduction" that "The average step of a certain particle seems always to be the same even if the hydraulic conditions or the composition of the bed changes." This statement is important, as it forms the "backbone" of the analytical procedure, and its validity appears to be confirmed, as the value of λ_0 is found empirically to be constant for most of the data. From the writer's observations of bed-load movement, it appears that the steps increase in length as the velocity of flow increases. Although most of these observations were on light-weight materials, the phenomenon of equal steps was never noted by the writer and was never mentioned by any of his co-workers at the U. S. Waterways Experiment Station, Vicksburg, Miss., who had done extensive experimentation with sand movement. The fact that λ_0 actually does appear to be constant indicates to the writer not that the assumption of equal steps is correct but instead that λ_0 is an arbitrary constant that does not have the physical meaning attributed to it.

Finally, the evident discrepancy of certain of the data presented in Fig. 3 is explained as a result of differential sorting of the grain mixture forming the bed. The author states that this hypothesis is not subject to direct proof. The U. S. Waterways Experiment Station, during the conduct of the investigations analyzed by Mr. Einstein, made periodic analyses of the material moving into the sand trap. It would appear that these data should furnish sufficient direct proof as to whether or not appreciable sorting is occurring. Data for one sand are reproduced in Fig. 4. The curve is typical, showing that the larger grains move first, but that, as movement increases in intensity, the material in motion becomes representative of the material in the bed.

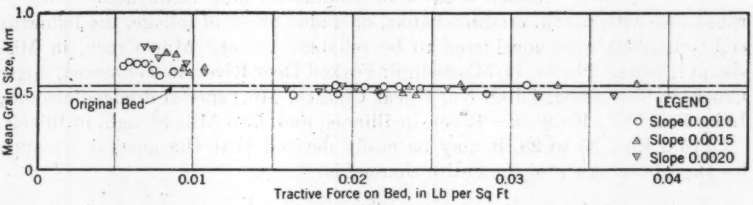

FIG. 4.—MEAN GRAIN SIZE OF MATERIAL IN MOTION; EXPERIMENTATION STATION, SAND 3

However, even without these data, the explanation appears faulty from the plotted data presented in the paper. It appears that, if the hypothesis is correct, the grouping of points along curve (*S*) in Fig. 3 is caused by the formation of a coarse protective layer of grains, and the plotted points would fall along curves (1) and (2) if the grain size of this protective layer were used in the formulas instead of the mean grain size of the original bed material. The same analysis may be applied in the reverse direction. Knowing the location of the plotted data and the bed-load equation, the grain size of the protective layer may be determined.

From Eqs. 16*a* and 16*b*, $\phi \sim \frac{1}{F} \times \frac{1}{D^{1.5}}$; and $\psi \sim D$. Taking sand 6, for example, there is a grouping of points at about $\phi = 0.0025$ and $\psi = 6.0$. By cut and try, it may be found that the points fall on curve (1) if $D = 0.125$ cm, giving $\phi = 0.00025$ and $\psi = 24$. Thus, if the author's explanation is correct the protective layer is composed of grains of an average diameter of 0.125 cm.

However, the reference from which Mr. Einstein obtained these data gives a grain-size distribution curve of this sand. There are no particles as large as 0.125 cm in the sand mixture, and less than 2% by weight of the particles composing this sand mixture are even half as large. Obviously, sorting alone is not the answer.

The writer has also noted, with interest, the contents of Appendix II regarding elimination of side-wall influence, as he has made a somewhat extensive investigation of this subject.[23] Although the author's method has been used by many investigators, published data actually verifying the method are rather rare. Most data on open channel flow in laboratory flumes have an experimental error of such magnitude as to obscure small variations in roughness. Natural channels, on the other hand, do not tend to have a marked change of roughness at some particular depth. The ideal channel to investigate would be one of sufficient size so that errors in measurement have negligible weight, and which has channel boundaries that have a definite change of roughness at some stage, with uniform roughness below this stage, and uniform but different roughness above. Some drainage ditches approximate this condition, and an analysis has been made of data published in the Department of Agriculture's bulletin, "Flow of Water in Drainage Channels."[24]

After rejecting channels because of insufficient data, insufficient change of roughness with depth, erodible banks, or undue effect of foliage, the following eight channels were considered to be reliable: Twenty Mile Creek, in Mississippi; Bogue Phalia, in Mississippi; Forked Deer River, in Tennessee; Sugar Creek, in Tennessee; Ditch No. 1 near Chaffee, Mo.; special dredged channel, Lake Fork, Ill.; Kaskaskia River, in Illinois; and Two Mile Slough, in Illinois.

From Eqs. 25 to 28, it may be easily derived that the general equation for the Manning's n of the entire channel is:

$$n^{1.5} = \frac{\sum_{m=1}^{N} n^{1.5}{}_m P_m}{P} \qquad (34)$$

Most of the dredged drainage channels have slight flow for the major part of the year, and a greatly increased flow for short periods of time. Thus, the lower part of the channels tends to be free of vegetation, whereas the banks are more or less thickly vegetated. If it is assumed that the perimeter is composed of sections of two uniform roughnesses (that is, the bottom and the banks) the general equation may be written

$$n^{1.5} P = n^{1.5}{}_1 P_1 + n^{1.5}{}_2 P_2 \qquad (35)$$

in which P_1 is the wetted perimeter of the lower section of the channel, P_2 the remainder of the wetted perimeter, and n_1 and n_2 their respective roughness coefficients.

The value of P, of course, is dependent on the depth of flow. For flow in the lower part of the channels, the value of P_1 varies with the depth of flow, and P_2 is zero. For greater depths of flow P_1 is constant and P_2 varies with stage. Thus, Eq. 35 may be written in two parts:

$$n^{1.5} P = n^{1.5}{}_1 P_1 \qquad (36a)$$

if the flow is in the lower part of the channel and

$$n^{1.5} P = \text{constant} + n^{1.5}{}_2 P_2 \qquad (36b)$$

if the vegetated banks form part of the wetted perimeter.

---

[23] "Flume Experiments on the Transportation by Water of Sands and Light-Weight Materials," by O. G. Haywood; submitted in 1940 to the Massachusetts Institute of Technology, at Cambridge, Mass., in partial fulfilment of the requirements for the degree of Doctor of Science.

[24] "Flow of Water in Drainage Channels," by C. E. Ramser, *Technical Bulletin No. 129*, U. S. Dept. of Agriculture, November, 1929.

When the value of $n^{1.5} P$ is plotted against wetted perimeter, the points therefore will lie on two straight lines. One line passes through the origin, with its slope determined by the value of "n" for the lower part of the channel. The slope of the other line is determined by the roughness coefficient of the banks, and intersects the lower line at a value of perimeter corresponding to that stage at which flow against the vegetated banks first occurs.

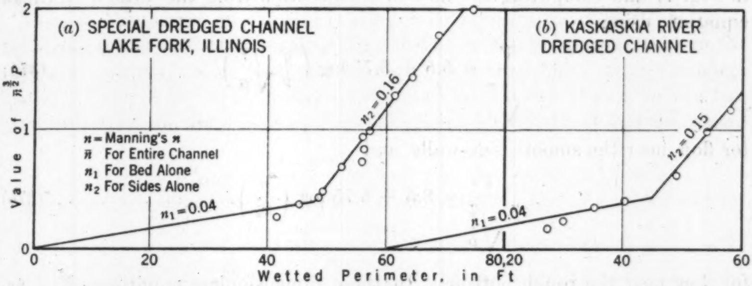

FIG. 5

Two of the graphs made by the writer are reproduced in Fig. 5. It will be noted that the data check the predicted straight lines very closely. All of the aforementioned drainage ditches were plotted in similar graphs, and none were

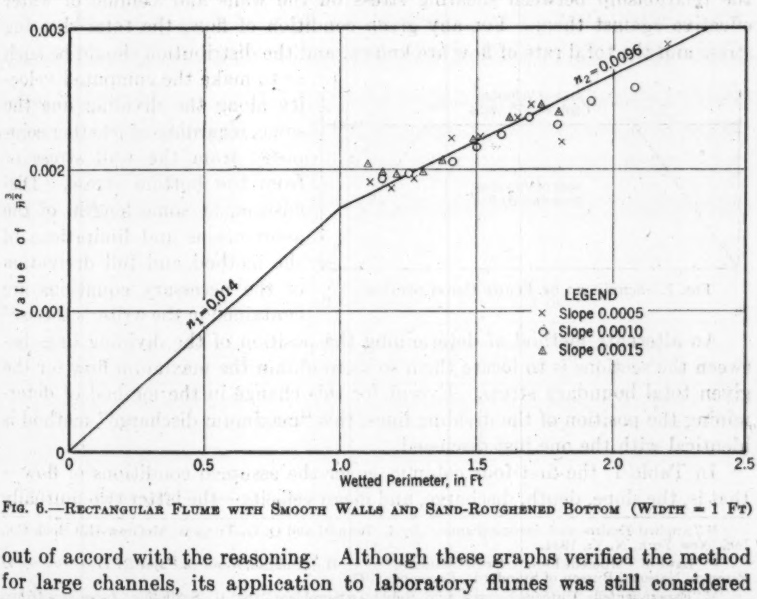

FIG. 6.—RECTANGULAR FLUME WITH SMOOTH WALLS AND SAND-ROUGHENED BOTTOM (WIDTH = 1 FT)

out of accord with the reasoning. Although these graphs verified the method for large channels, its application to laboratory flumes was still considered questionable. Certain of the author's assumptions appeared valid for large values of the Reynolds number, but more questionable for lower values such as those obtained in flumes. Some experimental data taken by the author in a flume with smooth walls and sand-roughened bottom are shown in Fig. 6.

As a further check on the method, the writer attempted an entirely different approach based on the Prandtl-Kármán theory of flow,[25] following to some extent the reasoning of G. H. Keulegan[26] and H. Schlicting.[27] The basis of this method is the division of the flume channel into three sections as shown in Fig. 7, and computing the flow in each section from the Prandtl-Kármán equation, using

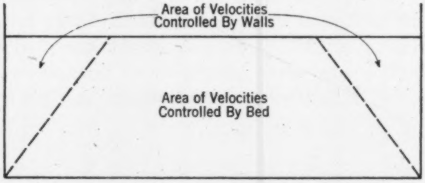
$$\frac{V}{\sqrt{\frac{\tau}{\rho}}} = 5.5 + 5.75 \log \left(\frac{y}{\nu} \sqrt{\frac{\tau}{\rho}} \right) \ldots\ldots\ldots\ldots\ldots\ldots (37a)$$

for flow near the smooth side-walls, and

$$\frac{V}{\sqrt{\frac{\tau}{\rho}}} = 8.5 + 5.75 \log \left(\frac{y}{k_s} \right) \ldots\ldots\ldots\ldots\ldots\ldots (37b)$$

for flow near the rough bottom. In these dimensionless equations, V = velocity at any point at distance y from the boundary, τ = shearing stress on boundary, ρ = fluid density, ν = fluid kinematic viscosity, and k_s = "equivalent sand roughness" of boundary.

The position of the dividing lines between the sections was determined by the relationship between shearing stress on the walls and volume of water effective against them. For any given condition of flow, the total shearing stress and the total rate of flow are known, and the distribution should be such as to make the computed velocity along the dividing line the same, regardless of whether computed from the wall stress or from the bottom stress. Discussion, at some length, of the assumptions and limitations of the method and full derivation of the necessary equations are contained in the writer's thesis.[23]



Area of Velocities Controlled By Walls
Area of Velocities Controlled By Bed

FIG. 7.—SCHEMATIC OF FLUME CROSS SECTION

An alternate method of determining the position of the dividing lines between the sections is to locate them so as to obtain the maximum flow for the given total boundary stress. Except for this change in the method of determining the position of the dividing lines, this "maximum discharge" method is identical with the one just discussed.

In Table 1, the first four columns cover the assumed conditions of flow—that is, the slope, depth, discharge, and mean velocity—the latter two mutually dependent quantities being dependent on the roughness of the bed.[23] The effective discharge is that part of the discharge that is effective against the bed; that is, the total discharge minus that part dissipating its energy against the walls. Computations for the effective discharge under the various conditions of flow were made by two methods, as shown in the table, the "writer's method" being that based on the Prandtl-Kármán method, and the "author's method" being that described in the paper.

[25] "Applied Hydro- and Aeromechanics," by L. Prandtl and O. G. Tietjens, McGraw-Hill Book Co., Inc., New York, N. Y., 1934.

[26] "Laws of Turbulent Flow in Open Channels," by G. H. Keulegan, *Research Paper RP1151*, *Journal of Research*, National Bureau of Standards, December, 1938.

[27] "Experimentelle Untersuchungen zum Rauhigkeitsproblem," by H. Schlicting, *Ingenieur-Archiv*, Vol. VII, No. 1, February, 1936 (abridged translation in *Proceedings*, Am. Soc. C. E., November, 1937, Translations, p. 16.)

The tractive force on the bed is the total boundary shearing stress minus the stress acting against the walls. In addition to computations based on the "writer's method," the "author's method," and the "maximum discharge method" (described briefly herein), computations are also shown for the two limiting values, the first based on the walls offering no resistance and the second on the walls offering resistance equal to that of the bed. The first is the familiar du Boys tractive-force equation,

[a] Water temperature 16° C (60° F); all other computations are for a water temperature of 24° C (75° F).

$$\tau = \gamma D S \qquad (38a)$$

in which τ = drag, or boundary shearing stress, γ = unit weight of fluid, D = depth of water, and S = slope of energy gradient or, for uniform flow, slope of water surface. The second,

$$\tau = \gamma R S \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38b)$$

is the same equation with the hydraulic radius substituted for the depth.

The substantial agreement of the writer's and the author's methods, especially for the values of bed tractive force, will be noted. Although it is fully realized that this agreement does not definitely prove that either method gives correct results, the two methods are based on quite different assumptions and analytical procedures, and their substantial agreement is encouraging. As extreme accuracy in analyzing bed-load data is not necessary because of the large experimental error always present, it is concluded that either of the two methods, and probably any other method based on rational consideration of velocity and shear distribution throughout the cross section, is sufficiently accurate. However, it should be noted that, if the average tractive force on the bed is computed by Eq. 38(*a*), serious error is introduced, particularly in deep, narrow channels. It is not intended herein to question the validity of the du Boys expression for large, natural channels where the depth is small in comparison with the width of the channel.

Samuel Shulits,[28] Assoc. M. Am. Soc. C. E. (by letter).—This scholarly probe into the realm of a universal law for the transportation of bed load is inspiring and merits the careful consideration of researchers in solids transportation. Since the ultimate end of all such analytical inquiries is a rational and practical implement for engineers, it may be interesting to conjecture what the reaction of a river engineer might be to the proposed method.

The largest part of available experimental data on bed-load movement is that measured by G. K. Gilbert, A. Schoklitsch, E. Meyer-Peter, and the U. S. Waterways Experiment Station[4]—and perhaps F. Schaffernak. Others have made a few scattered flume tests and then produced a bed-load formula, based on their own tests and those of the aforementioned authorities. All the formulas are different, with varying claims for their applicability, although some can be shown to resemble each other very closely. The author presents a law of transportation, the empirical coefficients for which are determined from the Zürich[7] (Meyer-Peter) and Gilbert[8] data and then finds that the U. S. Waterways Experiment Station measurements do not fit very well. Professor Meyer-Peter and the U. S. Waterways Experiment Station have offered their own formulas for their measurements, whereas Mr. Gilbert arrived at no generally usable equation. Professor Schoklitsch calculated another formula with his own and the Gilbert data. Of what avail is all this research if different investigators can create different results from the same basic data? Can the river engineer take one formula and use it with assurance or with some indication of its inherent error? The maze becomes worse when one realizes that not all the proposed formulas have been mentioned in this paragraph.

The author does not favor the concept of a critical value pertaining to the flow at which transportation begins. This factor is of physical significance, since there are flow conditions at which no bed-load movement occurs—a demonstrable fact with which river engineers like to deal. Little is gained by discarding the idea of a critical value, as the complicated formulas of this paper reveal. Why discard it when it is usually of little influence in practice? To illustrate this view, consider merely as an example the Schoklitsch bed-load formula,[29] derived from simple rational premises:

---

[28] Mississippi River Commission, Vicksburg, Miss.

$$G = C\,(Q - Q_0) \quad \text{(39a)}$$

In Eq. 39a G is the bed load, Q the instantaneous discharge, and Q_0 the critical discharge at which movement begins—all in cubic feet per second; whereas C is the dimensionless bed-load coefficient. Eq. 39a is also dimensionally pure. In actual calculations, Q_0 is negligible in comparison with Q, and its exclusion or inclusion is simply a matter of judgment, still necessary regardless of the bed-load formula preferred. The formula then becomes

$$G = C\,Q \quad \text{(39b)}$$

There is no valid logical objection to the concept of such a critical parameter. Its magnitude is not yet definitive, to be sure, but that is the problem of research and does not vitiate the significance of this physical concept. Similarly, the author refers to grain diameter and settling velocity, which are two parameters still far from being "nailed down" in a utilitarian sense.

The difference between the Schoklitsch formula, for example, and the Einstein law is, briefly: The former predicts the mathematical relationship between certain parameters, and then strives by means of experimental data to prove the basic reasoning and to determine certain coefficients; whereas the author devises two dimensionless functions and the determines empirically (from experimental data) their mathematical relationship (f) and certain coefficients (A and B). The first method is usually accepted as the best research procedure. As far as usefulness is concerned, it cannot be claimed that the second method is superior, although it may not be inferior. The river engineer may like to use Eq. 18, which states that ϕ is a constant times ψ; but he will then have to use constants and a function (f) which, strictly, fit only the Zürich and Gilbert data. Thus, there is no assurance of the universality of the constants or function, even if dimensionless characteristics are desirable.

Since Eq. 18 can be written:

$$\phi = \frac{\psi}{0.465\, e^{0.391}} \quad \text{(40)}$$

the possibility of a straight-line plot is indicated, rather than the semilogarithmic presentation in Fig. 3. Has the author investigated this possibility?

John S. McNown,[30] **Jun. Am. Soc. C. E.** (by letter).—The equation presented by the author, for bed-load movement, marks a forward step in the solution of this complex problem. A phenomenon that is subject to so many variables does not lend itself readily to a general analysis. For this reason the tendency of the experimental points to approach a single curve for movement of a uniform bed load, as shown in Fig. 3(*a*), is remarkable. The principal variables included in the experimental data used in this paper are amount of bed load, depth (or hydraulic radius), and particle density. Of necessity other variables such as water discharge, water velocity, and channel slope are included because of their dependence on the principal variables.

---

[29] "The Schoklitsch Bed-Load Formula," by S. Shulits, *Engineering*, June 21 and 28, 1935, p. 644.

[30] Instr. of Math., Mechanics and Hydraulics, Univ. of Minnesota, Minneapolis, Minn.

Some factors of probable importance are apparently omitted in the analysis. That the effect of a nonuniform bed is not included is obvious from a comparison of Fig. 3(*a*) and Fig. 3(*b*). Whether or not the shape of particles used in the two sets of experiments has an effect is not clear as no mention is made of this factor by the author. The plotted data show no trend that could be accounted for in this way. The application of this equation to the data obtained by Ho Pang-Yung[31] using irregularly shaped particles would be of assistance in settling this point. Also, the writer is of the opinion that the solution of the bed-load movement will be incomplete until the degree of turbulence is included as a variable. This cannot be done, of course, until an instrument for measuring turbulence conveniently is devised.

The agreement obtained is all the more remarkable as some of the underlying assumptions are admittedly uncertain. The existence of a constant ratio between the length of step and the size of particle seems improbable to the writer. Under this condition all particles in a uniform bed would have to take steps of the same size. Also a particle of a certain size would have to make the same size of steps under all conditions of movement. This implies a regularity that the writer has never observed in bed-load movement. If the same result were to be obtained by the assumption of a variable step length the plausibility of the derivation might be increased. This can be done by a slight change in the method of obtaining Eq. 1.

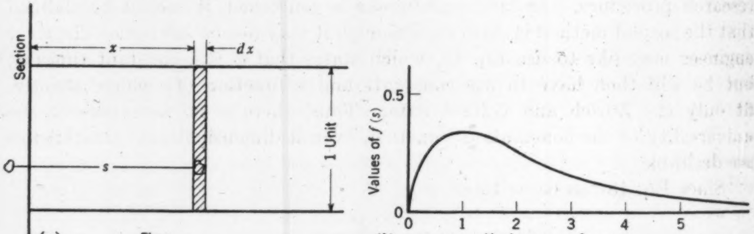

FIG. 8

The number of particles per second that cross the line labeled "Section" in Figs. 1 and 8(*a*) must be equal to the number of particles starting a step of variable length in one second that is long enough to cross the line. The two sets of particles are not identical but the equality must exist for continuous flow. The number of particles per unit width, beginning a step in one second from the differential area, which is a distance x from the line, is given by

---

[31] "Abhängigkeit der Geschiebebewegung von der Kornform und der Temperatur," by Ho Pang-Yung, *Mitteilungen der Preussischen Versuchsanstalt für Wasser-, Erd- und Schiffbau*, Heft 37, Berlin, 1939.

$$N = \frac{dx}{A_1\, D^2}\, p_s \ldots\ldots\ldots\ldots\ldots\ldots\ldots (41)$$

as shown in Fig. 8(a). The probability that a step will cross the line is designated as p_x. The functional relationship defining the frequency distribution of the variable-step length s should satisfy the following conditions: (1) The probability of making a step of zero distance is zero, (2) the probability of making a step of infinite distance is also zero, (3) the function must exist and be positive at all points between zero and infinity, and (4) the total probability or area between the distribution curve and the s-axis must be equal to one. One function (see Fig. 8(b)) that satisfies these conditions is

$$f(s) = s\, e^{-s} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (42)$$

This curve may be thought of as a special case of the family of skewed frequency curves generally designated as Pearson's Type III. The probability that $s > x$ is given by

$$p_x = \int_x^\infty s\, e^{-s}\, ds = (x + 1)\, e^{-x} \ldots\ldots\ldots\ldots\ldots (43)$$

The total number of particles beginning steps that are long enough to reach or cross the line per unit width is then

$$\int \frac{dx}{A_1\, D^2}\, p_s\, p_x = \frac{p_s}{A_1\, D^2} \int_0^\infty (x + 1)\, e^{-x}\, dx = \frac{p_s}{A_1\, D^2}\, 2 \ldots\ldots (44)$$

From the integral the term 2 is seen to have the dimension of a length and is approximately three fourths of the mean step length for the distribution that was assumed. By considering this value as simply a characteristic length, the length, L, may be substituted for it by a change of units and the author's expression, $\frac{p_s\, L}{A_1\, D^2}$, is obtained for the number of particles crossing the line, per second per unit width. The introduction of a constant would have no effect on the final result so that L could be taken as the average length of step. The author's assumptions on step length would then be applied to the mean value rather than to a single step.

In Eqs. 9 and 10 the effective velocity in determining the lift is assumed to be the wall velocity. The criticism that the author applies to the concept of critical movement would apply here also. Were the lifting force dependent on the wall velocity alone a critical velocity would necessarily exist. The wall velocity is probably not as important in the movement of particles as is the vertical component of the instantaneous velocity. An increase in the velocity criterion used should indicate an increase in the probability that the lift would exceed the weight of the particle rather than an increase in the lift itself. Using a turbulence criterion such as the root mean square of the vertical component of the instantaneous velocity, a gradual transition would result because of the nature of turbulence. Under comparable experimental procedures the wall velocity and the turbulence velocities may have a nearly constant ratio. Should this be the case no serious error would be introduced by the use of the wall velocity. This question, like so many others, must await a more complete experimental study of turbulence.

The critical values that have been used particularly in formulas for bed-load movement based on the du Boys concept are more likely misnamed than incorrectly conceived as the author maintains. Their use can be interpreted as simply the introduction of a constant to fit the general equation to the experimental data. The measurements corresponding to this particular value mark the end of the transition between no bed load and conditions that fit the particular formula. Some such value is necessary just as the quantity A in Eq. 17 is necessary in the author's derivation.

The value τ in Eqs. 10 and 11 designates the boundary shear, not the variable internal shear. If τ were replaced by τ_0 this fact would be shown more clearly.

This paper should certainly serve as a valuable analysis on which further developments in this intricate problem can be based. The methods and equations used by the author are somewhat complex but, in general, basically sound. The author is to be complimented for his excellent paper.

H. A. EINSTEIN,[32] ASSOC. M. AM. SOC. C. E. (by letter).—All discussions of this paper definitely show how little is known about bed-load movement. Mr. Shulits, for instance, asks of what avail is all this research if different investigators can derive different results (formulas) from the same basic data. This is the fate of all empirical research, because, when one tries to fit a mathematical curve through a group of scattering points, it is always possible to use fundamentally different functions that will all fit the points equally well within a certain range. Only by enlarging the range of measurements into a region where the different curves diverge can one choose among them. In this respect the writer was extremely fortunate in having the Swiss experiments[5] available, since they extend the range of experimental data considerably toward the greater depths and coarser grains.

In 1934 the writer developed[7] what is today generally known as the Meyer-Peter formula. This formula was based on the same experiments as the ϕ-ψ formula and satisfied a great number of them, especially those with coarse sediment. Accordingly, it proved very useful and dependable in its application to mountain streams with steep slopes and coarse sediment. It is well known that this formula will not describe the transportation of fine sediment, such as Gilbert's sands, smaller than 1 mm in diameter.

The ϕ-ψ method of describing bed-load transportation, and the Meyer-Peter formula, are both based on similar principles, but the ϕ-ψ method is more flexible. For this reason it can be correlated to all known experiments. The parameter ϕ is a measure of the intensity of transportation and seems to be of special importance, as most known bed-load formulas are valid only in certain ranges of ϕ. However, even if this method permits all measurements to be represented, it is still doubtful if any one mathematical curve will describe the entire range of known experiments. Conditions in large rivers with fine sediment are characterized by still higher values of ϕ, for which no flume experiments have ever been made. Any final curve should certainly embrace this range of higher values.

---

[32] Hydr. Engr., SCS, U. S. Dept. of Agriculture, Greenville, S. C.

The general pattern of research in the bed-load problem includes, since the first work of Gilbert[8] and Schoklitsch,[33] the following three steps: (1) Flume studies on beds of uniform grain; (2) extension of the results to mixtures; and (3) application to rivers under natural conditions. The ϕ-ψ method of representation is developed from the first stage alone. Its application to problems of the second step has been tried by the writer, using the experiments[10] made at Vicksburg; but he was forced to the conclusion that some kind of sorting must have occurred, contrary to Captain Haywood and the testimony of Fig. 4. Bed-load investigations conducted by the U. S. Soil Conservation Service in a small creek seem to give an explanation for this discrepancy. In these experiments the ϕ-ψ graph also shows points between curves (2) and (*S*) (Fig. 3(*b*)), and the composition of the bed as a whole is definitely the same as that of the bed load moving on it. In the top layers of the bed, however, a definite sorting took place, accumulating the coarse grains in a certain layer and the fine grains above and below. Depending on the extent to which this coarse layer is exposed, the rate of transportation may change for any one flow. Very likely the same thing has happened in the Vicksburg flume, and therefore could not be detected by samples as represented in Fig. 4. Investigations by the Soil Conservation Service on this problem are still in progress (November, 1941) and may soon yield definite results. If the writer's explanation is correct, the entire space between curves (2) and (*S*), Fig. 3(*b*), would constitute a possible range for non-silting and non-scouring channels. Elaboration on the extreme importance of this question is probably not necessary.

The average single step as introduced in statement (*c*) of the "Introduction" has been determined in a great number of measured distributions similar to the one presented by Mr. McNown in Fig. 8(*b*). Their averages, not the steps themselves, are independent of the flow, but seem to vary considerably with form and roundness of the particles. Further discussion of this question does not seem desirable at this time, as the complicated formulas were presented in 1937,[5] and relatively few readers would be interested in their derivation.

Professor Kalinske asks what particles are included in the description of bed load given in the "Introduction." This is very easy to answer: All particles in any flume experiment with uniform material, rolling or in saltation. It just happened that under the conditions of all these experiments particles did not seem to go into suspension. There is no single flume study with uniform grain available in which bed load and suspended load have been measured simultaneously.

The term "critical tractive force" is so familiar to every one that it seems almost impossible to do without it. Unfortunately, it is a condition that does not exist in nature. If it did, the points somewhere near the upper end of curve (2) would approach a horizontal line. The top points, representing a rate of transportation of some few pounds per hour in a 6-ft wide flume, would definitely be called zero transportation by all observers. If this small rate is measured, however, the data are found to fit curve (2). The writer would readily change his opinion about this point if any one could cite some experiments that show this break in curve (2); but apparently the break does not seem to exist.

---

[33] "Ueber Schleppkraft und Geschiebebewegung," by A. Schoklitsch, Verlag Wilhelm, Engelmann, Leipzig & Berlin, 1914.

It is clear that for the practical engineer the concept of a critical tractive force or critical value of ψ is very useful, since it indicates the flow under which a natural or artificial bed will be stable. For this purpose one must remember that an exact limit of transportation does not exist, but that the erosion can be reduced to any safe amount by choosing the proper ψ-value according to the expected duration of the critical flow.

The final important point under discussion is the influence of turbulence. R. A. Bagnold[34] shows indirectly that turbulence is greatly responsible for the transportation of bed load. Describing his transportation experiments conducted in a special wind tunnel, he states:

> "Sand placed at the mouth itself was never disturbed even at the highest speeds used, despite the fact that the drag and the normal velocity gradient must be a maximum there."

He does not give any explanation for this fact, but it is obvious that at the mouth of the wind tunnel turbulence has not developed yet and that this lack of turbulence can be the only reason for the failure of the sand to move.

The term turbulence includes all pulsatory velocities in the flow. The influence of vertical turbulence velocities on a moving grain is the action typical for suspension and has been excluded from the problem as such. Such vertical velocities might to some extent be responsible for the deviation of the finest grain sizes in Fig. 3(*a*) by increasing λ. Any influence of vertical velocities on grains in the bed, however, is impossible, as those vertical turbulence velocities do not exist in the immediate proximity of the bed (the water would have to stream out of the bed). Therefore, only horizontal velocities are available to move particles out of the bed. Since Mr. Bagnold proved that the average velocity without turbulence is definitely not able to cause the movement, it must be concluded that the horizontal turbulence or pulsations are responsible for the movement. (Mr. Kalinske may remember that in Mr. Shields' experiments the flow outside the laminar sub-layer was definitely turbulent and that the disturbances due to the eddies reached well into this sub-layer.)

Mr. Rubey[4] chose as the title of his paper: "The Force Required to Move Particles on a Stream Bed," thus indicating that his investigations deal with the forces acting on particles, like particle *a* in Fig. 9, that are on the bed rather than on particles like *b* which are in the bed. Close observation of bed-load movement shows that most moving particles are dislodged from positions in the bed. Thus, it is easily understood why Captain Haywood found a constant $A_4 = 0.01$ for the lift on the particles, and this is also the reason why the writer always refers to a "lifting" force. The low value of A_4 in itself excludes the possibility of any impact or push, such as would take place in the case of particles in position *a*, Fig. 9. Captain Haywood's rather high value of $t = 0.32$ sec may be correct. An explanation could be that before removal the particles first must be freed from the surrounding particles by small vibrating movements. In motion pictures of bed-load movements these vibratory movements can be seen readily.

---

[34] "The Movement of Desert Sand," by R. A. Bagnold, *Proceedings*, Royal Soc. of London, Series A, Vol. 157, 1936, p. 600.

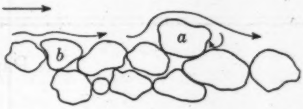

FIG. 9

The writer believes that he has answered the most important questions raised in discussion. Much could be added. In conclusion he would like to emphasize the fact that the problem is far from being solved and that a great number of the most important questions pertaining to sediment transportation cannot be answered because the necessary measurements do not exist or because they are incomplete. Every one investigating problems of sediment transportation would do well to keep Mr. Johnson's remarks in mind.

VALUE OF PUBLIC WORKS

By J. P. Hallihan,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Clarence W. Post, Uel Stephens, William J. Wilgus, Bernard L. Weiner, Albert Ed. Scheible, H. B. Cooley, Philip W. Henry, Baxter L. Brown, Evan S. Martin, Isador W. Mendelsohn, W. W. Crosby, and J. P. Hallihan.

Synopsis

It has long been the theory in the United States that cyclic depressions in industry, due to lack of a market for the goods produced, resulting in large-scale unemployment, could be alleviated materially by increased activity in the field of public works—in the construction of facilities requiring no market except the approval of the people. The opinion was also widely held that the transfer of the man power released by industry into the operations of public works would be a simple process performed with no great loss of time, and that the equivalent employment would sustain the purchasing power of the nation until industry returned to a normal basis.

The nine years 1931 to 1939 have furnished an opportunity to test these theories, and it may be useful to review the record to determine to what extent they have been supported in practice.

The Volume of Public Works

There are only two sources of public works—those incident to the development or protection of the national resources or the requirements of national defense, defined as federal works, and those required by states and lesser political subdivisions to meet the needs of their respective communities, defined as non-federal works. In the larger sense, the public interest is dominant in all these works, since any construction or employment adds to the national income, but the federal works can be initiated and financed only by federal action, whereas the non-federal works are wholly dependent on the willingness of the people directly benefited to assume the necessary financial obligations.

Financing of Public Works

When it became apparent, late in 1930, that extraordinary efforts must be undertaken to find employment for the millions of workers dropped from the

---

Note.—Published in February, 1941, *Proceedings*.

[1] Director, Municipal Eng. Section, WPA, Washington, D. C.

industrial rolls, the potentialities of state and municipal public works were explored. A survey conducted at the request of the Hoover Committee on Employment, by the American Engineering Council, through Engineering Committees voluntarily serving in each state,[2] reported in April, 1932, that a great reservoir of state and municipal projects for basic improvements existed in each state, typified by an estimate of $490,000,000 in the state of Michigan on a 5-yr program, and that this general proportion of needs to population was characteristic of the entire forty-eight states. The Committee further reported that, although a considerable proportion of the estimated volume had been in contemplation for some time and was in line as to general plans for early construction, it could not be financed through community sources because of dwindling tax revenues and a reluctant bond market. A considerable stimulus in the form of federal aid would be required to bring it within the range of availability.

FEDERAL AID

Federal aid was authorized by the Emergency Relief and Construction Act of 1932, through the Reconstruction Finance Corporation (RFC), in the form of loans on self-liquidating projects. As that definition admitted only projects for water supply and sanitation covered by rates to users, vehicular bridges and tunnels covered by tolls, and public transportation facilities covered by fares, it was not utilized in sufficient measure to assist the situation materially and was terminated on June 26, 1933. The National Industrial Recovery Act (NIRA) of June 16, 1933, creating the Federal Emergency Administration of Public Works (PWA) and authorizing loans on useful projects at 5% interest to the extent of 70% of the cost and a federal grant for 30%, brought more of the basic projects of municipalities into the construction stage.

The continuing increase in unemployment and in the number of persons coming on the relief rolls made it apparent that a more liberal stimulus must be provided to overcome the inertia of municipalities in the planning and presentation of public works. In consequence, the grant was raised to 45%, and the interest rate on loans was reduced to 4%.

In the meantime, as an emergency measure, the operations of the Federal Emergency Relief Administration (FERA), which made grants to states for direct relief and cultivated relief work projects, were supplemented by the Civil Works Administration (CWA), which put men at work on any kind of project that would provide work and succeeded in employing more than 4,000,000 workers in the winter of 1933–1934.

As a measure to furnish more immediate employment for unskilled labor, the Emergency Relief Appropriation Act (ERA) of 1935 authorized the creation of the Works Progress Administration (WPA) to take over the work programs of CWA and FERA and to operate as a general contractor in furnishing relief labor and a part of the material on projects designed by state, county, and municipal sponsors, suitable for force-account administration.

Thus, although the necessity of immediate expansion of public works was voiced in 1930, and became imperative in 1933, it was not until 1935 that it began to operate effectively in the works program. In the meantime, heavy expenditures for direct relief and work expedients started the national income up from a low of 40 billion dollars in 1932 to 42.3 billions in 1933, and 50.1 billions in 1934. Reflecting the influence of advance in public works, it rose to 55.2 billions in 1935, 63.5 billions in 1936, and 71.9 billions in 1937. A reduction in the national income to 64.0 billions in 1938 is generally attributed to a reduction of federal aid in the latter half of 1937.

---

[2] President's Emergency Committee for Employment, Government Printing Office, Washington, D. C., 1931.

The federal aid extended to construction in the years from 1933 to 1939 is shown in Table 1. This table includes sponsor's contributions, which were an integral part of PWA and WPA projects, as compiled by the Construction Statistics Section, WPA. The PWA operated four months in 1933, CWA operated two months in 1933, and WPA operated five months in 1935 (see Table 1).

TABLE 1.—EXPENDITURE OF EMERGENCY FUNDS IN CONSTRUCTION, AND EMPLOYMENT CREATED

No.	Description	1933	1934	1935	1936	1937	1938	1939

FINANCIAL LIMITATIONS OF MUNICIPALITIES

The delay in organizing a public works program was not due to any lack of useful projects. Many other considerations intervened between promise and performance, such as (1) the rapidly increasing poverty of municipalities, (2) statutory legislation, and (3) established procedure.

(*1*) *Rapidly Increasing Poverty of Municipalities.*—Cities derive their principal revenue from property taxes. In 1932 the assessed valuation of all real property in the United States was estimated at 163 billion dollars. In 1922, the corresponding value was 125 billion dollars and in 1912, 70 billion dollars (Bureau of the Census, 1932). In 1937 it was estimated by experienced analysts to have dropped to 90 billion dollars. In the business district of a typical large city the drop was 40%. This condition made it impossible for many cities to furnish the share of the cost required by the federal agencies, either from tax resources or by borrowing.

(2) *Statutory Legislation.*—In times of prosperity there is a tendency for communities to over-extend themselves in construction and to incur financial obligations beyond their ability to carry when tax revenues fall off. This tendency is controlled by statutory limitation of use of community credit and tax resources to a definite percentage of the current assessed valuation, generally about 10%. Exemptions from the bond limitations are made in the case of municipally owned public utilities that are made self-supporting by service charges to the users—as water, light, power, and public transportation facilities. Further restrictions on municipal borrowing, quite as effective as direct statutory and charter limitations, are found in state laws limiting investment of funds of savings banks, life insurance companies, trust companies, and sinking funds to bonds meeting the test of rigid financial standards. In many states municipal bond issues are automatically prohibited when tax delinquencies exceed a definite ratio of the current tax levy.

(3) *Established Procedure.*—Municipal improvement bonds must be submitted to the people at a general election and must be approved by at least a majority, and usually 60% of the total vote on the question. Even in times of prosperity, projects of recognized necessity may have to be submitted several times before approval is secured. In recent elections, in cities having more than 50,000 population, statistics secured by the Department of Commerce show that 65% of the bond issues were disapproved.

From the experience gained in this period of experimentation, it may be fairly stated that the theory that public works may be depended upon in times of depression to take up the slack in industrial employment is tenable only in part.

Effect on Construction Industry

The quick action necessary to make the theory effective practically is not possible of attainment under the foregoing conditions. Comparatively few of the projects presented to PWA in 1933 could be brought into line with respect to legal and financial requirements in time for approval under the authorization of funds for that program. Defects in bond issues required new legislative action in many states to make the bonds acceptable in the bond market. In this connection, the powers, limitations, and scope of action of the federal agencies conducting works programs of non-federal sponsorship should be understood.

Differences in Authority of Relief Agencies

Although both PWA and WPA are designed to stimulate the production of jobs for the unemployed, there is a considerable difference in their powers and limitations and, in consequence, in their scope of action.

The PWA may grant 45% of the cost of a public works project only when the sponsor has first furnished the remainder of the cost in the form of sequestered funds, bank credits, or definite commitment to purchase the securities to be issued; but it may further assist the sponsor by direct purchase of the securities issued for his share which are stipulated to bear 4% interest with provision for amortization in thirty years or less. The work must be performed under contracts acceptable to PWA and under its engineering supervision, and must employ not less than 25% of relief labor. The direct authority of PWA thus extends down to the job.

The operations of WPA are on a different basis. It has no authority to make grants of money. It may meet the entire payroll on public works projects designed by the sponsor on which at least 95% of the federal funds expended for labor are applied to payment of labor certified from the relief rolls, and may also contribute toward the rental of specified equipment and purchase of materials in definite proportion to the volume of employment created. The sponsor designs and supervises the work and accepts full responsibility for completion in the event that the relief labor finds other work or WPA comes to the end of its appropriation. The WPA executes the work through its state administrators who have sole authority to select for operation, from a general list of projects approved by the President of the United States, those projects that are most suited to the current needs of the local relief program.

TABLE 2.—CONSTRUCTION

No.	Description	PRE-DEPRESSION				
		1925	1926	1927	1928	1929

12	For the period	Average, 485				
	(c) NATIONAL INCOME,					
13	Totals[a]	72.7	74.9	73.7	77.6	81.1

[a] From "Construction Expenditures and Employment 1925–1936 and 1937 Compared with 1936," by 1939, in "National Income Produced"; U. S. Department of Commerce. National income for six years prior to for 1924, 67.9.

These differences in limitations and restrictions have resulted in a division of the public works assisted by these agencies along lines more or less determined by the quantity of material required by the project. Public buildings, schools, hospitals, water purification plants, sewage treatment plants, power plants, bridges, grade separations, and subways, which require a large proportion of manufactured material and skilled labor, averaging approximately 40% labor and 60% material, constitute the majority of PWA projects.

Because one of the determining rules of eligibility for WPA expenditures is that federal funds should be conserved for wages in the greatest degree consistent with proper execution of the job, the work undertaken runs largely to construction of roads, streets, dams, water mains, storm and sanitary sewers, airports, armories, landscaping of school grounds and parks, recreational facilities, drainage, and mosquito elimination, in which the labor-material proportion averages approximately 70% and 30%, respectively.

The works developed, however, were highly effective in retarding the disintegration of the construction industry, which was very seriously affected by the great drop in private construction. The highlights of the construction situation from 1925 to 1939 and the effect of construction employment on the national income are shown in Table 2.[3]

EXPENDITURES AND EMPLOYMENT

Peter A. Stone, Construction Statistics Section, Works Progress Administration. Corrected to December 31, 1925 was reported as follows: For 1919, 67.3; for 1920, 68.1; for 1921, 50.7; for 1922, 58.6; for 1923, 68.0; and

---

[3] "Construction Expenditures and Employment 1925–1936 and 1937 Compared with 1936," by Peter A. Stone, Construction Statistics Section, WPA. Corrected to December 31, 1939, in "National Income Produced," U. S. Dept. of Commerce.

It may be observed from Table 2 that public works construction constitutes only about 20% of the total volume of construction in normal times (1925–1929), the remaining 80% being made up by private construction. In the depression period from 1930 to 1939, the total volume of construction fell to 53% of normal, but of this reduced volume 50% (2.3 times its normal proportion) was furnished by public construction. Taking the average expenditure in the 5-yr period from 1925–1929 as a base, the cumulative deficiency in private construction since 1929 is more than 53 billion dollars, whereas the cumulative excess in public construction is more than 4 billion dollars. Employment from private construction averaged only 41% of its former value, whereas public construction employment averaged 316% of normal.

It will be noted in Table 2 that in the 5-yr period, 1930 to 1934, inclusive, there was a continuous drop in both public and private construction to a low in 1933; but at the end of 1933, public construction was still 80% of its normal volume, whereas private construction was less than 15%. The rise in volume thereafter was principally due to public construction which arrived, in 1939, to 176% of normal, whereas private construction is still only 45% of normal.

Possibilities of Public Works

It appears, therefore, that, although the expansion in public works fell considerably short of expectations, in point of immediate availability, the results obtained in the maintenance of the construction industry fully demonstrate the high value of public works in the national economy.

It appears quite evident, also, that, in similar circumstances in the future, the immediate effect sought cannot be achieved unless there is present an ample reservoir of projects that have gone through the time-consuming preliminaries of engineering examination and legal and financial authorization, and are ready to go into operation as soon as financial arrangements can be perfected. It is not easy to develop such a program in advance of need. The restrictions attending advance planning in municipalities and the development of construction programs are not likely to be materially reduced in the future. Accordingly, dependence must be placed on projects of national scope or local projects in which the national interest warrants federal participation in planning and financing.

There is no paucity of such projects. The nation has a definite interest in the elimination of 232,000 railroad grade crossings, most of which are in cities and are daily adding to the sum of fatalities and injuries from motor accidents. First-stage improvement on 2,000,000 miles of rural roads to make them passable in all weathers would affect, beneficially, the fortunes of 20,000,000 people and would be a sound investment of federal funds. It might be found justifiable, in view of their importance in national defense, to assist the railroads in catching up with their deferred maintenance of roadway and track, estimated by railroad authorities to require an investment of $400,000,000 annually on a 5-yr program.

Construction of wide thoroughfares through slum districts of large cities and the creation or betterment of public transportation facilities would merit federal assistance. The engineering surveys precedent to developing a program for such projects should properly be under federal control and direction through the appropriate works agency. The consolidation, in 1939, of government construction agencies under a single control in the Federal Works Agency, an administrative betterment long urged by engineers, and a similar consolidation of government loaning agencies under the Federal Loan Agency, have made possible a continuous coordination of effort with the National Resources Planning Board in the preparation and financing of a program of federal public works designed to permit the orderly development of the nation's resources.

The machinery is available, therefore, to inventory and classify the public works of the nation and to determine in what degree the national benefit derived from basic non-federal projects justifies their inclusion in a federally controlled and federally aided program of such volume, variety, and territorial coverage as to be really serviceable in taking up the load of industrial unemployment.

Many of the most important civic projects are unable to proceed because funds are not available for the purchase or condemnation of the lands or right of way required, as with rehabilitation of blighted or slum areas, elimination of grade crossings, and widening of important traffic arteries. The powers of the loaning agencies might reasonably be adjusted to meet such emergencies by long-term, low-interest loans, or the federal government might acquire the lands directly and lease them to the communities on a long-term recapture basis.

Another handicap to development of a program of first-grade projects is the limitation of federal aid to an annual basis, leaving a community with no assurance that a project may be prosecuted continuously to completion as a usable asset. Such handicaps can readily be removed by suitable legislation, but while they exist they operate to prevent the development of a public works program of the first order of usefulness.

CONCLUSION

On a foundation of preparedness and with administrative machinery geared for prompt action and control, there is every reason to believe that public works can be brought much closer to expectation as a compensative employment element. To make a program of public works fully effective in assisting to take up the slack in industry, its full power must be thrown in promptly upon the inception of the depression. For that reason, federal works, which are immediately controllable upon congressional authorization, must be prepared to furnish the greater volume of projects.

Under the most favorable conditions, a certain time is required to bring non-federal projects into operation. In times of industrial depression, cities are always in a straitened financial position from loss of revenues and impaired banking credit. To cut down this time, arrangements for federal loans on a long-term, low-interest basis for programmed projects should be perfected in advance of need.

ACKNOWLEDGMENT

Acknowledgment is made to Peter A. Stone, chief of Construction Analysis Unit, WPA, for valued assistance in compilation of the construction and employment statistics used in this analysis.

DISCUSSION

Clarence W. Post,[4] M. Am. Soc. C. E. (by letter).—In this paper, Major Hallihan places sewage treatment plants and water purification plants in the category of projects that naturally fall into a class handled by the PWA. In New York State this has not been true; some of the largest and best projects that the WPA has constructed in the state have been for water treatment, sewer systems, and treatment plants. These range from a small complete sewer system and treatment plant at the Village of Ft. Ann (population in 1940, 437) to the interceptors and treatment plant for the Ley Creek Sanitary District, Syracuse, which cost more than $3,000,000, and which was designed for a population of 30,000 and a daily average flow of 4½ million gal.

Under the WPA program, thirty-four treatment plants have been constructed and twenty-seven plants enlarged and improved. Projects for interception and treatment plants have also been started in many more communities. In addition to these plants, 1,900 miles of sanitary and storm sewers have been installed. Two storm relief tunnels driven through rock have been built in the City of Rochester, and a third submitted for approval.

The plans and specifications for this type of work must be prepared by either regular civil service employees of the engineering bureaus of the various cities, or by consulting engineers. All plans and specifications must be approved by the Division of Sanitation, New York State Health Department, before any work may be performed.

When a project is placed in operation the selection of a superintendent to have charge of the operation is of utmost importance. Applicants' personnel records and construction background are examined and the final determination and approval for employment comes from the director of operations or the chief engineer of the New York State Work Projects Administration.

One other factor helps in this type of work in New York State: Each community signs an agreement to furnish the necessary skilled labor if such skills are not available from the relief rolls. Small buildings have been, and are being, built successfully by the cooperation received from the sponsors who, in many instances, have furnished the bricklayers and any other skilled artisans who are lacking from the relief rolls. In every instance, however, the federal expenditures on these projects are only about 30% to 40% of the total cost.

The plants can be built with relief labor when care is exercised over the selection of key personnel to supervise the work.

Uel Stephens,[5] M. Am. Soc. C. E. (by letter).—The subject which Major Hallihan has so ably presented is most appropriate at this time when the entire attention of the United States is being centered on its defense requirements. Now is the proper time for the engineering profession to formulate plans for "carrying on" after the flush of defense construction subsides, and buying begins to decline, and finally reduces to a minimum.

---

[4] Deputy State Administrator & Chf. Engr., New York State WPA, Albany, N. Y.

[5] Asst. Regional Director, Dept. of Public Works, Defense Public Works Div., Federal Works Agency. Fort Worth, Tex.

It is a well-established fact that every period of unprecedented construction and spending activity must be followed by a period of below-normal activity that usually will exceed both in duration and intensity the preceding period of above-normal activity. It appears that the amplitude or distance between the crest of the wave of prosperity and the bottom of the valley of the depression increases in direct proportion to the degree of industrialization. The capability of industry and small political subdivisions to combat the periods of depression, and to keep within reasonable bounds the extent of expansions during periods of abnormal development, appears to become less and less, and the tendency to look to the federal government for the solution increases proportionately. These facts being accepted, it then behooves the federal government through its proper agencies to begin at once, and rapidly develop, a vast plan that will contain a large reservoir of worth-while public projects that can be placed under construction rapidly and economically in accordance with adequate engineering designs.

The engineers who experienced the many phases of public building from the Emergency Relief and Construction Act of 1932 to the defense construction programs of 1940 and 1941 should realize, better than members of any other profession, the dire needs for adequate and proper planning before the depression comes. Their experience in rushing into great construction programs in 1933 and 1934 clearly demonstrates the waste and inefficiency that cannot be avoided unless some one central agency has planned and can be given the necessary authority to execute some well-developed and properly coordinated plan for construction projects of all types. Probably one of the most important duties of such a federal planning agency would be the coordination of the activities of various agencies. Competition between governmental agencies, such as existed between the PWA and the WPA and now (1941) is occurring between the WPA and the PRA (Public Roads Administration), should be made impossible.

If the federal government, through its National Resources Planning Board, could provide funds in the form of grants to municipalities to pay the engineering cost, in part or in whole, for the preparation of preliminary plans and specifications covering such projects as could be undertaken for construction, there would be an incentive for private engineers to plan a program that could be constructed with little delay when the necessity arose. Such an organization must be local to the extent that the study of prevailing local conditions can be made. Such work could not be done successfully by a central organization in Washington, D. C., for the reason that local conditions could not be comprehended readily. By decentralizing and placing complete responsibility in the hands of state organizations, the local engineers would be more prone to plan and study projects if they thought that final consideration could be given locally rather than being reserved by a central office—some located great distances away.

In conclusion, Major Hallihan is to be complimented for the very able paper he has presented. Based on experience and on the records that have been kept, it is evident that the present is the proper time to begin planning for the next depression, which is sure to follow in the wake of the present unprecedented construction program.

WILLIAM J. WILGUS,[6] HON. M. AM. SOC. C. E. (by letter).—In these days of peril it is noteworthy that Major Hallihan's thoughtful paper should have appeared simultaneously with the report[7] of the National Resources Planning Board in favor of the "storing up [of] a reservoir of non-defense public works which can be loosed when the pace of rearmament slackens." There would seem to be no room for argument that the United States now should prepare for the defense of its institutions from attacks from within as well as from without. It is not difficult to visualize what will occur if countless of its citizens are to be permitted again to suffer from unemployment when the war boom ends. In a word, the two kinds of preparedness must go hand in hand if wisdom is to prevail, even though many may feel that preparedness for internal peace should "take a back seat" while the nation is engaged in preparedness for external war. To win in one and not in the other will spell ruin.

It is widely urged that the furtherance of projects "which are either economically non-productive or of a sort which displaces private enterprise in its own legitimate field" will mark "a plunge headlong into state socialism and totalitarian government."[8] There is indeed risk of this in a world afire; but if large-scale employment ceases, and with it the buying power of multitudes thrown out of work, what will enable free enterprise to take up the slack any more than in 1933? Idle money means idle men—the death not only of free enterprise but of all else that Americans hold dear.

No one knows what new order of society will come forth from the existing world chaos. Whatever it may be, men and women must be given opportunities to earn their daily bread in the production of things worth while, whether economically productive or desirable in a social sense. Now is the time, as proposed by Major Hallihan, to prepare plans in advance, rather than, by neglect in this respect, to invite a return of the soul-crushing, leaf-raking days of 1933.

The field for advance planning is well-nigh limitless. Many projects at once come to mind, such as water supply and sanitation; the control, purification and shore protection of streams; conservation of natural resources; light, heat, and power; housing and hospitals; parks and parkways and the beautification of the roadside; and transportation by rail, highway (including back roads), water, air, and pipe line. What a land this would be could a fraction of the money expended for destruction be devoted to construction of such a high order. Idealistic? Yes; but were people ever more in need of ideals to buoy their hopes for a better day? With it, however, must go the practical to save civilization when the present false prosperity ends.

It is not alone for the future postwar era that the planning of public works is needed. Right now much of it is required for wartime defense, as stated by

---

[6] Weathersfield, Ascutney P. O., Vt.

[7] "Development of Resources and Stabilization of Employment in the United States," National Resources Planning Board, January, 1941.

[8] *The Wall Street Journal*, March 20, 1941.

Major Hallihan. Perhaps this is most true with the railroads. Deferred maintenance in that field gives ground for alarm; and, too, the lowest inventory ratio to operating revenue in thirty years, barring three, reported in the *Railway Age* of March 29, 1941, which in case of invasion or a similar emergency might spell disaster to the Nation.

Obsolescence of railroad equipment is marked, the Federal Reserve System's bulletin of October, 1940, reporting that in the period between 1930 and 1940 the percentage of locomotives less than ten years of age had dropped from 20 to 6, and of freight cars from 34 to 14. This condition is emphasized in the *Railway Age* of January 4, 1941, which, in prophesying car shortages, calls attention to the locomotive situation in which 68.5% in service in 1940 were twenty-one or more years old against 57% five years ago. Planning coupled with action in this field is needed immediately, not only for normal peacetime traffic, plus an evenly distributed comparatively small increase for defense traffic, but also for the many exigencies of war in case of home invasion or military operations beyond the borders in Canada or Mexico, or in more distant lands.

In their fixed properties the railroads also call for immediate planning and corresponding action in order that they may not obstruct the progress to be expected in equipment, service, and operating efficiency. The strengthening and refinement of many thousands of miles of track, including bridges, the repair and modernization of yards, locomotive terminals, shops and shop tools, fuel and water facilities, work equipment, signals and interlocking, and freight and passenger stations; numerous other improvements such as by-passes around centers of congestion and the separation of grades; and the making good of deferred maintenance—all these call for several years of expenditures amounting to something like a billion dollars annually, in which is included provision for equipment. The aforementioned issue of the *Railway Age* goes into this question in great detail, as does its issue of January 7, 1939.[9]

The urgency of the need for doing something about the railroad situation is made startlingly apparent in the *Railway Age*, which states in its issue of January 11, 1941, that "to be frank, the financial results of the operation of the railways lend some color to the the charge of 'decadence,'" and that "the Nation cannot be restored to economic health and military invincibility if it continues to nurse along a transportation cancer within its economic body." That "military invincibility" in this respect is not to be expected from the railroads, unaided by federal intervention, is indicated by these quotations from an authoritative railroad source:

> "War participation * * * is outside of a consideration of the railroads' ability to carry on under conditions properly incident to that of National defense."
>
> "It would be unreasonable to anticipate the financing of equipment for such purposes from funds collected for the transportation of passengers and goods in a competitive transportation endeavor."

---

[9] See also "Financial Requirements of Railways," Interstate Commerce Commission *Statement No. 3911*, March, 1939; and "Report of Committee Appointed September 20, 1938, by the President of the United States to Submit Recommendations Upon the General Transportation Situation," December 23, 1938.

> "Enemy invasion of the United States * * * does not appear likely in the near future."
>
> "Plans on the part of the Government for activities under National Defense * * * have not heretofore been revealed to railroad managers."

In the light of these circumstances the value of public works on which Major Hallihan dwells would appear to be clearly evident; likewise, the wisdom (as he states under the heading "Possibilities of Public Works") of having "present an ample reservoir of projects that have gone through the time-consuming preliminaries of engineering examination and legal and financial authorization," coupled with prompt action in such instances as that of the railroads.

Bernard L. Weiner,[10] **M. Am. Soc. C. E.** (by letter).—Considered merely as a tabulation of statistics, the author's data may probably be accepted as substantially correct—even though definitions of such terms as "national income" are not given. It is obvious that, unless care is taken, duplication may easily occur. For the purpose of this discussion, however, it is not necessary to go into refinements. It will be sufficient for the purpose even if the data are accepted as being merely indexes of relative values. In any case, it seems to the writer that the conclusions drawn from them are not justified. It is only necessary to plot the statistics to see that the conclusions as to cause and effect are unwarranted. Fig. 1 shows that, in relation to national income, the variation in public construction is so slight that it is unreasonable to suppose that the latter is the cause of the variation in the former. The author states that the 1938 drop in income is generally attributed to the reduction of federal aid in the latter half of the preceding year. The chart shows that, while there is a slight wiggle in the public construction curve, the total construction curve remains practically level. The ratio curves show further that, just prior to 1932, construction was decreasing faster than income and then increased slower than income. One is led to believe that construction and national income are both affected by factors other than those treated in this paper—factors that are of a magnitude comparable to the results they are supposed to control.

The author shows that in the ten-year period, 1929 to 1939, there was a loss of 53 billion dollars in private construction, whereas public works showed a gain of a mere four billions. During the same period, the loss in national income based on the 1929 income was about 250 billion. The four-billion dollar increase in public construction can hardly be credited with having more than a very minor effect on these large sums; the increase shrinks into insignificance by comparison. It might be argued that the 1929 income is not a just base for comparison since it is a maximum; but the fact remains, nevertheless, that the same industrial and agricultural capacity, as well as the manpower that was available and capable of producing the maximum amount in one year, had the same potential physical ability to produce a like amount in any other year. Whatever it was that prevented the national economy from functioning at the same level—or at even a higher level, as might reasonably be expected in a dynamic economy—was also responsible for the lag in construction. The "drop in the bucket" that constitutes public construction cannot, it seems to the writer, be the cause of the rise in the national income after 1933. The true controlling causes or factors, however, must be found; and it is perhaps no exaggeration to state that it constitutes the most important problem confronting the United States and the world today.

---

[10] Designer, Air Depot Archt. Engrs., New York, N. Y.

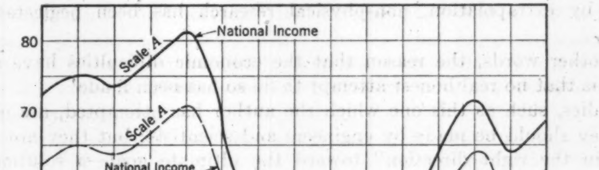

FIG. 1

To declare that the most important problems that confront the nation are immediate recovery and long-range planning for the stabilization of industry is to state the obvious. The fact that the nation is now engaged in an undeclared war—or is in state of non-belligerent intervention, if this characterization is preferred—does not change matters. It is the opinion of the writer that the so-called domestic problem cannot be solved without taking the international situation into account and the two problems are so inextricably intertwined that they are really one and the same problem. Many panaceas have been offered for the solution of both problems treated separately, no two being alike. The conclusions drawn by the author are merely the echos of a political party pointing with pride to its supposed achievements—and at best, the paper is merely another panacea. The fact remains that the world is confronted with a failure of more than major importance—civilization is threatened. All methods from the appeal to the brotherhood of man to self-interest have been tried—and all have failed. In the domestic field, industry has been spending vast sums of money on physical research with the result that, as the products of industry approach perfection, the economic crisis becomes more and more acute. At the same time, wars are becoming ever more frequent and more destructive. On the other hand, except for such superficial studies as the charting of market trends in an effort to forecast the future by extrapolation, non-physical research has been neglected almost entirely.

In other words, the reason that the economic difficulties have not been solved is that no real honest attempt to do so has been made!

Studies, such as this one which the author has attempted, are necessary, and they should be made by engineers and scientists; but they are merely a "step in the right direction" toward the ultimate goal—a solution to the problem of war and poverty. That a solution is possible should be obvious. There is no reason to suppose that this problem with which the world is faced is somehow so peculiar that it will not yield to the same scientific treatment that has solved so many other problems. The same mind of man that is capable of producing the truly great marvels of modern civilization should also be capable of producing the solution for this non-physical problem. Engineers and scientists have been sadly remiss in their duties as citizens in this respect. They are both peculiarly fitted by the very nature of their training to tackle the economic problem.

A little consideration should show that the engineer in the rôle of economist is not at all a strange or far-fetched idea; in fact, it is very logical that he should be peculiarly fitted for it. What else is the work of the engineer—in the broad sense—but bringing order out of chaos? How else but by research to determine the facts, and by analysis to determine the solution from the facts, does the engineer work? Most important of all, the engineer has another qualification. It has been remarked often that the engineer acts for both his client, the owner, and for the contractor, and the disinterestedness of his judgment is never questioned. In other words, the engineer has the recognized distinction of being free from bias in forming his judgments. The very fact that those who have attempted to solve the economic problem have been led astray by their biased, preconceived ideas is one of the principal reasons why failure has always resulted. Those who succeed finally in finding a solution must be able to follow their studies through with scientific rigor, no matter where they lead—a specification that fits the engineer more than it does any other group. Finally, the same methods that made possible the physical basis of modern civilization should and could, logically, be applied to achieve the primary purpose of all human endeavor: To make the necessities and even the luxuries of life available to all mankind.

It might really be said that it is not so much a question of the engineer's becoming an economist, as it is one of applying engineering methods and procedure to economics.

Albert Ed. Scheible,[11] Assoc. M. Am. Soc. C. E. (by letter).—The subject is both interesting and timely. It is interesting because there has not been much published on the subject in the form in which it is presented in this paper; and it is timely because many persons are already beginning to think about the future—what will happen after the present conflagration has burned itself out. One evening the writer listened to an address by a noted sociologist on the subject, "After the War—What Then?" Engineers of every branch would do well to study this question. If the engineer does not do this, members of some other profession probably will. That is what happened during the past depression when many avoidable mistakes were made. Those who had instigated the program failed to realize that such an undertaking could be handled best by engineers.

---

[11] Prin. Asst. Engr., R. F. MacDowell, Cleveland, Ohio.

It is the writer's opinion that here is a chance for professional and technical societies to take an active part in that "human engineering" which one hears so much about. Technical societies, working with the local professional groups, could do much to promote thought, and in some cases, could initiate a program of planning for the future.

As the author states, public works is not the entire answer to unemployment, but it can, and should, take the strain from other methods that will have to be adopted when a similar situation has to be met in the future. Based, then, on the experience gained in the recent past, it should be possible to make many improvements. To that end the organized engineering profession should bend every effort.

Having been directly connected with non-federal projects, both as a government employee and later as an employee of a consulting engineer, the writer would like to present some views regarding the subject.

The hectic days at the beginning of the program in 1933 may be discounted. The present WPA program seems to have reached a point of more or less stability and, of course, PWA has ceased to function, at least in the matter of accepting new projects.

Those persons entirely unfit for manual labor, including the aged, should not be employed on construction projects. Some attempt has been made to employ only men who are physically fit. For some reason, the government rules applying to physical fitness have not been enforced as stringently as have some of the other rules, many of which are not nearly so important. More recently, in an apparent attempt to keep the WPA alive, this regulation seems to have been "winked at."

A planning program is of the utmost importance. Although the federal government "foots the bill," or most of it for labor at least, it should not expect financially harried municipal officials to "jump through the hoop" every time the unemployment curve takes a sharp rise. Most municipalities are always understaffed, particularly with respect to engineering personnel. Indeed, many small municipalities have no engineering departments, which may be one of the reasons for such poorly planned projects. The time to plan projects is now. As emphasized by the author, municipalities are becoming poorer for obvious reasons. They have no money with which to plan projects that may not be executed in the near future. The federal government should make funds available now, by grants to municipalities, for this work.

Under the present program (referring particularly to the WPA), it seems that all kinds of construction work, with the possible exception of paving, must be done in the winter time. An effort to find more protected work in the winter time would be very helpful. A program planned far enough in advance might aid in this respect, and perhaps a frank admission that most construction work, now being done or attempted, is out of place in the winter time. However, this reverts to the need for some other type of program during the winter months when the unemployment curve seems to rise. The writer believes that this frank admission should be made and that a new approach to the problem should be sought. The present program seems to have been started and then left hanging.

The contractor, it appears, is the forgotten man in the entire program. He did have some work under PWA but the program was so short that the average small contractor was lucky to secure one or two jobs, and at a ridiculously low sum. Every WPA form requires that the sponsor make a statement to the effect that the work proposed is not a normal function of the sponsoring body, and yet the writer has before him the report of a department of a certain state giving the amount of sewer and water work done with WPA aid during 1940, work that heretofore was done mostly by contract. If this condition continues, the contractor will soon take the place of the American Indian as the Vanishing American.

Due to rules and regulations, local offices must take a very arbitrary stand on all matters of policy. In the business world there is a saying, "the customer is always right." In the case of the WPA it is very often difficult to tell which is the customer. The local offices should have a certain degree of authority and there should be a certain degree of elasticity in the actual operation of a project. The writer hazards a guess that never has a construction project been executed in which everything was completed to the smallest detail as planned; and yet this is what is expected under the present system.

The need for the program is obvious. The administration is to be commended for its courage in initiating it. There is still much room for improvement. To that end every effort should be made by those on whom so much of the future will depend—the engineers.

H. B. COOLEY,[12] ASSOC. M. AM. SOC. C. E. (by letter).[12a]—Many of the difficulties that faced the execution of the public works program in the depression period are stated clearly by Major Hallihan. The writer feels that it is not too early to begin to lay the ground work and prepare for the inevitable adjustment period that is bound to occur with the cessation of hostilities and the armament program—whenever that may occur. Major Hallihan mentions some of the many difficulties that should be overcome and outlines remedial steps; but will the next occasion find the United States as unprepared as did the last period?

It should be remembered that the enlargement of public works as a method of alleviation of cyclical depression is merely one theory for the accomplishment of this purpose and is not "The" theory, as was stated in the "Synopsis" of the paper. Consequently, the advantages and disadvantages of the public works theory must be weighed against the advantages and disadvantages of various other theories. That there is any single remedy for our economic ills is doubtful and the increased expenditure for public works in times of decreased spending by private enterprise is undoubtedly an aid, but this increased spending should be accompanied by other measures that will supplement the program rather than work against it.

---

[12] Asst. Prof. of Economics and Business Administration, West Virginia Univ., Morgantown, W. Va.

It seems to the writer that there are a number of reasons which may be given in justification of an expanded public works program in times of depression. By such a program is meant one that will take up the slack in normal construction—which norm would in itself be a varying term and would probably refer to the average volume of construction existing in a period of years immediately before the particular depression. Thus a program to relieve conditions in the depression of the 1930's would refer to the period of the late 1920's as normal, whereas a program in the 1940's would refer to the level established just before that period.

One justification for such a program might be the maintenance of the existing construction industry—the equipment, financial resources, workers of all types, the suppliers of materials and equipment—in a condition as similar as possible to that existing before the depression. Such an objective would presuppose the use of existing methods of letting contracts and the use of existing organizations, contractors, equipment manufacturers and distributors, and material producers and dealers, wherever possible. This would assume costs on a comparable basis with the pre-depression costs, with, roughly, the same volume of business, the only differences being a shift from private construction to public construction and a change in emphasis from types of construction generally undertaken by private industry to types which could be undertaken by a public agency. In such a program, the flow of money through the various channels would be largely the same as the flow in the so-called "normal" period before the depression.

Another justification may be found by considering the increased public works as an offset to a decrease in private industrial activity. This would include not only normal construction activity but also the decline in manufacturing and distributing functions. If such a purpose is to be achieved the construction industry not only must be kept at its pre-depression level but it must be expanded to provide employment for those released in activities outside the construction industry and its related fields. This purpose may be accomplished by increasing the dollar volume of construction at the same unit costs, by maintaining the same dollar volume at decreased unit costs, or by altering the methods of construction so that a larger number of men may be employed on the same physical volume of work.

A third justification may be to find employment in the construction industry for all unemployed laborers who are capable of working and hence are employable. It seems to the writer that such a proposal is not feasible as many of the unemployed are not suited to construction activities. This applies to women, to the elderly worker, and to the majority of the so-called "white collar" workers, among others, although places can be found for some of these on construction projects. To attempt to place labor, which is not suited to such work, at work in a construction program must result in the creation of made work and "boon-doggling" projects, the value of which may well be questioned.

The values given in Table 2 indicate that the enlarged public works program failed to take up all the slack in the previous program when only the dollar expenditures are considered. Although public construction increased from an average expenditure in the pre-depression period of $2,318,000,000 to an average amount in what Major Hallihan terms the "post-depression" period of $3,268,000,000, there was actually a decrease in total expenditures from an average of $10,536,000,000 in the pre-depression period to $6,374,000,000 in the post-depression period, and from a high annual amount before the depression of $11,060,000,000 to a high annual amount after 1934 of $7,778,000,000. If the values are at all comparable it is apparent that the enlarged program of public works failed to meet the needs of the construction industry as it existed in pre-depression years and certainly could not have contributed toward the elimination of the slack in other industries not related to the construction industry. If costs were materially reduced per unit of physical work produced, due to a general decline in labor and material prices, then it is possible that the same physical volume was maintained even though the dollar expenditure was less. Such a decrease in costs, however, would have to be about 40% less than the pre-depression costs, based upon the total values.

Table 2 does show, however, that the average employment increased, as a result of the program, from 2,396,000 persons in 1928 to 3,493,000 persons in 1938, with a low of 1,001,000 in 1932. Was this increase of approximately 1,000,000 persons between 1928 and 1938 due to a change in methods of executing construction work or are the numbers comparable in any way? Due to the smaller number of hours worked per man each month, it is natural to suppose that the increase in the average number of men employed is due to this factor as much as to the increase in public expenditures from $2,484,000,000 in 1928 to $3,373,000,000 in 1938, especially when the decline in private construction from $8,576,000,000 in 1928 to $3,268,000,000 in 1938 is considered.

To judge the works program only on the basis of dollars expended or the number of men employed would seem to be fallacious. To what extent did it replace the existing industry of the 1920's; or did the shift from projects with a higher percentage of payment for material to the later projects with a higher percentage for labor tend to create other conditions which decreased the benefits flowing from the expenditure of the individual dollar in the first instance? In the former case the money was more widely circulated, and hence benefited more industries and more workmen, than was the result when a large part of the construction dollar was spent for construction labor and was immediately expended for consumption goods.

What was the ultimate value to society of the money spent on construction projects? Did the results obtained compare favorably or unfavorably with the results achieved in the preceding period in the 1920's? It seems to the writer that the cost of the works program should be evaluated from two viewpoints. One is the social view; and consideration must be given to the fact that large numbers of people were given employment who would otherwise have been idle.

The other consideration is the cost of the construction under such a program when compared to the cost of the same improvements by using, what might be termed for want of a better name, more orthodox methods. Men may be kept employed by having them spend their time on useless projects, "boondoggling," or they may be selected and employed so as to achieve the maximum efficiency for their labor without regard to the number employed. Also, an intermediate course may be pursued that will afford employment to larger numbers than in the second case but at the sacrifice of efficiency. The latter course was the one pursued and may have been the best course but it would seem desirable to know just what was achieved by such a program, both from the human viewpoint and also from a construction efficiency viewpoint, and just how much was sacrificed on the one hand in order to achieve the benefits on the other. Until this information is obtained, publicized, and discussed, it would seem that any plans based upon past experience rest upon a weak foundation. The two objectives are confused and merged into one another so that it is difficult to determine just what benefits have been derived from the program in the past.

To illustrate this confusion reference may be made again to the expenditure and employment values of Table 2. It was noted that the total employment increased by a yearly average of about 1,000,000 persons between 1928 and 1938, whereas the total expenditures for construction decreased $4,419,000,000 per year in the same period. Assuming that construction costs decreased during this period, that living costs also decreased and that, due to a change in types of projects and methods of executing the work, there was a larger percentage of the construction dollar paid to labor, what does this indicate? Was the individual workman benefited in proportion to the amount expended or were his annual earnings reduced? It may be that his standard of living was materially lowered because of a reduction in his actual annual wage. On the other hand, the steadiness of his employment throughout the year, even though for fewer days in the month, may have increased the average annual wages per worker. Which is correct and how does this benefit to the individual (after all there was a benefit to some when total unemployment was the alternative) compare with the cost to society for this social benefit to the human being and the physical benefit as measured by the actual value (not the cost) of the physical structures?

The situation may well be likened to that of a manufacturer producing a number of different products. His over-all operations result in a profit and for this reason he may be lulled into a feeling that all is well with the business. More detailed information, however, might reveal the fact that certain operations are unprofitable and that the entire enterprise would be benefited by discontinuing certain activities. Such an analysis might well be undertaken with relation to the public works program.

PHILIP W. HENRY,[13] M. AM. SOC. C. E. (by letter).—Congratulations are due the author for presenting so clearly and concisely the expenditures made by the federal government during the recent depression in order to aid state, county, and municipal construction projects and to afford employment for those who were out of work. The details given in Tables 1 and 2 present a clear picture of the situation; and the inclusion in Table 2 of the national income for the years 1925 to 1939, inclusive, is pertinent. A statement of the yearly direct federal debt for the same period would also have been appropriate. Therefore, the writer has taken the liberty of including it in Table 3 for the purpose of comparison with the cost of public construction and national income, which are taken from Table 2.

From this statement it appears that in the depression period, when presumably governmental help was most needed, there was actually a slight decrease in the yearly average of public construction, notwithstanding an increase of 1.772 billion dollars (9.5%) in the federal debt, and a decrease of 25.1 billions (33.0%) in the national income.

In the post-depression period there was an increase of 0.950 billion dollars (40.9%) in the yearly average of public construction compared with the pre-depression period, an increase of 16.661 billions (89.4%) in the federal debt, and a decrease of 11.4 billions (15.0%) in the national income. Evidently the federal government was slow in coming to the rescue, and its greatest expenditures, shown in public construction and increased debt, were in the post-depression period instead of during the depression itself. The author, noting this, states (see heading "Conclusion"): "To make a program of public works fully effective in assisting to take up the slack in industry, its full power must be thrown in promptly upon the inception of the depression."

TABLE 3.—COMPARISON OF NATIONAL FINANCES, 1925 TO 1939

Year	YEARLY AVERAGE, IN BILLIONS OF DOLLARS					
	Public construction	Increase %	Federal debt [a]	Increase %	National income	Decrease %
Pre-depression, 1925–1929	2.318	0.0	18.641	0.0	76.0	0.0
Depression, 1930–1934	2.312	0.0	20.413	9.5	50.9	33.0
Post-depression, 1935–1939	3.268	40.9	35.302	89.4	64.6	15.0

[a] For fiscal years ending June 30; values are from the *Monthly Bulletin* of the National City Bank of New York for February, 1941.

Although no doubt most, if not all, of this public construction was well planned, well executed, of permanent value, and desired by the community, was it advisable for the federal government to assist state, county, or municipal projects by donating part of their cost? The local people know whether such projects—no matter how desirable—are really needed. If so, they should pay for them in full. The federal government could properly purchase local securities issued for construction (if sound) during the period of a reluctant bond market. Later on there would be no difficulty in selling them to the public, as has been demonstrated by the sales made in recent years by the Reconstruction Finance Corporation of such securities.

---

[13] Cons. Engr., New York, N. Y.

As far as public construction is concerned, the writer is not in accord with the author when he says that the "* * * heavy expenditures for direct relief and work expedients started the national income up from a low of 40 billion dollars in 1932 to 42.3 billions in 1933, and 50.1 billions in 1934." Table 2 shows a decrease in public construction from 1.878 billions in 1932 to 1.827 billions in 1933 and an increase to only 2.619 billions in 1934. More likely the increase in the national income was due to the recovery of the people from their state of panic that started in 1929. In the opinion of the writer the recent depression was similar to the major depressions of 1837, 1857, 1873, and 1893, all of which showed distinct recovery in six years or less with little help from the government.

Just what the federal government should do during major depressions is a moot question. In the depression of 1893 which, in the memory of the writer was just as serious as that of 1930–1934, the President of the United States took the position that it was not the function of the government to support the people, but that it was the function of the people to support the government. At any rate, the depression of 1893 was over in four years with an increase of only $262,336,000 in the federal debt (for the purchase of gold), whereas, in the depression of 1930–1934, it was increased from 16.185 billion dollars in the fiscal year, June 30, 1930, to 40.440 billions in 1939, a net increase of 24.255 billions. Therefore, this new method of dealing with depressions cost the people of the United States as much as did World War I, when the debt increased from 1.225 billions in 1916 to 25.482 billions in 1919, a net increase of 24.257 billions.

Not all, by any means, of this increased debt between 1930 and 1939, was due to public construction, for, although there was an increased debt from 1930 to 1939 of 24.255 billions, the author shows in Table 2 that the total excess of public construction during that period amounted to only 4.720 billions, or about 20%. However, the total excess of public construction for the post-depression years (1935–1939), which amounted to 4.750 billion dollars, was 35% of the increase in the federal debt of 13.387 billions, during that period, when the debt ascended from 27.053 billions in 1934 to 40.440 billions in 1939.

The writer has no complaint to make of the good intentions back of the public construction policy, and indeed back of all the other expenditures undertaken to counteract the effects of the depression; but he points out that the effect of any legislation is the same, regardless of the motives back of it. No individual can pursue a policy of borrowing continuously for ten years without experiencing the consequences, but his policy will affect only a few people; but when a government pursues such a policy, however, all the people are affected. Of course, in times of war greatly increased governmental expenditures are necessary, and have been incurred in all our wars, regardless of consequences; but, inasmuch as in previous depressions the country has recovered with little or no help from the government, the writer is not at all convinced that the increased expenditures for public construction, noted by the author, and other expenditures, represented by the increase of 24.255 billion dollars in the federal debt between 1930 and 1939, were justified. This seems particularly true when the similar depression of 1893 caused a rise in the public debt of only 1% of that amount.

BAXTER L. BROWN,[14] M. AM. SOC. C. E. (by letter).—Major Hallihan's paper may be termed prophetic for the reason that at the time he prepared it (early in 1940) there did not exist the movement for the tremendous expenditures for national defense that now (June, 1941) is in progress.

The demand for public work will be enormous on account of the large number of men who will be out of employment after the defense program is concluded. Therefore, it is incumbent not only for the government to prepare for federal work, but for the states, counties, and municipalities to do likewise in preparing for non-federal work. There will be a still greater demand for public work when the army is demobilized. Looking to the future, under these conditions, the writer's judgment is that plans should be prepared for work of a non-defense character, which can be postponed until the necessity arises. Naturally, there will be some work that will have to be undertaken as emergency work.

An interesting item that can be used to illustrate this proposition is the project to beautify Memorial Plaza in St. Louis, Mo. The money for this work is available, but it would be of no value in the defense program and, therefore, should be deferred until a later date. The City of St. Louis also has some betterments and enlargements of city-owned hospitals and institutions that should be undertaken with a view to the possible necessity of taking care of sick or injured should the United States enter the war.

On account of prosperity brought about by expenditures for national defense, it probably will be much easier to vote bonds for public works than it has been in the past few years. For instance, in St. Louis, bonds were voted in 1920 and 1923 by much more than the required two-thirds vote.

EVAN S. MARTIN,[15] ASSOC. M. AM. SOC. C. E. (by letter).—Planning public works to be undertaken primarily to furnish employment during disturbed and disordered economical periods, it is to be hoped, is no longer imperative. There is only one sound and sufficient reason for public works—and private enterprise as well—namely, to serve the public in the way it wishes to be served. Although private enterprise must be attuned to voluntary public demand for its market and success, there is the danger that some public promotion may be forced which does not serve the public to a degree comparable to its cost. Private misadventures are discerned by their financial failure, but not so with public developments. The writer has classed the New York Barge Canal as a public benefit not equal to its cost. Then, too, there are examples of developments resulting in partial losses through arbitrary change of public policy. Such are the Grand Trunk Pacific Railway in Canada, which was to facilitate the development of a large new area but suffered because such development was arrested by the Great War and the subsequent drastic restriction of immigration; and the Soo Line Railway, planned to carry international trade, which was estopped by a protective tariff policy.

---

[14] Cons. Civ. Engr., St. Louis, Mo.

[15] Toronto, Ont., Canada.

Major Hallihan sets forth the narrow domain of public works. It is rather the narrow-minded notions held in the past regarding public service. Rivers, harbors, and perhaps mineral deposits, it is generally agreed, are natural resources. Well, what are the forests, soil, and crops of the fields and the inhabitants? Anything that serves the public is certainly public service regardless of its ownership and management. If the use of one's mind is to be hamstrung by precedent, he will continue to be inconveniently handicapped in thinking.

One of the restraints mentioned in this paper is the requirement of self-liquidation of an investment. During the past two centuries of almost continuous and intensive development, man has accustomed himself to "getting his money out of an investment." This is a phrase totally unrelated to the merits of an investment. One liquidates an investment by means of outright sale or by accumulating a surplus of receipts over expenditures during a term of years. No one can collect more money than he pays out except as others pay out more than they get. This means that investments are capable of being liquidated only when, and to the extent that, others make investments—that is, as development continues.

When the investment dollar stopped circulating in 1931–1932, it did so because further investment seemed unsound. Investment was unsound because a long, active period of development had increased the capacity of national economy much above present standards of living, which provide the market. The proper remedy was, and continues to be, a much higher wage level or lower interest rate—the latter having the same effect. No artificial public works program can give relief for long from making the proper adjustment.

Isador W. Mendelsohn,[16] **M. Am. Soc. C. E.** (by letter).—Major Hallihan presents succinctly a timely subject that affects the foundations of the future national existence of this country and that merits, of the engineering profession most of all, sober judgment divorced from partisan politics and personal jaundice. Public works as related to the entire construction field and unemployment and its far-flung effect upon the economic and social structure of the nation has received surprisingly little, and generally superficial, attention. So delineated, the value of public works still remains to be determined.

It is the purpose of this discussion to assist with a number of brief pertinent observations in the equable comprehension of the significance and the rôle of public works in national economy and welfare.

1. Statistical data presented in the paper's two interest-arresting tables concern such terms of widely varying meaning (as "construction," "employment," "national economy," "post-depression," etc.) that it would have aided in their understanding had appropriate definitions been included. Government and private economists and agencies differ in their use of these terms. Statisticians annually revise their construction statistics in the light of more complete and accurate data.

---

[16] Capt., Corps of Engrs., U. S. Army, Schenectady, N. Y.

2. There is reason to question the implication of Table 2 that the depression is ended. Unemployment is still prevalent on an extensive scale. Piecemeal construction programs provide piecemeal employment, whether in public works or national defense. Upon completion of a few months' construction project, the same workers are looking for other employment. Entrance into the present war will only postpone the inevitable struggle with this problem. Thorough understanding of the fundamental causes of unemployment and the depression has not as yet been attained because the necessary analysis has not been carried through to completion. When such analysis is made, far-reaching changes in mode of life may be necessary to curb heedless "rugged individualism," whether of man or corporation, in behalf of the better public welfare necessary for enduring democratic national existence.

3. As presented in Table 2, the data do not warrant the presumption of marked correlation between public works construction and employment and national income. Although construction is a significant factor of national economy, there are many others, some of which are of greater importance. A comparison[17] of several major branches of economic activity in the United States during the period 1920–1930 shows the following estimated average annual production—

Estimated average annual production for all:	Billions of dollars
Manufactured products	59.7
Agricultural products	11.2
Retail sales	34.9
Goods marketed at wholesale	74.9
Foreign trade (imports plus exports)	8.8
Construction, of all types, including maintenance and repairs	11.6

The same authority gives the number of workers directly dependent upon the respective industries mentioned for their livelihood (annual averages, in millions of workers) as 11.2, 10.6, and 6.5 for retail and wholesale trade combined; and 3.1 for construction. Fluctuations in national income as presented in Table 2 may very well be due largely to these other factors instead of to construction. In a report[18] of the National Resources Planning Board, the definite statement is made that "present levels of public construction expenditure cannot be considered the major determinant of the level of business activity and national income * * * the determination of the national income is the product of many variables."

4. The term "construction" as used in the paper refers to new construction only. This is verified by comparison of the data with the table on "Estimated On-Site Employment on New Construction, by Sources of Funds, 1925–38."[19] As a matter of fact, there is considerable annual construction for maintenance of fixed works and structures. For the period 1926–1939 inclusive, the estimated value of maintenance construction[20] varied from 1,543 to 3,112 millions

of dollars annually, representing 20% to 38% of total annual new, maintenance and work-relief construction, private and public.

5. The paper refers only to on-site employment created by new construction, by its comparison with the table of the reference[21] mentioned in the preceding paragraph. Construction of any kind also provides for employment which is directly attributable to the construction project but which is provided away from the site, primarily in the manufacture and transportation of the materials.

> "On-site and off-site employment together constitute the identifiable effect of public construction on the volume of employment. They do not constitute the total effect of such construction, since additional employment is generated by the expenditure of the wages and incomes received by those engaged in construction or the supplying of materials. These further effects are not statistically identifiable." [22]

6. Public works place less emphasis on on-site employment; much of the expenditure is for materials that provide a considerable volume of off-site employment; a comprehensive volume of heavy construction is undertaken, and, typically, the work is performed under contract. This has been the procedure with PWA projects. The main purpose of work relief is to provide the maximum of direct, or on-site, employment to needy unemployed. Usually this work is done by force account and not by contract. These differences are not too sharply defined, but the broad purposes of public works and work relief make such a distinction necessary.

TABLE 4.—ON-SITE AND OFF-SITE MAN-HOURS PER MILLION DOLLARS OF PWA CONSTRUCTION CONTRACTS AWARDED[a]

(A = On-Site; B = Off-Site)

Description	BUILDINGS				WATER SUPPLY		SEWAGE DISPOSAL		STREETS AND ROADS		RECLAMATION		POWER AND LIGHT				NAVAL VESSELS	
	Non-Residential		Residential										Steam		Diesel			
	A	B	A	B	A	B	A	B	A	B	A	B	A	B	A	B	A	B
Man-hours[b]	344	657	410	615	262	876	358	667	475	669	402	645	161	620	161	641	491	589

[23] *Loc. cit.*, p. 109.

PWA Federal projects, 2.0 for PWA non-federal projects, 1.0 for regular federal projects, 0.6 for projects conducted by federal departments under the works program, and 0.16 for WPA projects. These estimates may represent more nearly the maximum than average ratios. The variations in the over-all ratios of the several programs, excepting work relief, result primarily from differences of project composition. For similar types of projects, the off-site ratios are practically identical. In this connection, it is of interest to note in Table 4 the list[24] of on-site and off-site man-hours per million dollars of PWA construction contracts awarded, by types of projects.

8. Public works construction has an important effect upon the materials output of certain industries (see Table 5).[25]

9. In various periods different types of new construction projects are favored. In the period 1934–1940,[20] with public works construction aided by federal funds, highways, sewage disposal, water supply, public buildings, educational buildings, hospitals and institutions, and social, recreational, conservation, and development projects received more impetus than in the preceding years. In 1917–1918, as at present, military and defense construction projects received major consideration. During 1926–1929, commercial, factory, private residential, and public utility construction were preeminent. According to the National Resources Planning Board report[26]

TABLE 5.—MATERIALS PURCHASED FOR PWA CONSTRUCTION PROJECTS (RATIO OF ORDERS TO TOTAL PRODUCTION, 1934–1937[a])

Type of material	1934	1935	1936	1937[b]
Brick and hollow tile	23.5	26.9	42.7	27.7
Cement	73.6	36.8	16.8	13.2
Structural and reinforcing steel	39.8	35.9	23.8	12.3
Cast-iron pipe and fittings[c]	35.0	30.0	31.8	17.7
Sand and gravel	37.7	26.6	16.6	9.9

[a] PWA orders include certain distribution costs. [b] PWA expenditures curtailed in 1937. [c] Estimates for cast-iron pipe and for structural and reinforcing steel from data supplied by National Resources Committee; all others from Bureau of Labor Statistics.

> "* * * as the proportion of public works increases relative to that of private construction, we tend to get, at any level of total construction, relatively fewer factories, office buildings, public utilities, and housing, and relatively more highways, schools, recreational facilities, and conservation work. Furthermore, the trend of recent years seems to indicate that, within the field of public works, expenditures for conservation, the development of natural resources, and, as yet in only embryonic form, low-cost housing, are increasing in significance."

It is worth considering whether such planless construction as the foregoing, an outgrowth of heedless individualism, works to the best interests of the nation as a whole.

[24] "The Economic Effects of the Federal Public Works Expenditures, 1933–1938," National Resources Planning Board, November, 1940, p. 54.

[25] "America Builds—The Record of PWA," Public Works Administration, 1939, p. 27.

[26] "The Economic Effects of the Federal Public Works Expenditures, 1933–1938," National Resources Planning Board, November, 1940, p. 23.

10. Public works in the depression years have been of inestimable value[27] in numerous other ways. For many years practices obstructing best construction have been multiplying, such as the wage "kickback," misclassification of laborers, lax inspection, political or personal favoritism in award of contracts, collusive bidding, unbalanced bidding, restrictive specifications, and inadequate performance bonds by certain contractors. All these have been guarded against and practically eliminated in the strictly public works programs. Public works have raised the standards of communities in public construction by: Insistence upon employment of competent engineers and architects, and prompt payment to them of reasonable fees; the institution of acceptable accounting practices in small communities; aiding in revamping the financial structure of small communities; improving municipal credit and reduced bond interest; furthering the incorporation of local districts and the creation of public authorities, thus enabling the construction of numerous public works; developing revenue-bond financing, which made possible hundreds of public works projects; and furthering the preparation of thorough project plans and specifications.

11. The letter of transmittal accompanying the report[28] of the National Resources Planning Board to the President of the United States contains pungent paragraphs, on the rôle of public works in construction, which merit the attention of the engineering profession.

12. As mentioned so aptly in the paper, public works have sustained the construction industry during the depression years, preserved contracting organizations, maintained consulting engineer staffs, and revitalized construction material industries. Now in time of increasing emergency, the nation is reaping the benefit of this indirect aid in increasing measure. Many of these consulting engineer firms and contracting organizations have designed and built new Army and Navy camps, airfields, sea bases, and munitions plants, and the supply industries have furnished the vast quantities of defense construction materials and equipment.

13. Engineers, lawyers, statisticians, accountants, clerks, and typists who were employed and trained by federal agencies on public works during the period 1933–1940 are now being employed in the War and Navy departments and other federal defense organizations, applying the skill, technical information, and training acquired in public works construction to serve the nation in defense construction.

14. On June 5, 1941, the President stated:

> "Our defense production is a gigantic assembly line. Transportation is its conveyor belt. If raw materials cannot flow freely to our great industrial plants and the products cannot move continuously to the front, defense breaks down. Bottlenecks in transportation are as serious as shortage of power."

The tremendous federal highway construction programs during depression years will prove timely in moving troops, materials, and supplies in these emergency days. Educational buildings constructed in recent federal programs now (1941) are useful for training technicians and skilled-trades operators, and educating hundreds of thousands of others in defense tasks that are in the making. Hospitals and institutions so sorely needed heretofore to serve civilian populations will provide improved medical facilities for the military wants of the emergency. Waterworks and sewerage systems sponsored by federal aid during the period 1933–1940 have increased public health safeguards as no similar construction work in any 25-yr period in the nation's past, and thereby will indirectly further national defense. Conservation and power projects such as Hoover Dam, Bonneville, Grand Coulee, Santee-Cooper, the All-American Canal, Tennessee Valley Authority projects, the Nebraska projects, and a host of others are developing hitherto forgotten sections and resources of the United States and are furnishing power to industries serving national defense.

[27] "America Builds—The Record of PWA," Public Works Administration, 1939.

[28] "The Economic Effects of the Federal Public Works Expenditures, 1933–1938," National Resources Planning Board," November, 1940, p. iii.

15. Table 1 shows that federal funds expended for emergency construction exclusive of loans for the period 1933–1939 totaled $10,892,000,000, of which PWA[27] funds were $3,143,000,000. This federal aid has been criticized profusely, at times somewhat vituperatively, as to its advisability, the efficiency of the expenditures, the permanent value resulting therefrom, and whether greater benefits could not have been obtained through other and less costly measures. The Great War, to April 30, 1919, cost the United States $21,850,000,000 of federal funds alone, exclusive of loans to Allies. How many Americans have wondered as to the value of participation in that war, its advisability, the efficiency of expenditures, the permanent value resulting therefrom, and whether greater benefits could not have been obtained through other and less costly measures? Already federal appropriations for the present military emergency amount to $42,000,000,000. How much more will be required is unknown, but the total sum will be stupendous. How many Americans are considering the value of participation in the present war, its advisability, the efficiency of expenditures, the permanent value resulting therefrom, and whether greater benefits cannot be obtained through other and less costly measures?

Must the path to national democratic existence lead through vales of wars and depressions in rapid succession? In view of national experiences since 1917, do Americans feel greater gratification with expenditures for war than for public construction?

16. The United States is facing a war that may test the nation's very foundations. During World War I, for the period April 6, 1917, to July 1, 1919, with combined armed forces of 4,800,000, the total deaths of United States citizens numbered 125,500, of which approximately 43% were due to battle in a period of less than nineteen months.[29] It is within the realm of possibility that the coming war may last five years, may require the combined armed forces of more than 10,000,000, and may entail deaths of more than 1,000,000, both military and civilian. Great as was the dislocation of national life resulting from World War I, it is likely that the aftermath of the coming war will present a far greater cataclysm. It is none too soon to plan and prepare for the ex-

---

[29] "The War with Germany," by Col. Leonard P. Ayres, War Dept., August 1, 1919.

pected rehabilitation work. World wars may be necessary in this century to maintain free nations, but of equal if not greater importance for enduring national existence is proper after-war recovery. Planning for utilization of national resources in men, materials, money, and morale in behalf of national interests is a vital necessity. If Germany at war can find time for planning the subjugation of conquered nations, it behooves the United States to plan for maintaining its democratic ideals of national existence after war as well as during war. Public works that have sown the seeds of planning in thousands of communities in depression years should play an important rôle in planning for national recovery and the better American way of life after war.

W. W. Crosby,[30] M. Am. Soc. C. E. (by letter).—Utterly allergic, from his breeding, education, and experience, as the writer admits himself to be, to all such hypotheses as "spending for prosperity," "the end justifies the means," and the "survival of the unfit," he nevertheless wishes to avoid in his remarks political argument or even discussion of the political economy involved and to offer only such comment as might be helpful to those of another persuasion who may really and sincerely believe that such postulates can be established as principles of the "American way of life."

Therefore, he now passes without further comment the wastes of "leaf-raking" and "boon-doggling," claimed to have been justified by some of the early "emergencies," to the practical defects as observed by him in the substantial work later attempted to be marketed for the "approval of the people."

The writer enjoys a ringside seat at a relatively small (in area) but active arena where a dozen public, and several different corporate, authorities contend for results from large funds apparently regarded as limitless. The wastes, the lack of cooperation, and the want of coördination evident are reminiscent of a "battle royal." They do not make for "public approval" when the early glamor of the frenzied activities has worn off.

Public discrimination is increasingly keen. Engineers have encouraged its development. They must keep ahead of it. This is not done merely by "making one dollar do the work of two"; nor by "Heath Robinson" or "Rube Goldberg" schemes to effect a temporary result.

Investigation here reveals an apparent cause for the conflicts of efforts and results. It lies in the "tunnel vision" (hemianopia) of the separate authorities. The planners have failed, or been unable, to regard considerations outside of each one's immediate, individual goal. In some cases each one seems to have disregarded consideration of contiguous interests.

The more obvious cases have given the public the idea that the projects were badly planned and wasteful; and the writer believes that the American people are not yet fundamentally wasteful and extravagant, although they may be induced to be at times.

The local public of any locality is inclined to credit the higher authority with greater abilities and perspective. The local planners and executives are too familiarly known and often do have a lack of outside knowledge and experience to offset their familiarity with local conditions. However, it does not follow that the county or state planners prove more competent. Often they show a neglect of points known to be of local importance.

---

[30] Cons. Engr., Coronado, Calif.

It is when the planning gets into bureaucratic control that the value of the product in the market is often most questionable—if only from the aspects of narrowness of design and uncoordinated response to the needs in the wider field visible to the public. The public has learned that "made in Washington" does not guarantee satisfaction.

If deficiencies in locally made plans could be removed as they went up, and their final approval should signify that the project did actually fit in the entire picture, the market values would be greater and the demand then might stimulate local support.

Bureaucracy seems too often incapable of cooperation and coordination with others. Whether or not this defect in the setup can be overcome remains to be seen. If all such work is to be done under "emergency," "unlimited emergency," or "super de luxe emergency" conditions, and without a competent coordinating head, the prospect does not seem inviting. It may yet be that an earlier statement, reputed to have been made once by a most eminent authority, to the effect that "this country is too big and too diversified to be run [and, inferentially, to be planned] by one man or one group of men" will be proved and remembered.

The writer means no criticism of the motives of those in authority. Their limitations are generally those of law and environment. However, there is a need for a "catalyst" or some kind of an efficient agent to bring order out of the confusion if the general approval of the public is to endure.

The writer thinks that Major Hallihan has most conscientiously and illuminatingly set forth the case of the proponents of his theory. His recognition of the difficulties of localities in meeting the conditions imposed by higher authority, of the local limitations to action, of the objections found to bond issues by disappointed electorates, and of the belated (if not lacking) establishment of a coordinating or reviewing authority seems to indicate some agreement with the writer's comments.

J. P. HALLIHAN,[31] M. AM. SOC. C. E. (by letter).—The writer is gratified that his attempt to make an analysis of the value of public works has met with such generous discussion. That was his hope, as it is evident that, when an emergency problem of this character is presented, an analysis of the actual results obtained under experimental processes and the troubles encountered in the pursuit of a relief works program will be of the greatest possible aid in determining the possibility of future betterment in methods. For all practical purposes, the paper might just as well have been entitled "The Value of Time," since the results indicate that lack of preparedness was a very important factor in delaying the process of getting the program of public works under way.

The analysis of the situation in the United States as a whole, under the conditions of stress and disturbance of the national economy that were made evident in 1930, required much the same collection of facts as would be presented to a receiver of any large private property that suddenly found itself unable to meet its current necessities. For example, one becoming unexpectedly heir to a great ranch property in a run-down condition would find his primary consideration directed to an inventory of his assets—the condition of the ranch in regard to summer and winter feed, the water supply and its possible distribution to bring it within easy reach of the grazing herds, the creation of adequate reserves against long droughts, and the question of whether the cattle stocked were of breeds best suited to the ranch conditions. All would be basic situations to be considered before entering upon a program of rehabilitation of the property.

---

[31] Director, Municipal Eng. Section, WPA, Washington, D. C.

Similarly, there existed in 1930 only very sketchy information on the condition of the natural resources of the United States, its forests, lands, water resources, and in particular its mineral resources in the light of the possible demands of national defense. Progress has since been made toward catching up on this deficiency. In many cases it has been found that great losses have been sustained by failure to have reasonably complete information available and to determine whether properties previously regarded as assets were still in that category or were in an advanced stage of depletion requiring long periods of conservation and building up processes before they could again be considered as assets.

The writer did not intend to convey the impression that the development of a public works program was the only thing necessary to do in combating an industrial depression. The record shows that it proved to be the most readily available measure to provide the necessary employment quickly and to secure the greatest salvage in the creation of needed facilities against practically the same expenditure on direct relief pending what was thought by many to be the certain revival of industry if let alone.

In the period beginning in 1930, no effort of consequence was made by the vast industrial machine to set up a program that would take the place of a federal-aid public works program. The privately owned industries are not to be blamed for reluctance to gamble their reserves, which would certainly be needed to rebuild obsolete plants on the resumption of industrial activity, in the expenditure of such sums before the trend of recovery became clearly defined. The same hesitancy and doubt caused the hoarding of private capital rather than expenditure in private construction, such as housing, not wholly dependent upon industrial recovery but facing the imperative necessity of taking up obsolescence. In this field the deficiency was so great that it would have required something like three times the volume of public construction to approximate the same relative volume of total construction. In the face of this condition, the writer is of the opinion that the program of public works so painfully developed was the only measure that had any effect in stopping the descending spiral caused by the combined effects of acceleration of unemployment and diminishing purchasing power. In considering its beneficial effects, the collateral employment created in the industries supplying materials and in the service industries should not be overlooked. The United States as a whole perhaps may be grateful at some future date that attention was thus brusquely called to its own deficiencies and that through the experience of corrective efforts and mistakes a plan may be devised that will find the Nation, in the event of recurrence of similar conditions, with a comprehensive plan of operations that will make it able to meet the same kind of emergency with measures adequately prepared in advance of need.

The writer is impressed with the comments of Mr. Henry in comparing the depression of 1893 with the depression of 1930 to 1939, and the thought that the quick recovery from 1893 to 1895 (which was followed by the silver campaign depression, equally quick in recovery, and a continued long period of prosperity to 1907, a temporary money panic) could have been duplicated in 1930. In 1893, the United States was still only partly developed, and the opportunity to initiate individual enterprises and to develop lands, mining, and transportation offered quite a different set of conditions to those confronting the country beginning in 1930, when the depression was affected not only by the conditions in the United States but by world-wide conditions.

In a chart[32] prepared by Brig.-Gen. Leonard P. Ayres the line of normal conditions shows depressions at various intervals, dropping in 1893 to a maximum of 20 points below the economic line (which was the greatest drop since 1808) and to 26 points below normal in the primary postwar depression of 1921. What is termed by General Ayres as a secondary postwar depression, commencing in 1930, fell in 1932 to a low of 48 points below normal and, after a brief temporary rise above normal in 1937, dropped again in 1938 to 36 points below the normal line, from which it ascended to 4 points above normal at the end of 1939, dropping again in 1940 to 14 points below, and is now (1941) again on the road up due to the defense boom.

General conditions in the United States were also different in 1893. It was not considered unusual for men to move from a place of unemployment to a place of employment where they worked in camps, and to follow the harvest. The country was in the process of terminating the work on its great trunk line railroads and feeders, where the method of operation was to draw raw labor from the congested centers, transport it to the job, and train it on the job to do the work required. That was the same kind of operation that has been required in the six years 1935 to 1941 under the relief works program, except that the relief program was obliged to find work at the point where the excessive unemployment existed. The writer believes, therefore, that the possibilities of early recovery that were present in 1893 did not exist in 1930. Conditions had become too crystallized. The temper of the people was less resilient. Time was lost from 1930 to 1933 by waiting for some evidence of the spontaneous recovery indicated by Mr. Henry, and it appears doubtful that in any future similar situation it would be logical to expect any such recovery by private initiative under the conditions now prevailing.

In Captain Mendelsohn's discussion the point is made in paragraph 7 that the practice of the PWA in contracting the work on public works financed by loan and grant of federal funds produced a greater proportion of off-site employment than the WPA methods, leaving the inference that the indirect payroll through high mechanization was of greater importance than the direct payroll in relieving the unemployment and in increasing purchasing power. The writer is unable to agree with this view as the direct payroll produces an almost immediate effect in circulation through the channels of trade, whereas there is a considerable lag in the final distribution of the indirect payroll. The quantity of materials purchased for the same type of structure, of course, would be the same, regardless of the method of construction.

---

[32] "Annual Business Activity Since 1790," by Leonard P. Ayres, 14th Ed., October, 1940.

In Table 5, Mr. Mendelsohn presents the ratio of PWA orders for structural materials to the total production of such materials, indicating the beneficial effect on the suppliers by reason of such orders. The effect would be more clearly shown had he included the substantial volume of orders for materials placed by the WPA in the same period. Purchases of principal construction materials by the WPA and sponsors (not including purchases by other federal agencies financed by allocation of WPA funds) for the period from July 1, 1935, to December 31, 1940, aggregated $987,563,052.

The writer does not consider it within the scope of the paper to discuss questions that have been posed concerning the comparative cost of work done under contract methods and under the limitations of the laws governing the operation of relief agencies. One statement may be made, however, toward clarifying the thought on this subject. The cost of a public works job performed by contract methods, where the contractor may mechanize the operation to its fullest extent and exercise unrestricted freedom of selection of the cream of the labor from the general labor pool, does not include one important element of cost, which is the cost of maintenance, in condition ready to serve, of the general labor pool. The objective of the laws governing the operation of relief agencies in aiding public works projects with federal funds is that primary consideration should be given to the greatest possible employment of labor. In this operation, the proportion of cost attaching to the project for the maintenance of the labor pool is measurably included. It has been made clear in this emergency that this cost is a fundamental element that has heretofore been sustained by the entire Nation. It may be best that it should be so sustained because of the obvious difficulty in designing a method to apportion the collateral costs equitably to the particular work involved. It has been made equally clear that no equitable comparison between the cost of contract work and the cost of work performed under the relief program can be made without consideration of this factor.

The writer expresses his appreciation of the high quality of the comments and papers presented in the discussion and invites attention to the creation on June 24, 1941, by the Federal Works Agency, in cooperation with the National Resources Planning Board, of a division of planning entitled the Public Works Reserve, which presents great potentialities as a measure of preparedness.

The primary purpose of this division is stated to be the promotion of comprehensive studies of the situation in municipalities preliminary to the planning of improvements covering at least a 6-yr period with general plans and preliminary estimates of over-all cost, and the selection from such plans of projects deemed most necessary by the communities concerned for inclusion in a tentative construction program. Thus such projects may be ready for immediate consideration with respect to the financing and development of working plans for contract bidding or assignment of labor forces promptly upon the coming of emergency conditions.

It is apparent that in such studies any deficiencies in statutory or charter legislation will be brought to light and measures for correction prepared for action by the appropriate legislative bodies. These studies and plans involve no financial commitments but are designed to present an adequate picture of possibilities and to clear the field for action by reducing to the lowest point all legal and procedural retarding elements.

RELIABILITY OF STATION-YEAR RAINFALL-FREQUENCY DETERMINATIONS

By Katharine Clarke-Hafstad[1]

With Discussion by Messrs. Paul V. Hodges, C. S. Jarvis, Howard W. Brod, Merrill Bernard, Charles F. Ruff, Eugene L. Grant, Waldo E. Smith, Robert L. Lowry, Jr., Herbert C. S. Thom, and Katharine Clarke-Hafstad.

Synopsis

The accuracy of rainfall frequency values should be considered carefully in the design of flood and erosion control structures. This paper is concerned with the factors affecting the accuracy of rainfall frequency determinations. A method involving a statistical test for persistence is suggested for estimating the reliability of frequencies calculated by the station-year method.

Introduction

Determinations of the frequencies with which rainstorms of certain extent and intensity occur, together with measures of the reliability of these determinations, are essential to the solution of problems of flood control and of soil and water conservation. In the construction of soil-conserving devices such as terraces, check dams, and contour furrows, designed to decrease runoff and soil loss, it is necessary to know the range of stresses to which rainfall will subject these various devices, and the frequency with which these stresses will occur.[2] The size of dam or other control structure which it is economical to build on a given watershed depends chiefly upon the size and frequency of floods in that watershed. In order to predict the frequencies of various amounts of runoff, a knowledge of the frequencies of rainstorms of various sizes is required.

In the present state of the knowledge of the physical controls of weather and climate, the only feasible method for predicting the probable frequencies of certain amounts of rainfall is one based on a statistical study of precipitation history. The record of past precipitation, available in the form of measure-

[1] Asst. Climatologist, Section of Climatic and Physiographic Research ,Div. of Research, Soil Conservation Service, Washington, D. C.

[2] "Climatic Research in the Soil Conservation Service," by C. Warren Thornthwaite, Benjamin Holsman, and David I. Blumenstock, *Monthly Weather Review*, U. S. Weather Bureau, Vol. 66, 1938, pp. 351–368.

ments by rain gages, however, provides an extremely inadequate statistical basis for making predictions of future precipitation. Rain gages set up to sample rainstorms have been very widely spaced, an insufficient number have been of the continuously recording type, and relatively few years of record have been obtained. As a result of the inadequate sampling, very little quantitative and reliable information is available concerning the areal extent of rainstorms, their duration, intensities, and frequencies.

Primarily to mitigate the limitation of the paucity of years of record to be used in calculating probable rainfall intensities and frequencies, the station-year method was devised. This method makes possible the determination of the frequency of those very intense rainfalls which occur so infrequently that only a few observations of their occurrence will be found among the records of a group of stations. It is particularly useful for determining the average number of occurrences of a given amount in a certain length of time when this period is longer than the actual number of years of rainfall record.

Although first applied to records of stream gages,[3] the station-year method was used as early as 1917 by the engineers of the Miami Conservancy District in their elaborate study of storm rainfall of Eastern United States.[4] Their technique has been used in its general outline by all subsequent investigators who have desired to determine for any locality the maximum rainfall to be expected once on the average in any given length of time.

The method consists essentially of collecting for an area all the rainfall records of whatever length, and treating the sum of all the records for all stations (called the "station-year record") as if it were a single record for the midpoint of the area under consideration. A certain time interval is then selected, which may be anything from minutes to months, depending upon the information desired and the data available. All rainfall quantities for this time interval appearing in the aggregate record are then arranged in order of magnitude. The highest amount is considered to be the maximum to be expected in the area, on the average, once in the period of years represented by the station-year record; the second highest amount may be expected once in one half the aggregate record, and so on for smaller quantities. The combined experiences of all stations in the area are assumed "* * * to give a weighted average which may be regarded as the probable average experience for any one point within that area."[5]

The maximum rainfall to be expected with a certain frequency is termed the "pluvial index" for an area. These pluvial indexes are plotted on charts and iso-pluvial lines drawn by interpolating between the indexes. In drawing these lines the assumption is made that the pluvial index refers to the midpoint of the area for which it was determined rather than to any point. This may or may not be a correct assumption, depending (as will be shown) upon the distribution of stations and the homogeneity of rainfall characteristics of the area.

Analysis of the station-year method shows that by this technique one is determining, in effect, the reciprocal of the average number of occurrences of a given amount of rainfall, per station per year. If 500 station years of record yield 5 occurrences in excess of a certain amount, the average number of occurrences per station per year will be $\frac{1}{100}$. This is equivalent to an average frequency of 100 years per occurrence, which is the same result that would be obtained by taking the fifth highest amount in a station-year record of 500 years.

[5] *Loc. cit.*, p. 63.

It should be noted that the station-year method is a simple statistical procedure for arriving at an approximate answer to a problem which it is hoped may some day be solved more satisfactorily either from a consideration of the meteorological processes producing rainstorms, or through the accumulation of more detailed data and a study of rainstorm morphology. Ideally, one would like to know the frequency of rainstorms of certain area, intensity, and duration—not simply the frequency of a certain amount of rainfall for a point in an area. Aside from the restriction due to length of record, the chief limitation in the usefulness of the station-year method is its failure to indicate the size of area which may be expected to receive the given amount of precipitation. At present very little information is available on the intensity-area relations of storms, and this is due to the fact that, until recently, recording rain gages have been so widely spaced that storm areas could not be determined with any degree of accuracy. This deficiency of gages is gradually being remedied.

In certain areas of Eastern United States many more rain gages have been installed within recent years. In the watersheds of the Susquehanna River and the Ohio River above Pittsburgh, Pa., in September, 1940, there were about 100 automatic recording gages in operation, approximately 1 for every 400 sq miles. No single agency assumes responsibility for maintaining all these gages. The Pennsylvania Water and Power Resources Board; the United States Geological Survey, Weather Bureau, Forest Service, and Soil Conservation Service; local power companies; and other agencies have each placed their gages in locations most advantageous to themselves. The collection and compilation of the data from all these gages, however, will contribute fundamental information on rainstorm frequency and intensity that will be extremely valuable to all agencies concerned with the precipitation on this watershed. Similarly, in the Tennessee Valley,[6] a region of approximately 40,000 sq miles, there were, in July, 1940, about 460 rain gages maintained by various agencies, of which approximately 70 were of the recording type. Most of these gages have been in operation 5 years or more. The maintenance of such networks as these, together with the very dense net of automatic gages, 500 in 8,000 sq miles, established by the Soil Conservation Service on the Muskingum Watershed in Ohio, will make possible the determination of the frequencies of rainstorms of given area and intensity.[7] The reliability of the frequency data from these networks of stations will increase rapidly as the years of record increase.

FACTORS AFFECTING THE ACCURACY OF FREQUENCY DETERMINATIONS

The simple computation of average frequency by the station-year method requires no information regarding the relation of rainfall amount to the associated storm, but a knowledge of the characteristics of rainstorms is necessary for the correct interpretation of the results.

If there is a closely spaced, well-distributed net of recording stations in an area, and a large number of years of record—not station years, but actual years of time—the average frequency of a specified amount of rainfall computed by the station-year method is a reliably representative one for the midpoint of that area for which it was determined. The relationship between the length of record and the accuracy of the average frequency is the chief concern of this paper. The arguments will be based on the fact that the statistical theory of probability makes it possible to indicate, by a percentage of error in the average, how the reliability of a frequency value is related to the length of independent record.[8]

Number and Distribution of Stations.—Some of the ways in which the accuracy of the average frequency will be affected by the number and distribution of recording stations will be briefly mentioned before treating the effect of the length of record, although it should be emphasized that much more data and study on intensity-area relationships are required before any improvement can be made in the accuracy of frequency determinations.

C. Warren Thornthwaite[9] has shown that with a widely spaced net of stations it is highly improbable that the maximum rainfall occurring in a storm will be recorded at any station. This is illustrated by the fact that no gage recorded the rainstorm which produced a flood on the Republican River in May, 1935. If maximum quantities are not recorded for all rainstorms, the computed maxima to be expected with a certain frequency certainly will be too low.

An average frequency value for an area calculated from the data for several stations will be representative for any point in the area only if the rainfall characteristics are fairly uniform throughout the area. Although no area in the United States as large as a quadrangle of 2° of latitude and longitude is homogeneous with respect to its rainfall characteristics, the engineers of the Miami Conservancy District stated that the station-year method, as used in their study, presupposes

> "* * * that the rainfall characteristics, especially with regard to high rates of precipitation, are essentially uniform at all points within the area of a 2-degree quadrangle of the earth's surface."[10]

They recognize, of course, that this supposition is not strictly true because on the charts of pluvial indexes[11] they have drawn iso-pluvial lines which indicate transitions from one pluvial index to another across a 2° quadrangle.

---

[11] *Loc. cit.*, Figs. 13–36, pp. 69–80.

Since it is obvious that no 2° quadrangle of the earth's surface will have uniform characteristics of rainfall, other methods of selecting areas should be considered. More representative frequency-intensity values could probably be obtained by calculating the averages for overlapping circular areas whose radii would be equivalent in length to one side of a 1° quadrangle and whose centers would be corners of 1° quadrangles.

More accurate values might be obtained, also, by selecting the homogeneous areas on the basis of regions having the same pluvial indexes as shown by the iso-pluvial lines on the Miami charts. Eugene L. Grant,[12] M. Am. Soc. C. E., has proposed the use of the χ^2-test to delimit a homogeneous area whose pluvial index would be representative of any point in the area.

In regions with mountains or other features that result in great differences in rainfall characteristics in short distances, it is practically impossible to obtain average frequencies that have any real significance for large areas. A very dense and uniformly spaced net of rain gages would be necessary to record all the areal differences in order that the average value would represent the area as a whole, and even this value would depart greatly from the true value for certain parts of the area. Average frequencies for mountainous parts of the United States are especially unreliable because in these regions the rain gages are insufficient in number and are located chiefly in the valleys.

An irregularity of station spacing will seriously affect the values of average frequency in areas with non-uniform rainfall characteristics. If there are 2 gages, in any area, several miles apart, one may record 3 occurrences of a certain amount per year, and the other gage 6 such occurrences; but if there had been a third gage so close to the gage recording 6 occurrences that it gave an identical record, the average for the area would be distorted in favor of the higher number of occurrences. Since there is probably no area with absolutely uniform rainfall, an irregularity of station spacing will affect all frequency determinations to some extent.

The accuracy of frequency values depends to a very great degree upon the adequacy of the sampling of rainstorms. It is logical to question whether, from a given net of recording stations, fair and adequate samples of the various rainfall quantities are being obtained. This depends not only upon the number and distribution of the stations, but upon the relation of this distribution to the distribution of precipitation.

In general, rainstorms are of two types: (*a*) Those of wide extent (sometimes hundreds of thousands of square miles, and characterized by a small range of intensities, which results in a rather uniform rainfall pattern); and (*b*) those limited in area to a few hundred or thousand square miles (characterized by a wide range of intensities resulting in a very spotty distribution pattern). Gradations from one type to the other occur, and combinations of the two types result in very complex patterns.

The fundamental distinction between these two patterns is based on the type of physical process that causes the precipitation. The spotty rainfall pattern results primarily from rain originating through a convective process; the widespread homogeneous pattern almost always results from frontal

FIG. 1.—TOTAL PRECIPITATION ON THE MUSKINGUM WATERSHED, OHIO

activity whereby moist, less dense air is cooled adiabatically by ascent over colder, more dense air to the point where the moisture condenses.

The two general types of precipitation patterns are illustrated by the storms of November 12–13 and August 9–10, 1937, which occurred in the Muskingum Watershed in Ohio (Fig. 1). Rainfall measurements from the 500 automatic recording gages installed by the Soil Conservation Service on the 8,000 sq miles of this watershed provide the data for the maps of these storms. The November storm illustrates the uniform pattern in which a large area received very nearly the same rainfall in a 24-hr period; and the August storm illustrates a spotty pattern with large ranges in amount in small distances.

A wide spacing of stations would suffice to give a fairly accurate value of the average frequency of rainfall quantities if all storms were of the large-area, homogeneous type shown in Fig. 1(*a*); but a more dense net would be necessary to obtain the same degree of accuracy for the quantities associated with a spotted pattern like Fig. 1(*b*). Since the storms of more uniform intensities, in general, are those of low intensities, the frequencies will be more accurately given for the smaller amounts. Very high rainfall may occur over large areas and give a fairly uniform pattern. Such storms are rare, however, and produce the widespread major floods such as that experienced in the Ohio Valley in January, 1937. A few stations would suffice to give a good sample of the intensities in such storms, but very many years of record are required to give reliable values of their frequency. On the other hand, there are many occurrences of high intensities equivalent to those of the widespread storms, but associated with the spotty type of rainfall, in which there may be several centers of small area receiving very heavy rainfall. The many flash floods that occur throughout the United States every year, washing out soil conserving terraces and small dams, result from this spotty type of rainfall. Although more frequent than the storms producing the major floods, their area is so small relative to the average spacing of stations that many occurrences are not observed and consequently their frequencies cannot be determined accurately.

When several years of record are available from a battery of closely spaced stations, such as that operated in Ohio by the Soil Conservation Service, it will be possible to make comparisons of the average frequencies derived from various spacings and locations of stations, and consequently to provide corrections to be applied to the frequencies obtained from widely spaced, poorly distributed sets of recording stations, in regions with rainfall characteristics similar to the Ohio area.

The Length of Independent Record.—The second factor to be considered in estimating the reliability of an average frequency of specified rainfall is the length of record from which the average was determined. It is obvious that the reliability of a mean frequency based on data from a single station is a function of the length of record for that station, because the longer the record the more occurrences there will be upon which to base a frequency calculation. This must be true, also, for a mean frequency based on the data from several stations in an area. The station-year method simulates a long record for a single station by placing contempory records, from several stations, end to end.

Although by this method more storm experiences may be obtained than in a record for a single station, it obviously cannot be assumed that more actual years of time are being sampled by this expedient. A record from 10,000 rain gages operating on an area for one year cannot replace 10,000 actual years of record for one station although both records could conceivably include the same number of storm experiences. The reliability of an average frequency computed from these two 10,000-station-year records might be the same, but only if each rainstorm of given intensity affected only one station.

The use of additional station records does not increase the reliability of the frequency determinations in direct proportion to the number of station records that are used. An average frequency for an area calculated from a station-year record for several stations, however, is more reliable than one calculated from the record of one of them. Because of the spottiness of rainfall, certain precipitation amounts will be recorded at some stations and not at others during a period of years, and the inclusion of records from many stations will increase the likelihood of including in the calculations of the mean frequency these more rare events.

Regardless of how many station years of record are used, there will always be a certain degree of unreliability in the frequency determinations simply because the actual years of record are not sufficient to sample all the possible annual variations in the rainfall characteristics. If every year had the same characteristics and if there were no abnormally wet or abnormally dry years, then, of course, any one year of record would give as reliable values as any other year. Furthermore, if there are cyclic or secular changes in rainfall, the frequencies from data obtained during a part of a cycle or period may not be applicable to other parts of the cycle. The Miami engineers recognized that the station-year method was valid only if "there are no permanent or cyclic climatic changes affecting the occurrence of high rates of rainfall."[10] This might have been expressed in another way by saying that there will be a high degree of unreliability in the frequency values if there are cyclic or permanent changes in the occurrences of high rates of rainfall.

A quantitative measure of the reliability of average frequencies is needed in order to compare the reliability of the frequency value obtained at a single station with that derived from the composite record of several stations.

In any sampling process the reliability of an average is proportional to the square root of the number of observations upon which the average was determined. The conventional method of expressing the reliability of a mean is in terms of its expected fluctuations, these fluctuations being measured by the standard deviation. The standard deviation of a distribution of means is called the standard error of the mean, and for a normal distribution it is equal to the standard deviation of the sample divided by the square root of the number of values entering the mean. Certain definite relations exist between the size of the standard error and the number of values in the distribution that differ from the mean for the entire population by certain specified amounts. From these established ratios it is possible to indicate the extent to which additional samples may be expected to vary from the average obtained from a single sample. Suppose, for example, that in a 500-yr rainfall record for a single station, 100 occurrences of a certain amount are observed, giving an average of one occurrence in 5 years, and that the standard error of this mean is 10% of 5 years. Then, knowing the relationships between the size of the standard error of the mean and the distribution of values in the normal curve, one could say that there are 99.7 chances out of 100 that the mean computed for these 500 years (if they are random) is not more than three times the standard error or 30% away from the true average for many thousand years; and there are 68.3 chances out of 100 that this mean will not exceed or fall short of the true mean by more than the standard error, 10%.

The usual formula for the standard error of the mean cannot be applied to frequencies of rainfall because they do not form a normal distribution but rather a discontinuous one of the Poisson type. For this distribution type the standard error expressed as a percentage of the mean is equal to $\frac{1}{\sqrt{n}}$, in which n is the number of independent occurrences.[13]

For the foregoing example, the calculation of the average frequency and its reliability would be as follows: $\frac{500}{100} \pm \frac{1}{\sqrt{100}}$; or 5 years ± (10% of 5); or 5 years ± 0.5 year.

The maximum rainfall that has occurred in any record will have an average frequency (if an average can be said to be determined from a single observation) of once in the total years of record. When the number of observations, N_o, upon which the mean is based is small, generally less than thirty, the usual $\frac{1}{\sqrt{N_o}}$-law fails to give a reasonable estimate of the error, and $\frac{1}{\sqrt{N_o - 1}}$ provides a better though not rigorous approximation (it is inappropriate to discuss herein the difficulties involved in determining the errors in means derived from a few observations. Detailed consideration of the problem has been given by W. N. Bond[14] in 1935 and by G. Udny Yule[15] in 1936). The error of the frequency of the maximum rainfall amount, therefore, would be given by $\pm \frac{1}{\sqrt{1 - 1}}$ or ∞. This can be interpreted only as meaning that a single observation gives no clue to the size of its error; in other words, nothing actually is known concerning the frequency of a rainfall quantity from a single observation of its occurrence. Very high degrees of unreliability are encountered in the expectancies of all high rainfall quantities, inasmuch as the greater the depth the smaller will be the number of occurrences.

Determining the reliability of an average frequency for a single station record is a relatively simple statistical procedure. The next problem concerns its determination for a composite station-year record.

Referring again to Fig. 1(*b*), one sees that during this storm period 5 stations received 3.5 in. or more of rain. If each of the 500 rain gages in this area continued operation for one year, there would be 500 station years of record. Now, assume that 100 storms like that of August 9–10 occurred in this watershed during one year. There would be 500 occurrences (100 storms each affecting 5 stations) in 500 station years, giving an average frequency of one occurrence of 3.5 in. per year. If in this one year of record, instead of 100 storms, there were 500 separate storms each affecting only one station, or if there were one large storm covering the entire area and giving 3.5 in. at all 500 stations, the total number of occurrences of 3.5 in. would be the same, and likewise the average frequency of such an amount would be the same. The station-year method will give the same average frequency for a given number of station years and total occurrences regardless of the combination of numbers of storms and numbers of stations receiving the given amount which makes up the total occurrences.

---

[13] "Statistical Methods for Research Workers," by R. A. Fisher, London, 6th Ed., 1936, pp. 56–59.

[14] "Probability and Random Errors," by W. N. Bond, London, 1935, pp. 45–65.

[15] "An Introduction to the Theory of Statistics," by G. Udny Yule, London, 1936, pp. 277–278, and 353.

In so far as the average frequency will indicate how often, on the average, one may expect storms of 3.5 in. in a 24-hr period, however, it would probably be agreed that more reliance could be placed in an average frequency determined from 500 storms than in one based on only one storm. A single observation of a storm in a period of record, regardless of how many stations recorded this storm, tells nothing about its frequency. The storm that resulted in the great Ohio flood of March, 1913, provided 11 of the 16 six-day amounts of 8.7 in. or more of rain in a 1,650 station-year record.[16] The average frequency of this 8.7-in. rain is given as once every 100 years; but the fact that this storm occurred once in 1,650 station years (or even 16,500 station years, if there had been 10 times as many gages in the area) does not indicate whether it can be expected once every 100 years, or once every 1,000 years. In other words, the reliability of an average frequency, expressed as a standard error, should not be calculated from the total occurrences of a given amount in a station-year record, but rather from the number of storms.

In studies involving the station-year method, no reference has been found concerning the reliability of the pluvial indexes; in fact, the number of storms of given intensity is not recorded, and hence standard errors for the average frequencies, based on the number of storms, cannot be determined.

The rainstorm itself is really the independent event whose frequency one would like to know, but since the available data are not in such a form that storm frequencies can be calculated, it is assumed in this paper that the 24-hr rainfall period constitutes the storm, and is the independent event.

If it were true that all storms that result in a given rainfall at any point in an area were of the same areal extent, and if there were equal and fixed distances between recording stations so that the same number of stations recorded the specified amount in every such storm that affected the area, then one could simply divide the total occurrences of that amount in the station-year record by that number of stations and find the number of storms—that is, the number of independent events upon which the reliability of the average frequency should be based. Since storms of a given intensity do not always affect the same number of stations, the average number of stations affected by storms of this intensity may be used instead to determine the number of storms. This average number of stations will be designated simply as N_a herein.

---

[16] "Storm Rainfall of Eastern United States," Miami Conservancy District, Eng. Staff, *Technical Reports*, Pt. 5, Revised Ed., 1936, Dayton, Ohio, p. 66.

Consider again the case of 100 occurrences of rainfall of certain depth, this time occurring in a station-year record of 500 years derived from 20 years of record for 25 stations. Suppose, in this case, that the average number of stations recording the given amount in each rain period of 24 hours were five. There were, then, $\frac{100}{5}$ or 20 independent rain periods. The average frequency and its standard error would be given by $\dfrac{25 \times 20}{100 \pm \frac{1}{\sqrt{20}}}$; or 5 years ± 22%; or 5 years ± 1.1 years.

Compared with the average frequency for the 500-yr record for a single station, which had a standard error of ± 0.5 year, one notes that, although the frequency remains the same, the reliability is less when determined from the number of storms in a station-year record than when determined from the single station record of equivalent length.

It has been shown that the reliability of the average frequency should be determined from the number of independent events (that is, from the number of storms), and that this number may be obtained by dividing the total number of occurrences in the station-year record by N_a. The fact that frequently more than one station records the same storm may be described as dependence between stations. One phase of this problem of determining the reliability of the average frequency of rainfall quantities becomes, then, one of calculating the dependence between recording stations.

DETERMINATION OF DEPENDENCE BETWEEN STATIONS

Although it is possible to use the average number of stations per storm receiving the given rain quantity as the index of dependence between stations, another measure of dependence will be described herein that is an even better index upon which to base the reliability determinations. This index is calculated by a statistical technique, devised by J. Bartels,[17,18] and proposed originally for testing persistence in observations taken at equal time intervals. (A series of numbers having "persistence" is called a correlative series. There is a tendency in such a series for high values to be followed by high values, and low values to be followed by low values.) In the case of a time sequence successive observations are affected by a single event because of its extension in time; in the station-year record of rainfall amounts, adjacent stations may be affected by a single event because of the areal extent of the storm.

The technique for testing persistence is based on the fundamental theorem of probability that in a random series of numbers the ratio of the standard deviation of the means of equal-sized groups of these numbers to the standard deviation of the individual numbers of the series is equal to unity divided by the square root of the number of values in the groups ("randomness," as used herein, means that, on the basis of the numbers up to a certain point, the chance for the next number to be higher or lower than the mean for a long series is equal or unpredictable. A series of random numbers can be most

---

[17] "Zur Morphologie Geophysikalischer Zeitfunktionen," by J. Bartels, Sonderausg. aus den *Sitzber*, der Preussischen Akad. der Wiss. Phys.-Math., Klasse 30, 1935.

[18] "Geomagnetism," by S. Chapman and J. Bartels, Oxford, Vol. II, 1940, pp. 582–585.

easily obtained from a table of "Random Sampling Numbers," by L. H. C. Tippett[19]).

This may be explained more clearly by carrying through the calculations on a series of random numbers. One first marks off groups of a certain number of ordinates and forms the average for each of these groups. These group averages will approximate the normal more closely than the individual values. If, for example, groups of 25 ordinates were used, the scattering of the group averages measured by their standard deviation, σ_{25}, will be less than that indicated by the standard deviation, σ_1, for the individual numbers; but $\sigma_{25} : \sigma_1 = 1 : \sqrt{25}$; or $\sigma_{25} = \frac{\sigma_1}{\sqrt{25}}$. In general, if groups of s numbers, instead of 25, are formed, $\sigma_s = \frac{\sigma_1}{\sqrt{s}}$.

Returning to the theoretical case of 25 stations, each having 20 years of record, and storms of given depth always affecting 5 stations in each storm: From the 20 years of record for these 25 stations one may express the relationship between the standard deviations of the total occurrences for each year in the groups of 25 stations, and the standard deviations of the number of occurrences at the individual stations each year as

$$\sigma_{25} = \frac{\sigma_1}{\sqrt{\frac{25}{5}}} \qquad (1)$$

Substituting s for 25 and N_d for 5 in Eq. 1:

$$N_d = \left[\frac{\sigma_s}{\frac{\sigma_1}{\sqrt{s}}}\right]^2 \qquad (2)$$

in which N_d equals the number of stations on the average receiving the given amount in each storm day.

To show how this technique may be applied to a set of rainfall data, assume that one had 10 years of concurrent record for 10 stations. The total occurrences of a certain rainfall amount at each station for each year could be set up in a table of 100 values, with the 10 columns representing stations and the 10 rows representing years. If there is no dependence between stations or years, these 100 values will constitute a random series. Any departure from randomness will be a measure of the amount of dependence between the stations, or between years.

Artificial tables of rainfall data have been set up by using random numbers and introducing a known degree of dependence between stations.[20] Eq. 2 was tested by calculating N_d from such tables. In every case the correct value of the dependence within the standard error of N_d was obtained (the standard error of N_d was calculated on the assumption of a normal distribution since any error due to this assumption will be of second order. A more detailed consideration of the calculation of the standard error of a non-normal distribution is out of place in a non-mathematical paper such as this).

---

[19] "Random Sampling Numbers," by L. H. C. Tippett (Tracts for Computers 15, London Univ., Dept. of Applied Statistics, 1927).

[20] "On the Bartels' Technique for Time-Series Analysis, and Its Relation to the Analysis of Variance," by L. R. Hafstad, *Journal*, Am. Statistical Assoc., Vol. 35, 1940, pp. 347–361.

The χ^2-test and analysis of variance were tried on the table of random numbers, but since they gave only the information that the numbers in the rows were more alike than one would expect in a random sample, and that the numbers in the columns were about as in a random sample, these tests were discarded as inadequate for the determination of N_d, the number of dependent ordinates, or stations.[20]

If the average number of stations recording the given depth in a storm day were the same for every year, and if the numbers of storm days per year constituted a random series, then the value of N_d would be equal to N_a for the total years of data.

In actual rainfall data, a variability exists from year to year in the average number of stations affected per storm, and a greater fluctuation exists in the number of storm days than might be expected in a random series. The value of N_d is determined from the sums of the occurrences for each year, and there are wide fluctuations in these annual sums because they combine the fluctuations in the average for each year of the number of stations affected per storm, and the annual fluctuations in the number of storms. If there are wide fluctuations from year to year in the number of storms, then it is necessary to have more years of data to give an average frequency that is as reliable as would be obtained from a few years which had practically the same number of storms each year.

In addition to measuring the persistence between stations (average number of stations affected per storm), N_d measures also these fluctuations from year to year, and it is therefore a more conservative, but also a more accurate, index to use in calculating the reliability than simply the average number of stations affected per storm. The standard errors will be higher if determined from N_d than if determined from either the total occurrences or the number of storms.

USE OF N_d FOR ACTUAL RAINFALL DATA IN DETERMINING STANDARD ERRORS OF FREQUENCIES OF RAINFALL AMOUNTS

The calculation of N_d has been made from rainfall data for two areas in the United States in different climatic regions. The method of tabulation and calculation will be described in detail for one of these areas.

Twenty-one stations in the quadrangle between meridians 93° and 95° west longitude and parallels 41° and 43° north latitude in central Iowa, corresponding to Quadrangle 14-D of the Miami study,[4] were selected to represent that region. Tabulations were made of all daily rainfall depths of one inch or more at every station for 32 years, 1905 through 1936. Only stations at which observations were made in the evening, and only those stations having continuous records for the entire period, were used.

Tables were made of the total number of occurrences at each station during each year of daily rains of one inch or more, 2 in. or more, 3 in. or more, and 4 in. or more. Table 1 is a sample tabulation and compilation

TABLE 1.—THE NUMBERS OF OCCURRENCES OF DAILY RAINS OF ONE INCH OR MORE AT 21 STATIONS IN CENTRAL IOWA FOR THE YEARS 1905–1936, AND DATA FOR CALCULATING N_d

Year	Ames	Afton	Baxter	Belmond and Britt	Chariton	Cumberland	Monroe and Des Moines	Newton and Grinnell	Guthrie Center	Hampton and Allison	Humboldt	Jefferson	Knoxville	Lacona	Perry	Pocahontas	Rockwell and Sac City	Waukee	Webster	West Bend	Winterset	Σ	$\frac{\Sigma}{N}$	$\left(\frac{\Sigma}{N}\right)^2$

Totals (Sum of the squares of the individual values = 42,041)																						4,879	232.333	1,798.095

sheet, this one being for rains of one inch or more in 24 hours. By substituting the values from Table 1 in the formulas, the values of N_d were computed as follows:

$$\sigma_{21} = \sqrt{\frac{1{,}798.095}{32} - \left(\frac{232.333}{32}\right)^2} = \sqrt{3.4771}$$

$$\sigma_1 = \sqrt{\frac{42{,}041}{672} - \left(\frac{4{,}879}{672}\right)^2} = \sqrt{9.8476}$$

$$N_d = \left(\frac{\sqrt{3.4771} \times \sqrt{21}}{\sqrt{9.8476}}\right)^2 = 7.415.$$

The corresponding standard error equals 1.854. Calculations of N_d were made for rains of various intensities only up to 4 in. or more per day. Heavier rains were so few that N_d could not be determined with any degree of reliability.

Similar tabulations and calculations were made from 20 years (1917 through 1936) of rainfall data for 15 stations in the quadrangle between parallels 33° and 35° north, and meridians 79° and 81° west, comprising parts of North and South Carolina. This area is Quadrangle 7-H of the Miami study.

Table 2 gives the values of N_d and of N_a derived from the data for the areas in Iowa and in South Carolina. The values in the table show that, in general, the more intense storms cover a smaller area than those yielding lower quantities. When N_d or N_a approximate unity, the occurrences may be considered to be random events. On the average an occurrence of 3 in. of rainfall will affect only one station per storm day in Iowa, but in South Carolina about four stations would be affected, and this in spite of the fact that the stations are more widely spaced in South Carolina.

TABLE 2.—VALUES[a] OF N_d AND N_a, WITH THEIR STANDARD ERRORS, FOR VARIOUS RAINFALL DEPTHS, IN A 2° QUADRANGLE IN IOWA AND IN NORTH AND SOUTH CAROLINA

Rainfall, in inches per day	IOWA (21 STATIONS, 32 YEARS)		NORTH AND SOUTH CAROLINA (15 STATIONS, 20 YEARS)	
	N_d	N_a	N_d	N_a
One or more	7.42±1.85	3.52±0.58	8.49±2.68	3.10±0.57
Two or more	4.20±1.49	2.05±0.47	6.04±1.90	1.95±0.47
Three or more	1.46±0.73	1.72±0.40	3.90±2.08	1.72±0.41
Four or more	1.00 (approximately)	1.37±0.31	1.70±1.07	1.68±0.78

[a] N_d equals number of stations to be used in calculating the reliability of rainfall frequencies, and N_a equals average number of stations affected by storms of a given intensity.

There are three bases upon which one might compute a standard error of the average frequency of specified amounts of rainfall. One of these is the sum of the occurrences, which is the one assumed by the station-year method. Another is the number of storms, which is equivalent to the total occurrences divided by the average number of stations affected. The third uses N_d in place of average number of stations. The differences in standard error obtained by the first and the second of these methods have been shown earlier in the paper for a theoretical case. In Table 3 these comparisons are made for the actual rainfall data for the areas in Iowa and the Carolinas, the computations being:

TABLE 3.—COMPARISON OF THE STANDARD ERRORS OF RAINFALL FREQUENCIES BASED ON TOTAL OCCURRENCES, ON NUMBER OF STORM DAYS, AND ON N_d

Rainfall, in inches per day	(a) IOWA				(b) SOUTH CAROLINA			
	Frequency (years)	Standard Error (%) by:			Frequency (years)	Standard Error (%) by:		
		Station-year method	Storm days	N_d		Station-year method	Storm days	N_d
	(1)	(2)	(3)	(4)	(1)	(2)	(3)	(4)
One or more...	0.14	1.4	2.7	3.9	0.08	1.6	2.8	4.7
Two or more...	0.80	3.4	4.9	7.1	0.38	3.6	5.1	8.8
Three or more..	3.10	6.8	8.8	8.2	1.47	7.0	9.2	13.9
Four or more..	10.67	12.6	14.7	14.0 (approximately)	3.80	11.2	14.1	14.7

Column Nos.	Computation
1	$\dfrac{\text{Stations} \times \text{years}}{\text{Occurrences}}$
2	$\pm \dfrac{1}{\sqrt{\text{Occurrences}}}$
3	$\pm \dfrac{1}{\sqrt{\left(\dfrac{\text{Occurrences}}{\text{Average number of stations}}\right)}}$
4	$\pm \dfrac{1}{\sqrt{\left(\dfrac{\text{Occurrences}}{N_d}\right)}}$

The availability of either the value of N_a or N_d makes possible an approximate answer to the question proposed by C. S. Jarvis,[21] M. Am. Soc. C. E., and others regarding the equivalence of a station-year record to a record of the same length for a single station. In the Carolina quadrangle, for rainfalls of one inch or more per day, on the average 3 stations record that amount in a rain day. As a result there are only $\frac{15}{3}$ or 5 independent stations. The station-year record for this quadrangle of 300 station years (15 stations for 20 years each) could not be considered equivalent to 300 years for a single station, but would be more nearly equivalent to 5 × 20 or 100 years; one might call this the valid station years of record based on the average number of stations affected per storm. For the foregoing reasons it would be still better to use the value N_d rather than N_a. This would give 36 valid station years for rainfalls of one inch for the Carolina quadrangle.

---

[21] Discussion by C. S. Jarvis of "Rainfall Intensities and Frequencies," by A. J. Schafmayer and the late B. E. Grant, *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 394.

STANDARD ERRORS FOR FREQUENCIES OF PLUVIAL INDEXES OF THE MIAMI STUDY

Although the true reliability of frequency values should be determined on the basis of the degree of persistence in the data, it is possible to give some indication of the reliability from the total number of occurrences of the given rainfall depth appearing in the station-year record.

A practical application of the standard error as a measure of the reliability of rainfall frequencies may be made in connection with the charts of pluvial indexes for quadrangles in Eastern United States, published by the Miami Conservancy District.[11] For each 2° quadrangle these charts give the maximum rainfall (one day to six days) to be expected once in 15 years, 25 years, 50 years, and 100 years. There is given, also, for each quadrangle the total number of station years used in the computations.[22] The number of station years divided by 100 gives the rank of the 100-yr pluvial index in the series of rains arranged in order of depth. For example, for Quadrangle 8-E (see Fig. 2(*d*)) in western Ohio, the pluvial-index of 5.2 in. for the 100-yr frequency has a rank of 15, obtained by dividing 1,524 (station years) by 100. In other words, this pluvial index with an expectancy of once in 100 years was based on 15 occurrences. A percentage standard error in the frequency may then be given as $\frac{1}{\sqrt{15}}$, or 26%, and the average frequency should be written as 100 years ± 26 years. A percentage standard error on the basis of all occurrences has been calculated for all quadrangles of the Miami study for the 100-yr, 50-yr, 25-yr, and 15-yr frequencies, and these percentages are shown in Fig. 2. Errors were calculated from the total occurrences with no correction for dependence in the data.

Since the number of occurrences will depend upon the intensity, the number of years of record, and the number of stations, the reliability of the frequency will be least for high rainfall amounts in quadrangles with the fewest station years of record. It will be seen that about one fifth of the quadrangles have standard errors of 50% for the 100-yr pluvial index. For these quadrangles the expectancy should be given as once every 100 years ± 50 years.

SUMMARY

It has been shown that two factors affect the accuracy of average frequency values of precipitation determined by the station-year method—the number and distribution of stations and the length of independent record. The second of these factors has been discussed in some detail. It has been shown

(*d*) 100-YEAR FREQUENCY

FREQUENCY DETERMINATIONS OF MIAMI STATION-YEAR STUDY that the reliability of the frequency, as far as it is related to the length of record, can be expressed as a percentage error in the average frequency. An index of dependence, N_d, has been proposed as the best basis yet devised on which to compute the standard errors.

A measure of the reliability of frequency-intensity values can be helpful to those concerned with the design of soil-conservation and flood-control structures, since the margin of safety to be allowed in design should be in proportion to the reliability of the frequency determinations.

Little is known about the effect of station spacing and distribution upon the average frequency, primarily because it has not yet been possible to determine accurately the areal extent of storms of certain intensity. The question of the adequacy of sampling of rainstorms, also, depends upon the size and structure of rainstorms in relation to the spacing of rain gages. The fundamental data for studying rainstorm morphology are only now becoming available through the establishment of dense networks of rain gages such as those in the Susquehanna, Muskingum, and Tennessee watersheds.

New projects in the study of rainfall frequencies and intensities, therefore, will make use of these additional data in considering the sizes of storms and consequently the adequacy of sampling with various spacings of recording stations. A great weakness of the station-year method is its failure to indicate the areal extent of rainfalls of certain intensity and frequency. Studies of rainstorm morphology should supply this deficiency by making possible the determination of the maximum depths of rainfall which will cover a certain area and occur with a given frequency. The probable frequency of specified volumes of runoff can then be determined more accurately than can be done now with a pluvial index referring only to a point.

DISCUSSION

Paul V. Hodges,[23] **M. Am. Soc. C. E. (by letter).**—In the determination of the probable maximum floods to be expected in different parts of the country, the pluvial indexes and their standard errors give a basis from which comparisons and computations can be made. This paper is of considerable assistance and value in the proper appraisal of records of storm rainfall over the eastern half of the United States.

In an unpublished study of the Grand River, in South Dakota, by the writer, to determine the probable maximum flood, for a spillway design, the pluvial index of Quadrangle 18–B was used (see Fig. 2). The pluvial indexes, in inches, for this quadrangle are given in Table 4*A*. The indication of the standard error as it affects the frequency in years is as follows:

Frequency, in years	Pluvial index (in inches)
15± 3.3	2.7
25± 7.0	4.2
50±19.9	4.4
100±55.9	4.8

The extremes of these periods were plotted against the pluvial index. By connecting the plotted points the range in the pluvial index for any frequency is obtained as follows:

Frequency, in years	Range in the pluvial index (in inches)
15	2.3 to 3.5
25	3.5 to 4.31
50	4.3 to 4.85
100	4.54 to 5.27

The errors of these various quantities are reflected in their plotting. With more Weather Bureau stations, well distributed, and with longer records, the points, no doubt, would plot on smooth curves and the results would be more consistent.

Maximum Rainfall to be Expected Once in 100 Years.—To determine the probable maximum flood to be expected on the Grand River in northwestern South Dakota the "Hydrograph Method" was used and compared with the largest floods of nearby streams. The maximum rainfall to be expected once in 100 years for storms of different durations was derived for different areas. The pluvial index for quadrangles of the Grand River drainage area is given in *Technical Reports*, Part 5, of the Miami Conservancy District.[4]

The pluvial index gives the rainfall to be expected at any point. To determine what the depth over an area would be, a study was made of a number of storm areas and the time-area-depth relation was determined. Table 4*B* shows the depth of rainfall to be expected once in 100 years over different areas.

---

[23] Hydr. Engr., U. S. Indian Irrig. Service, Los Angeles, Calif.

The quantities given in this table were derived from the pluvial indexes of two quadrangles, 18–B and 18–C, in the northwestern part of South Dakota.

TABLE 4*A*.—PLUVIAL INDEXES, IN INCHES

TABLE 4*B*.—INDEXES OF RAINFALL TO BE EXPECTED ONCE IN 100 YEARS

Duration of storm, in days	FREQUENCY, IN YEARS				TIME-AREA-DEPTH RELATION			
	15	25	50	100	At the point	4,085 sq miles	5,664 sq miles	6,000 sq miles
1	2.0	2.5	3.4	4.0	4.50	3.20	3.03	3.00
2	2.7	3.3	4.1	4.2	5.10	3.60	3.43	3.40
3	2.7	4.0	4.3	4.5	5.50	4.10	3.93	3.90
4	2.7	4.2	4.4	4.8	5.70	4.30	4.05	4.00
5	2.7	4.2	4.4	4.8	5.80	4.40	4.15	4.10
6	2.7	4.2	4.4	4.8	5.80	4.40	4.15	4.10
%*	21.8	27.9	39.8	55.9	* Standard error (percentages)			

Flood Runoff, Grand River Near Wakpala, S. Dak.—The runoff of the Grand River near Wakpala to be expected once every 100 years is computed by using a depth of rainfall of 4.15 in. and estimating that 30% will appear as runoff:

Rainfall of 4.15 in. = 0.346 ft;
0.346 × 5,664 × 640 = 1,255,000 acre-ft of precipitation; and
30% runoff = 377,000 acre-ft of runoff = 190,000 sec-ft-days of runoff.

Flood Runoff, Grand River at Blue Horse Dam Site.—The runoff of the Grand River at the Blue Horse Dam site to be expected once every 100 years is computed by using a rainfall depth of 4.40 in. and estimating that 30% will appear as runoff:

Rainfall of 4.40 in. = 0.367 ft;
0.367 × 4,085 × 640 = 960,000 acre-ft of precipitation; and
30% runoff = 288,000 acre-ft of runoff = 145,000 sec-ft-days of runoff.

Unit Hydrographs.—From runoff records of the Grand River near Wakpala, hydrographs for a number of high-water periods were plotted, and the total discharge for the periods was computed and compared with the precipitation. A unit hydrograph was determined by computing the average daily percentages of the total flow during the periods. In order to determine a unit hydrograph for the Grand River at the Blue Horse Dam site, the peak flow was based on a comparison with the probable maximum peak of Grand River near Wakpala, and the base of the hydrograph was shortened to agree with the hydrographs of nearby streams having drainage areas of nearly the same size.

The discharge during a maximum flood period was computed to be as shown in Table 5. The plotting of these daily discharges shows that the peak discharge or flood peak would reach about 60,000 cu ft per sec for each of the locations on the river.

Comparative Method.—A study of recent floods, showing maximum peaks of record, occurring in South Dakota, Montana, and Wyoming, together with the expected Big Horn River flood from a hypothetical transposition of the 1923 Powder River storm to the Big Horn Basin, has been made. The aforementioned floods were exceptionally high and probably represent about the maximum for those streams.

TABLE 5.—MAXIMUM GRAND RIVER FLOOD

Day	NEAR WAKPALA		AT BLUE HORSE DAM SITE	
	Percentages	Average discharge (cu ft per sec)	Percentages	Average discharge (cu ft per sec)

The formula

$$Q = 933\,A^{0.491} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

shows the maximum flood to be expected, if such flood is of the same magnitude as shown by maximum recorded or computed hypothetical floods. Using Eq. 3, and computing for the maximum flood to be expected on the Grand River, the following quantities are obtained:

Location	Drainage area, A, in sq miles	Maximum discharge, Q, in cu ft per sec
Grand River near Wakpala	5,664	64,800
Grand River at Blue Horse Dam site	4,085	55,300

The station-year method of determining the accuracy of rainfall frequency gives the solution of the standard error of the frequency of rainfall as it occurs at particular stations. The "dependence between stations" is an attempt to show the areal effect, or to consider contemporary rainfall at nearby stations. It does not, of course, give the error of frequency of areal storm depths.

The results of this paper can be used and are adaptable for the areal determination of the limits of storm rainfall to be expected, as it appears certain that the standard error of storm frequency as computed by the station-year method is considerably larger than the standard error of frequency of areal storm depths.

The comparison between the standard error of frequency of rainfall and the approximate error in depth of rainfall is given for Quadrangle 18–B as follows:

Frequency		Depth of Rainfall	
Years	Standard error (%)	Inches	Error (%)
15	21.8	2.7	22.0
25	27.9	4.2	9.6
50	39.8	4.4	6.4
100	55.9	4.8	7.6

In the study of flood runoff the areal extent of storm rainfall is desired.

The flood study, from the pluvial index and the indicated standard error, was made to show its application to relatively large areas, and an allowance for the indicated error was considered, or in other words, a larger pluvial index was used to cover the possibility of the occurrence of a more intense storm.

The sizes of the probable maximum flood to be expected, as determined by using the pluvial index, adjusted for the probable error, and compared with the maximum floods of nearby streams indicate a fairly close agreement and show that the available data give a fair criterion for similar studies.

C. S. JARVIS,[24] M. AM. SOC. C. E. (by letter).—The station-year approach to rainfall frequencies, magnitudes, and normal patterns of distribution, intensity, and recurrence has long been accepted with some reservations and misgivings. Its use persisted because of the obvious advantages which it offered in cementing short segments and forming therefrom a synthetic record of impressive length and plausibility, with evident claims to reliability that could not be readily disproved.

The service performed by the author in making the exhaustive analysis, rigorous tests, and logical findings cannot be appraised adequately until one explores the labyrinths of disjointed, intermittent, and fragmentary records that have heretofore been set aside, much as is the custom for segregating refractory ores, in the hope that processes may yet be devised for their reduction and the sure recovery of their intrinsic values. Such a process is now available, largely as a result of this paper.

One must recognize, however, that more than one method is used for deriving frequency of rainfall. This subject is discussed under the heading "Introduction," where five occurrences in excess of a given amount within a record comprising 500 station years are regarded as "equivalent to an average frequency of 100 years per occurrence, which is the same result that would be obtained by taking the fifth highest amount in a station-year record of 500 years." Here is where another method has been used, along the following lines of reasoning: The maximum value occurred once in 500 years; the second from the top value, once in 250 years; the third is likely to occur once in 125 years; the fourth, once in 62.5 years; and the fifth, once in 31.25 years. The question is, which of the two methods should prevail, or is there a third approach? Should one recognize the zone between the values of 100 and 31.25 as being the range of uncertainty regarding probable frequency?

As it happens, nearly a comparable variation in results occurs under the heading, "Use of N_d for Actual Rainfall Data in Determining Standard Errors of Frequencies of Rainfall Amounts," in answer to the writer's question of some years ago. There, the

> "* * * 300 station years (15 stations for 20 years each) * * * would be more nearly equivalent to 5 × 20 or 100 years; one might call this the valid station years of record based on the average number of stations affected per storm. For the foregoing reasons it would be still better to

---

[24] Hydr. Engr., SCS, Dept. of Agriculture, Washington, D. C.

> use the value N_d rather than N_a. This would give 36 valid station years for rainfalls of one inch for the Carolina quadrangle."

Does this mean that the best one can do is to bracket the most probable values between those limits?

It was the writer's good fortune to view the early results of the author's current research, some years ago, and to utilize some of the findings to good advantage. Thereafter, the writer urged the need not only for further exploration and tests, but also for their prompt release to the profession through technical publications, such as have been chosen. The paper seems to present much data, many tests, and a certain maturity of concept beyond the tentative and informal accounts of research to which the writer had access some years ago. Now, having observed the modest beginnings, the step-by-step development, and the seemingly authoritative analyses and solutions of successive problems, and having tested them by the practical standards that have been acquired throughout a varied experience in hydrologic fields, the writer indorses the paper as a distinct scientific achievement.

Perhaps a lack of perception will account for the writer's inability to reconcile some minor details thus far, but he anticipates that these matters will be cleared up in the author's closing comments.

Howard W. Brod,[25] **Jun. Am. Soc. C. E.,** (by letter).—It is often more important to understand the limitations of a law than to know the law itself. The author unmistakably implies that the station-year method is applicable to large drainage areas. It is significant to point out that the Miami Conservancy District confined the use of the station-year method to the "* * * design of sewer systems, bridge and culvert openings for small drainage basins, and in the design of dams, levees, and channel improvements where the watersheds involved are not more than a few square miles in area."[26] Furthermore, the practice of grouping stations with markedly different rainfall characteristics is questionable.[27]

There are two fundamental weaknesses in the station-year method which restrict its applicability to a very limited class of data: (*a*) The variation of seasonal rainfall; and (*b*) the dissimilarity of rainfall stations.

(*a*) *Variation of Seasonal Rainfall.*—First, consideration will be given to the variations in seasonal rainfall quantities. From the interpretations that have been made of the longest available records of floods (Nile River, Egypt), it is evident that no secular or long-time changes in climatic conditions are taking place. Cyclic variations, however, are an integral characteristic of seasonal rainfall. There seems to be an inertia in the unbalance of the atmospheric forces which causes prolonged series of wet seasons and dry seasons to take place. The results that would be obtained if the station-year method were applied to a set of data which lies wholly within a wet phase or wholly within a dry phase might lead to tragic consequences, such as a dam failure or a shortage in water supply. Reference is made to the case cited in a National Resources Committee report[28] of a federal project which was based on a 20-yr hydrologic record. "Unhappily, the years of record seemed to have coincided with a wet period in the precipitation cycle. When the dry period came the project could be developed to only one-third its intended size."

[25] Engr., The Panama Canal, Diablo Heights, Canal Zone.

[26] *Technical Buletin No. 5*, Miami Conservancy District.

[27] "Rainfall Intensities and Frequencies," by A. J. Schafmayer, M. Am. Soc. C. E., and the late B. E. Grant, *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 344.

The relevancy of the cyclic variations of seasonal rainfall to the occurrences of high rates of rainfall is readily apparent to those who have tried to correlate major floods with annual rainfall. Although it is possible to have a major flood during a comparatively dry year, it would be the exception rather than the rule; by far the greater number of major floods occur in comparatively wet years. Similarly, a greater number of high rates of rainfall will take place during wet years than during dry years and, therefore, such occurrences will parallel the cyclic variations of seasonal rainfall.

(*b*) *Dissimilarity of Rainfall Stations.*—On a purely theoretical basis, the station-year method is invalid because it assumes that there is equal opportunity for every station to receive an equal quantity of rain. Of course, this is not true since the characteristics of rainfall stations are similar to those of fingerprints in that no two of them are alike. No two rainfall stations can have the same conditions of geographic location, elevation, slope, exposure, distance from the ocean or other large body of water, etc., and, therefore, the rain-catching potentialities of any two rain gages cannot be exactly alike.

The station-year method is valid only when the data do not conflict with the limitations made in items (*a*) and (*b*). Condition (*a*) may be satisfied by developing an "index" of mean seasonal rainfall for the region for a sufficiently long period of time to assure a reliable approximation of the mean seasonal rainfall. This may be accomplished satisfactorily on the basis of a single long-term record, but preferably more. If no long-term records are available in the region, a meteorologic study of the storm paths that are characteristic of the region should be made, and the characteristics of the "index" of mean seasonal rainfall of the adjacent regions which influence the rainfall of the region under consideration should be transferred to that region. Condition (*b*) may be considered negligible in small areas of comparatively uniform meteorologic characteristics and in certain regions where the differences in the areal distribution of rainfall quantities are equal to or less than the error with which a rain gage represents the average rainfall over the area in the vicinity of the rain gage.

There are several other phases of the subject of rainfall probabilities upon which the author touches which provoke discussion. Among these the determination of dependence or independence of the events or observations is of prime importance. Eugene L. Grant, M. Am. Soc. C. E., has pointed out that one of the weaknesses of the flood-probability method lies in the fact that "the successive floods on a given stream in a given year are certainly not independent events." The same is true regarding successive rainfall events of the frontal type. When a series of fronts (for example, cold fronts) invade a region in which warm air has been stagnating, the first cold front meets a great opposition in meteorologic characteristics. With the passage of subsequent fronts, the meteorologic characteristics of the region become modified and the differences between the invading air and the residual air become less. The phenomena are similar to the change in saturation conditions for successive floods. The meteorologic conditions often associated with major floods consist of a series of fronts passing over a region. The successive storms associated with the passage of these fronts are certainly not independent events.

---

[28] "Deficiencies in Basic Hydrologic Data," National Resources Committee, September, 1936.

The principal reasons for the superiority of rainfall probabilities over flood probabilities are that the aforementioned dependency is true for only a small part of a rainfall record and that rainfall is a function of much fewer variables and therefore requires less data to establish the position of the frequency curve.

The inadvisability of using the nominal, or published, 24-hr rainfalls as the basis of a frequency study is indisputable. This practice violates the requirement of independency of events and also brings up the question of "How great, in the long run, is the difference between nominal and actual maximum 24-hr rainfall?" The independence requirement of the rainfall events is violated when the end of the nominal 24-hr rainfall comes within the storm period and a single event is indicated as two occurrences. The differences in the results that may be obtained using nominal or published 24-hr rains are shown in Fig. 3. The example has been selected at random, and therefore it is probable that even more serious differences exist.

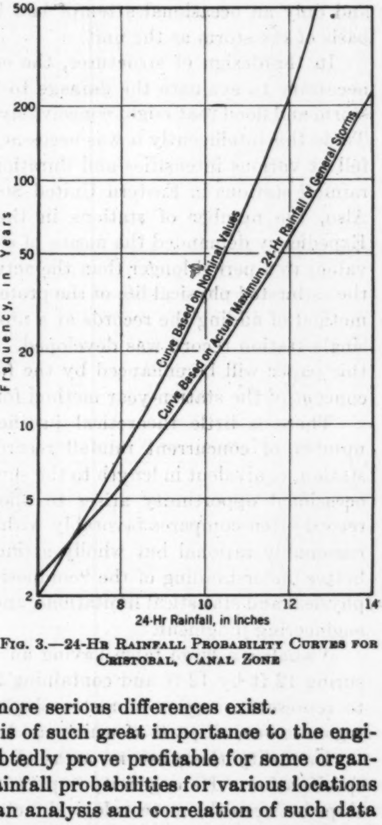

FIG. 3.—24-HR RAINFALL PROBABILITY CURVES FOR CRISTOBAL, CANAL ZONE

The subject of rainfall probabilities is of such great importance to the engineering profession that it would undoubtedly prove profitable for some organization to conduct an investigation of rainfall probabilities for various locations throughout the world. The results of an analysis and correlation of such data should prove of unlimited value. As the author points out, the introduction of the area factor into frequency studies of rainfall has not yet been made and is an outstanding deficiency in hydrologic research. The work of the hydrology organizations of the U. S. Soil Conservation Service and Tennessee Valley Authority is directed toward overcoming this deficiency and should represent a great advance in the application of probability technique to rainfall data.

MERRILL BERNARD,[29] M. AM. SOC. C. E. (by letter).—Efforts to inject mathematical precision into the treatment of hydraulic problems that rely upon precipitation for solution are timely. Too often progress in fields of applied science depends upon the ability to bolster an inadequate sampling medium with assumptions that are never wholly satisfying. Such was the necessity faced by the Miami Conservancy District in 1916. Until that time rainfall records were considered to be so many independent point experiences, and only an occasional attempt had been made to organize the data on the basis of the storm as the unit.

In the design of structures, the engineers of the Miami project found it necessary to evaluate the damage to be expected from the highly infrequent storm and flood that might conceivably damage or destroy the protection works. To do this intelligently it was necessary to know the frequency with which rain fell at various intensities and durations. At the time there were only a few rainfall stations in Eastern United States with records greater than 30 years. Also, the number of stations in the network was admittedly inadequate. Expediency demanded the means of extrapolating the frequency of the greater values to a period longer than the actual record and in reasonable accord with the estimated physical life of the protection system. Thus, the "station-year" method of adding the records at a number of stations to obtain an equivalent single station record was developed. It is believed that an understanding of this paper will be enhanced by the following attempt to present a simplified concept of the station-year method for determining rainfall frequency.

There is little theoretical justification for combining an indiscriminate number of concurrent rainfall records to arrive at the record for a single station, equivalent in length to the sum of the station years; and yet, where the occasional opportunity arises to allow such a comparison, the synthesized record often compares favorably with the actual. The writer will resort to a reasonably rational but wholly artificial means of attempting to arrive at a better understanding of the "composite record" or "station-year" method, its physical and statistical limitations, and any success it may have had in guiding engineering judgment.

Visualize a large table having an area confined within a raised edge measuring 12 ft by 12 ft and containing 20,736 sq in. The table top is intended to represent a region of meteorological homogeneity. By definition, such a region is one, all parts of which can be said to have the same rainfall regimen.

In reality there are no areas of appreciable extent that conform to this specification. Homogeneity implies, first, a complete stability in the relationships between the meteorological factors involved in the mechanism of a storm and, second, a consistent action from storm to storm of surface influences, such as mountain barriers, abrupt changes in elevation, and the proximity of appreciable water surfaces. It is understood, then, that the suggested demonstration "region" is homogeneous only within the tolerances imposed by the foregoing considerations.

---

[29] Hydrologic Director, U. S. Weather Bureau, Washington, D. C.

Next, prepare three sets of concentric rings of light metal, symmetrically spaced and held rigidly in place according to the specification in Col. 1, Table 6. For the moment, ignore the artificiality of the medium, and visualize, in the sets of concentric rings, the isohyetal pattern of rainfall idealized as to shape.

36	1,017	477	0.5	43	22	33	67	539	...	...	...	...

Usually such a pattern is elongated and irregularly elliptical. It is believed little would be added to the experiment if differences in pattern shape were included as a variable.

There are innumerable shades of difference in the characteristics of storms, and only a generalized classification is possible. A principal distinction lies in the inverse relation between intensity and the duration and areal extent of the storm. Three generalized storm types are pictured in the depth-area curves shown in Fig. 4. Storm *A* is the highly intense downpour of limited extent that produces the phenomenal depths of rainfall recorded in certain parts of the United States. Storm *C* is the typical "warm front" storm producing moderate intensities over considerable area; and storm *B* is of intermediate type, often combining the characteristics of types *A* and *B*.

In Table 6, consider the differences in the diameters to fix the widths of the concentric bands between the rings (isohyets) of each "quoit" (storm). It is realized that the duration of storms *A*, *B*, and *C* will vary considerably. It will not detract too greatly from the reality of the experiment if an average duration is adopted for all.

Although no attempt is made to simulate quantitative relationships found in actual storms, it will be reasonable to consider square inches in the model as equal to square miles of the prototype. Depths have been computed from Fig. 4 that are to be taken as averages for the concentric bands between the isohyets.

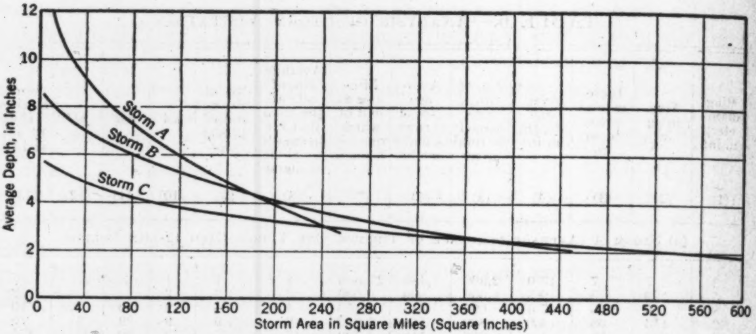

FIG. 4.—AREA-DEPTH CURVES, HYPOTHETICAL STORMS

A region of meteorological homogeneity also can be defined as one in which a storm, having entered it, can center over any point within its limits with equal probability. Without going into mechanical detail, assume the means of injecting the storm quoits to, and on, the table with the impersonal result of mechanically thrown dice, or under the assumption that the quoit, having had energy applied to it, is under perfectly balanced compensative influences so that it can come to rest in any position on the table with complete fortuity. Attention is now directed to Table 6, in which Cols. 1 and 2 are isohyetal diameter and enclosed area, respectively. Col. 3 is the area of the concentric band between a given ring and the next smaller one. Col. 4 is the assigned average depth of the concentric bands between isohyets. Col. 5 is the number of times the respective incremental areas are contained in the entire table area. (The circles could be adjusted actually to space by changing the shape or overlap, but this is not considered necessary to the purpose of the discussion.)

The following sequence of average storm visitation to the table (region) is adopted:

Minutes	Storm	Minutes	Storm
1	*C*	9	*B*
2	*C*	10	*C*
3	*B*	11	*C*
4	*C*	12	*A*
5	*C*	1	*C*
6	*B*	2	*C*
7	*C*	3	*B*
8	*C*	etc.	etc.

At the beginning of the initial minute (year) of the record, a small upright peg (station) is placed in an arbitrary position on the table (region). The experiment now begins under the foregoing schedule by putting the mechanical quoit thrower into action. The peg can be taken to mark the center of one of the 2,960 areas measuring 3 in. in diameter contained in the entire table top (Col. 4). It is possible that the first quoit thrown could center over it, or the entire 2,960 opportunities could be exhausted before the peg (station) was encircled by the 3-in. ring. If an indeterminate number of runs are made, it will be found that the peg will be ringed as often in the first half as in the last half of the series so that the most probable number of throws necessary to ring the peg would be the average, or 1,480.

With only one peg on the table, by far the greater number of throws will miss the peg entirely (no rain recorded at the station). The number of times the peg falls between the isohyets of greater diameter will be in proportion to the opportunity afforded by the greater area of the concentric bands between the rings (isohyets).

Col. 6, Table 6, gives the average number of throws under the schedule to bring the peg within the areas fixed by the various isohyetal diameters. Col. 7 gives, for each storm type, the average number of minutes at the end of which one hit was made in each of the concentric bands. Col. 8 gives the number of hits for each isohyet diameter within the average number of minutes taken to ring the peg in the smallest isohyet of each storm type. Col. 9 gives the number of hits within the average number of minutes taken to ring the peg with the smallest isohyet of the least frequent storm *A* (17,800 min).

It is now seen that the peg (station) has experienced through the record period of 17,800 min (months, years) the visitation of three types of storms in varying sequence, producing varying depths of rainfall. Although storm *A* contributed the two greatest depths, the remainder of the depth-range was represented generally by all three storm types. In order, then, to organize the record at the peg (station), it is necessary to assemble the number of occurrences for each average depth from each type of storm, as shown in Cols. 10, 11, 12, and 13. These values are arranged in order of depth-magnitude

TABLE 7.—ANALYSIS OF STORM FREQUENCY

Average depths, in in.	No. of hits	FREQUENCIES, *F*				Average depths, in in.	No. of hits	FREQUENCIES, *F*			
		One station	Two stations	Twenty stations	Thirty-six stations			One station	Two stations	Twenty stations	Thirty-six stations
(1)	(2)	(3)	(4)	(5)	(6)	(1)	(2)	(3)	(4)	(5)	(6)
13.0	1	17,800	8,900	890	494	4.3	70	254	127	13	7
9.3	2	8,900	4,450	445	247	4.0	79	225	112	11	6
8.3	6	2,960	1,480	148	82	3.3	119	150	75	8	4
7.5	10	1,780	890	89	49	2.2	224	79	40	4	2
7.3	10	1,780	890	89	49	1.7	287	62	31	3	2
6.3	17	1,050	525	52	29	1.1	393	45	22	2	1
5.7	29	614	307	31	17	1.0	424	42	21	2	1
4.9	44	404	202	20	11	0.5	637	28	14	1	1

in Col. 1, Table 7. The frequency with which one peg (station) will experience various depths of rainfall is given in Col. 3, Table 7.

The demonstration is thus complete for a record cycle of 17,800 min at the peg (station). If the cycle is representative, and if 13 in. is considered to be the maximum depth for the region, even if it were experienced in the first minute (month, year) of record, the peg (station) experience must continue throughout the course of the cycle if it is to be confirmed as a maximum value.

The analogy between the table top and the region is strengthened somewhat if the former is considered covered with green baize and the outline of each quoit (storm pattern) is made with chalk as each throw comes to rest. The result at the end of a complete series of throws will be a completely covered table top (regional map) with superimposed storm patterns giving the same impression as that gained by superimposing maps prepared by the Miami Conservancy District.[30]

If station 1 is 100 ft from station 2, it will be impossible for station 1 to have, say, 3 in. of rainfall without station 2 experiencing a fall somewhat near this quantity. In other words, the record accumulating at station 2 is not independent of that at station 1. As station 2 is moved away from station 1, its dependency upon the latter will become less and less until the two records no longer represent that of concurrent rainfall, although statistically both may have the same frequency curves.

Dependency may be illustrated on the table top and with the hypothetical storms *A*, *B*, and *C*. With station 1 at the center of storm *A*, the dependency of the record at station 2 for a storm of this type will reduce in proportion to the lengthening radius of storm *A* to its outer limit of 8 in. (miles). With the peg (station) at the outer limit of the storm, a distance between stations 1 and 2 must be equal to at least the diameter (16 in.) to insure complete independence of record. Under these requirements the minimum distance for storm *B* would be 24 in., and for storm *C* 36 in.

With this fact in mind locate peg (station) 2 at some arbitrary point on the table and at a greater distance than 36 in. from peg (station) 1. Now subject the table (region) to a series of storm visitations according to the established schedule. Because of the wholly fortuitous delivery of the quoits (storms), one station or the other will ring (record) the 3-in. isohyet of storm *A* for an average series of throws in a time period, equal, on the average, to one half of that taken to make the same hit with only peg (station) 1 on the table. If other pegs (stations) are added, the average time taken to ring the 3-in. isohyet of storm *A* in any series of throws will be equal to the result of dividing the period for one peg (station) by the number of pegs (stations).

The dependency relationship between stations is affected also by the relative importance of depth. Considering the diameter of the isohyets assigned to the various depths to be the minimum distance between stations, it is seen from Fig. 5 that, if complete independency is to be assured, no more than 20 pegs (stations) can be utilized in record combination if 0.5 in. is considered;

---

[30] "Storm Rainfall of Eastern United States," Miami Conservancy District, Eng. Staff, *Technical Reports*, Pt. 5, Revised Ed., 1936, Dayton, Ohio, Figs. 54 through 65.

no more than 36 if 1.0 in. or more is taken into account; and no more than 300 if a depth of 6 in. or more is to make up the significant record.

Again, it is necessary to call attention to the artificiality of the synthesized rainfall region and the limitations of the assumptions under which the demonstration has been made. One can draw from it, however, certain conclusions

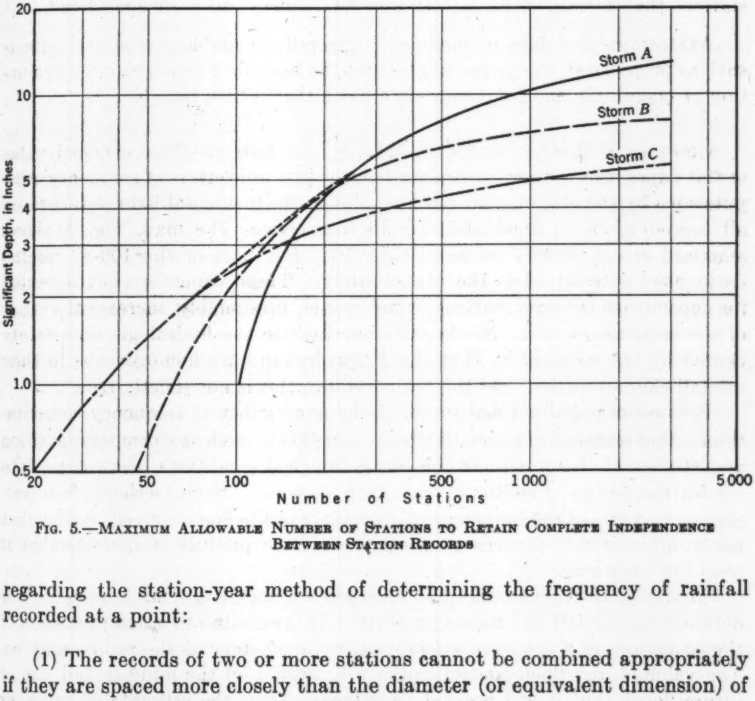

FIG. 5.—MAXIMUM ALLOWABLE NUMBER OF STATIONS TO RETAIN COMPLETE INDEPENDENCE BETWEEN STATION RECORDS

regarding the station-year method of determining the frequency of rainfall recorded at a point:

(1) The records of two or more stations cannot be combined appropriately if they are spaced more closely than the diameter (or equivalent dimension) of the storm area of significant rainfall depth.

(2) If a number of stations are so spaced, an approach to the ultimate record for one station, representative of the area, can be accelerated by combining their records, if they are of reasonable length—say greater than 5 or 10 years. From the synthetic example presented as Table 6, it is seen that 13 in. are reached at one of 36 stations in an average time of 494 min, whereas, at the end of this time, one of 20 stations would have registered about 10.0 in., and a single station only about 5 in. under the regimen of storm visitation adopted as typical.

(3) There is no basis in the combined records of a number of stations for the determination of the areal extent of storm rainfall. Records cannot be combined unless they are so spaced that only one station falls within the extent of the individual storm. As the station can occupy an infinite number of positions

within the storm pattern, its rainfall depth cannot be considered an index to depths at other points within the storm area.

(4) The apparent practical success of the station-year method lies in the fact that rainfall studies, such as that of the Miami Conservancy District, have been concerned primarily with the greater depths of rainfall; and therefore (as illustrated in Fig. 5) independency can prevail among a greater number of stations than if total storm rainfall and total storm area were considered.

As storm rainfall data are made more generally available, statistical methods such as proposed in this paper will become the basis for a much sounder evaluation of magnitude and frequency than has hitherto been possible.

Charles F. Ruff,[31] M. Am. Soc. C. E. (by letter).—The principal value of this paper is in the emphasis placed on the probable errors of frequency computations by the station-year method, and in the incidental light it throws on all computations of flood and rainfall frequency. The map, Fig. 2, shows standard errors of 30% to more than 50% for most of the 100-yr rainfall frequencies determined in the Miami study. These values are not corrected for dependence between stations, which would, presumably, increase the range of the statistical error. Neither do they include the hydrologic uncertainty caused by the assumption that the 2° quadrangles are homogeneous in their rainfall characteristics. As the author states, this is not strictly true.

Because of a general realization of the uncertainty of frequency computations, other methods of estimating maximum floods, such as storm transposition and studies of the worst possible meteorological conditions, have come into use for the design of spillways and other purposes. Such methods, however, give no measure of the frequency of occurrence of the flood derived, except that the number of coincidences assumed to occur to produce it indicate that it would be very rare.

Mrs. Clarke-Hafstad has not enlarged on the reason and necessity for determining rainfall and flood frequency. It is essential to a determination of the economics of a flood-control project, unsatisfactory as the results may be. The value of any flood-control works will depend on the number and size of future floods that it will prevent or reduce. Thus, the estimate of value, or "benefits" as it is termed, involves errors of the same order as occur in the frequency determinations. When the benefits far exceed the cost of the control works, such errors are not significant; but the writer has seen projects recommended in which the benefits were said to exceed the cost by as little as 10%. If a probable error of 30% in the frequency on which these benefits were computed exists, such a statement becomes misleading. The probable benefits would be roughly from 80% to 140% of the cost. It follows logically that in such a case the probable error of the frequency becomes critical in deciding whether the project is economically sound and should be built or not. The expenditure for such a project is not like the purchase of an automobile, but resembles more the purchase of a majority of the chances on a car which is to be raffled. The extent of the "gamble" involved is indicated by the standard error of the frequency determination.

---

[31] San. Engr., Caribbean Arch't-Engr., New York, N. Y.

Mrs. Clarke-Hafstad's paper deals only with rainfall frequency. For small works such as contour plowing and terracing, the rainfall can probably be used directly; but for larger areas, the methods used to transform the rainfall into flood runoff involve the assumption of values for percentage of runoff or infiltration rates. These values vary from time to time and constitute a series of independent events that combine with the rainfall to produce the flood. Thus, the flood from a 50-yr rainfall is not necessarily a 50-yr flood. The writer feels that comment on this phase of the problem would be helpful.

One of the most serious defects of the station-year method is the lack of areal significance, as mentioned by the author. For a watershed containing several stations the simultaneous rainfall at all these stations is needed to estimate the flood. If there were absolute dependence between stations, the 50-yr rain would occur at all of them at the same time. If they were entirely independent, however, such an occurrence would have a very long frequency, of the order of 50^n years, in which n is the number of stations. The writer wonders if Mrs. Clarke-Hafstad's measure of dependence between stations would permit estimating this frequency, or preferably the frequency and amount of rain at surrounding stations when a given station had its 50-yr rainfall.

The writer is familiar with a project in which the 50-yr rainfall was estimated for each of a group of stations in a watershed, of which nearly all had less than 20 years of record. This 50-yr rainfall was then assumed to occur at all the stations simultaneously and translated into a flood. The enormous damage done by this flood was then divided by the original 50 years of the rainfall frequency at one station as a part of the calculation of annual benefits. The writer cannot but feel that such a computation contains a very large probable error. This example illustrates the practical nature of the problems with which Mrs. Clarke-Hafstad's paper deals, and the importance, not only of reliable frequency determinations, but of a measure of their reliability.

The writer is in agreement with the author's statement that new projects of rainfall study should deal with storms rather than station rainfall readings. The latter depend on both the size of the storm as a whole and the location of the gage with respect to the storm, and are thus more complex quantities than the storm itself. Once the frequency of the storms of a region is determined, the frequency of rainfall at either a single station or the average over a given area can be computed.

EUGENE L. GRANT,[32] M. AM. SOC. C. E. (by letter).—The value of this excellent paper lies not only in its specific contributions but also in its implied suggestion that engineers dealing with problems of hydrology should be interested in statistical measures of the reliability of the conclusions of their studies. The station-year method presents two questions which constitute a challenge to the student of statistical technique. One question is whether or not the stations used are too far apart to be subject to the same cause system with regard to storms of the duration and intensity under consideration. The other question is whether the stations used are so close together that the same storm has been counted more than once. The Bartels' technique, explained in this paper, provides a satisfactory method of answering this second question.

---

[32] Prof. of Economics of Eng., Dept. of Civ. Eng., Stanford Univ., Stanford University, Calif.

One generalization which seems justified on the basis of the evidence now available is that the station-year method is particularly well adapted to dealing with high-intensity storms of short duration. The greater the intensity and the shorter the duration, the larger will be the area that seems to be statistically homogeneous and the smaller will be the area covered by an individual storm. It has already been shown[27] that a large area of Mid-Western United States is statistically homogeneous with regard to the frequency of certain extreme storms of 5-min to 120-min duration, although not so with regard to the frequency of less intense storms of the same duration. Table 2 shows how, in the Iowa and Carolina quadrangles studied by Mrs. Clarke-Hafstad, the value of N_d decreases rapidly with an increase in intensity; although a 1-in., 24-hr storm in Iowa affected more than 7 stations, a 4-in., 24-hr storm affected only one station. An examination of storm maps such as Fig. 1 serves to confirm the view that, the greater the intensity, the smaller will be the area that a storm is likely to cover.

As the author states, the dense networks of rain gages now established in several areas may be expected to provide better estimates of the areas associated with storms of various degrees of intensity. With regard to the very intense storms that cover only a few square miles, these networks will provide many independent station years of record in a very short time.

WALDO E. SMITH,[33] M. AM. SOC. C. E. (by letter).—A welcome addition to the literature relating to the frequency of rainfall is found in this paper, which provides a statistical analysis of the frequently accepted and widely used station-year approach. It gives an index to the probable reliability of rainfall frequencies determined by that method and provides further an outline of a new method utilizing the basic statistical record. Mrs. Clarke-Hafstad is to be commended for her splendid presentation.

As the paper has its background in the mathematics of statistics, the major part of which the author has intentionally omitted, there are questions which arise that the reader is unable to answer. One of these is in connection with the statement under "Factors Affecting the Accuracy of Frequency Determinations: The Length of Independent Record" that "* * * there are 99.7 chances out of 100 that the mean computed for these 500 years * * * is not more than * * * 30% away from the true average * * *; and there are 68.3 chances out of 100 that this mean will not exceed or fall short of the true mean by more than * * * 10%." The writer believes that a little more explanation on the normal curve leading to the 99.7 and the 68.3 would not be out of place.

It appears that this method should have application to flood frequencies based on the historical record at a given gaging station. Inasmuch as this is a matter of treatment, station by station, to a large extent, data are even more meager, in a way, than for the determination of rainfall frequencies. With 100 years of historical record, it has been customary to call the largest flood within this period the 100-year flood. It is indeed quite disconcerting to find that this is correct to within the limits of $\pm \infty$, or (see heading mentioned previously) that "nothing actually is known concerning the frequency * * * from a single observation * * *." This approach does not take cognizance of the fact that this is not truly a single observation, but bears a certain relationship to others of lesser magnitude. Similarly, the second highest flood in such a record, usually given with some confidence as the 50-year flood (although doubt is acknowledged on the frequency of the greatest flood), has a standard error of frequency of ± 100% (this cannot be − 100%). Inasmuch as the hydraulic engineer must, perforce, deal with the historic record and must base his designs on these elusive frequencies of great floods, this conclusion is likewise disturbing. It would seem more reasonable for this purpose to use the equation first given—namely, the standard error equals $\frac{1}{\sqrt{n}}$. This is probably nearer the truth. It acknowledges the possibility of a 100% error in the first value and about 70% in the second.

---

[33] Head, Hydrologic Land Use Section, Hydrologic Div., SCS, Washington, D. C.

The symbol N_a is defined as the average number of stations affected by a storm of given intensity, whereas N_d equals the number of stations on the average receiving a given amount in each storm day. Assuming that a day is the period for the N_a-values, the definitions would appear to the writer to be identical. The author indicates that there are very limited conditions only for which this would be true, which the writer has been unable to follow. The wide disparity between the findings of the two values indicates a wide difference in concept that should be more fully explained. The fact that either N_a or N_d is used in evaluating the equivalent of a station-year record to a record of the same length, for a single station, would imply that the values should not be greatly divergent.

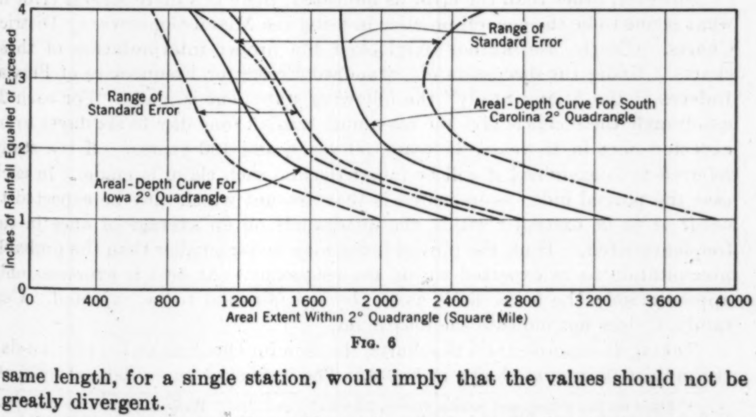

FIG. 6

An interpretation of N_a or N_d, with regard to regions and seasons for a given region, is that they may be, to a limited extent, indexes of the rainfall characteristics. On the South Carolina area, on which there is one station for each 1,055 sq miles, the average extent of 1-in. storms within the 2° quadrangle is 3.10 ± 0.57 stations or 3,270 ± 600 sq miles. In Iowa there is one station for each 677 sq miles and the average 1-in. storm within the quadrangle covers 2,200 sq miles ± 390 sq miles. Determining these areas for the other daily rainfall rates given, and plotting them, define the curves shown in Fig. 6. Inasmuch as heavy rains are of more general extent in South Carolina than in Iowa, one may conclude, at least tentatively, that they are affected less often by the purely convective influence. The plotting of the spread of the standard error gives an idea as to reasonableness of this value, determined on a statistical basis. It would appear in Fig. 6 that the standard error as found for 4 in. for South Carolina is definitely out of line with the others found, and one may feel some justification in applying an adjustment to the standard errors determined by the statistical method.

The author makes reference to the Republican River flood of May, 1935 (see heading "Factors Affecting the Accuracy of Frequency Determinations"), and states "that no gage recorded the rain storm which produced" the flood. An inspection of the published data[34] for this flood shows that several rain gages measured the rainfall, although it is true that no one of them secured the maximum catch indicated by certain unofficial measurements.

Robert L. Lowry, Jr.,[35] M. Am. Soc. C. E. (by letter).—It is fairly easy to prepare a diagram showing the "standard error" in relation to the number of observations for various frequencies. This has been done in Fig. 7, in which the equations for the standard error plat as straight lines on double logarithmic paper. From such a chart the probable errors in frequency for any given conditions can be determined without computation. The chart shows at a glance the magnitude of the errors when only short records are considered.

However, other than the error as indicated, there is a more serious error in what seems to be the general practice in using the Miami Conservancy District Charts. Clearly, the author overlooked the proper interpretation of these charts. Under the discussion of "Standard Errors for Frequencies of Pluvial Indexes of the Miami Study" the following statement is made: "For each 2° quadrangle these charts give the maximum rainfall (one day to six days) to be expected once in 15 years, 25 years, 50 years, and 100 years." If the study referred to is examined it will be found that no such claim is made. In each case the pluvial index as indicated is that amount which may be expected to occur or to be exceeded within the quadrangle on an average of once in the frequency cited. Thus, the pluvial index may be far smaller than the probable precipitation to be expected within the frequency. At best it expresses only approximately the lower limit as to the precipitation to be expected. Certainly, it does not indicate the maximum.

Taking an example from the charts, the data for Quadrangle I–14 for a 3-day storm were plotted as shown in Fig. 8. The frequency curve defined by these data has been extended in both directions purely for illustration. The interpretation of this curve is that the precipitation indicated for any frequency is that which may be expected to occur or be exceeded. By how much it may be exceeded is not known. That is where the trouble lies. Presumably, it could be anything up to the probable maximum that may be expected; but this probable maximum is also unknown. It is known, however, that for a 3-day storm in that quadrangle as much as 19.7 in. of precipitation has been recorded. Obviously, the maximum is some greater value.

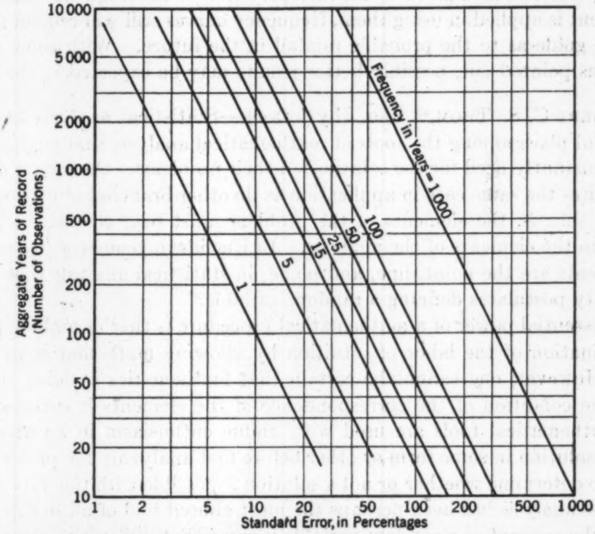

FIG. 7.—RELATION BETWEEN NUMBER OF OBSERVATIONS (IN THIS CASE, YEARS OF RECORD) AND THE STANDARD ERROR FOR GIVEN FREQUENCIES

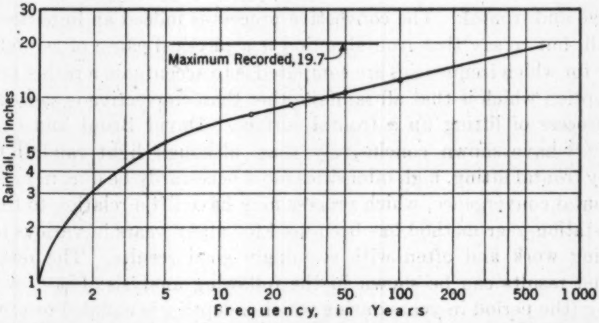

FIG 8.—DATA FROM MIAMI CHARTS FOR QUADRANGLE I-14 FOR A 3-DAY STORM

From the charts it is not possible to determine what the maximum rainfall for any frequency may be. Yet it is the maximum that is required in hydraulic studies rather than the value indicated by the charts. Therefore, when the maximum is unknown, it seems that the probable error in the lower limit is of rather small consequence.

If more attention is given to the interpretation of the frequency curves and if judgment is applied in using them, frequency curves still will remain the best available guide as to the probable rainfall in the future. With some of their limitations pointed out, possibly better results may be expected in the future.

HERBERT C. S. THOM,[36] ESQ. (by letter).—Statistical analysis has taken its rightful place among the tools of mathematical analysis that engineers and others constantly need for the solutions of their problems. As such it deserves and requires the same care in application as do other branches of mathematical analysis; that is, the elements of the problem must bear the closest possible relation to the elements of the analysis. In Euclidean geometry, for example, the elements are the point, line, and plane; in statistical analysis they are the probability postulates defining a random variable.[37]

The essential power of a mathematical procedure is that of making possible the elimination of the labor of intuition by allowing mathematics to do this work. However, one cannot be certain that mathematics is doing the work unless the condition of the correspondence of the elements is satisfied. Too often mathematical tools are used with undue enthusiasm in an attempt to obtain a solution in some form or other before first analyzing the problem sufficiently to determine whether or not a solution is possible with the data at hand. Statistical analysis has been perhaps the most abused tool of all in this respect because the concept of a random variable is somewhat difficult to comprehend. Nevertheless, it is a definite branch of mathematics and must be applied only to such problems for which it can give solutions—problems involving random variables.

The author classifies rainstorms into two types and then states that their fundamental distinction is based on the types of physical processes—namely, convective and frontal. The convective process is indeed an important cause of rainfall, but to say that frontal action is a physical cause of rainfall of the intensity for which frequencies are computed is to accentuate a rather prevalent misconception which is that all rainfall other than convective is caused by the simple process of lifting up a frontal surface. David Brunt and C. K. M. Douglas[38,39] have shown conclusively that, although light rainfall may be caused by frontal lifting, high intensities must necessarily be due, in most cases, to horizontal convergence, which process may have little relation to fronts.

The station-year method has been used for many years in various forms of engineering work and often with seemingly good results. The reasons for these good results can be shown in the following analysis: Let T = rainfall frequency (the period in years during which a depth y is equaled or exceeded); R = the number of years of record; $\bar{N}$ = average number of storms per year;

---

[37] "On the Statistical Analysis of Rainfall Data," *Transactions*, Am. Geophysical Union, 1940, p. 490.

[38] "Physical and Dynamical Meteorology," by David Brunt, Cambridge University Press, 1939, p. 354 *et seq.*

[39] *Memoirs*, Royal Meteorological Soc., Vol. III, No. 22, p. 34 *et seq.*

p = the probability of an event equaling or exceeding y; q = the probability of an event being less than y; and N_p = the number of occurrences equaling or exceeding y. Now

$$T = \frac{R}{N_p} \qquad (4a)$$

and

$$N_p = \frac{R}{T} \qquad (4b)$$

so that

$$p = \frac{N_p}{R\bar{N}} \qquad (5)$$

It can be readily seen that if station records are to be combined by means of the station-year method, the frequency curves must be the same at every station. Under this condition $\bar{N}$ will be the same at all stations. When more stations are added, N_p and R will vary directly; hence p will remain practically constant regardless of how many stations, independent or not, are added. This does not mean, however, that new information proportional in amount to the increased number of stations has been added.

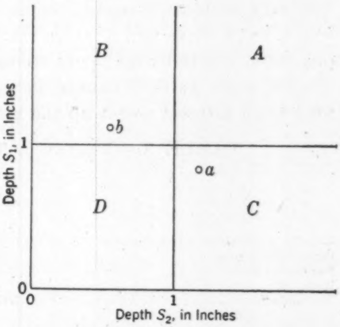

FIG. 9.—CORRELATION TABLE

The author purports to determine the dependence or correlation between stations by Bartels' technique[17] for obtaining the effective number of random components. Bartels claims his technique to be useful only in problems where the analogy with the casting of dice or drawing of random numbers is good. However, in a correlated multi-variate population such as is produced by a group of stations in a 2° quadrangle, the analogy is very weak and consequently Bartels' statistic is rather inefficient. The author has ignored much of the dependence by considering only storm events at the stations that exceeded 1 in. or some other base value. This can be seen clearly in Fig. 9, which shows a correlation table for depth at station S_1 against depth at station S_2. Thus, an event producing 0.8 in. at S_1 and 1.2 in. at S_2 would plot as point a in Fig. 9, whereas another event producing 1.2 in. at S_1 and 0.6 in. at S_2 would plot as point b. Since there are twenty-one stations in Table 1, there will be ${}_{21}C_2 = 210$ correlation tables. If the author's data were plotted in Fig. 9, only square A would contain observations. This procedure ignores any dependence introduced by the simultaneous occurrence of events in squares B and C as well as in D. The computation of the author's value of N_d for various other frequencies does not overcome this difficulty. A further and more serious criticism arises from the fact that the observations in square A do not constitute a random sample and, therefore, should not be operated on with statistical methods. The Bartels' statistic applied to completed tables of the form shown in Fig. 9 would be identical with the square correlation ratio. It is well known that the correlation ratio is an especially poor statistic when computed from tables with only two class intervals—for example, storms producing rains less than 1 in. and storms producing rains of more than 1 in.

R. A. Fisher[40] has decried the computation of a standard error for the correlation ratio because "even with indefinitely large samples the distribution of η for undifferentiated arrays does not tend to normality unless the number of arrays is also increased without limit." The standard error has little significance if the distribution is not normal.

Emphasis should be placed on the fact that only a single rainfall value at a particular station may be used from each storm; otherwise the successive events would not be mutually exclusive and no form of statistical analysis would then apply. If the author did not choose storm events so that they were mutually exclusive, then the results of her analysis would be very uncertain. The lack of mutual exclusiveness may be illustrated by the casting of a die which has a three and a six on the same face so that when that face turned up one could not tell whether to consider the event as a three or a six.

Although Table 1 cannot be analyzed by the analysis of the variance, it may be of interest to set up the variance table because the values can be used in other computations. The variance of a set of values is the expected value of the squared deviations from their mean. In the case of samples of greater than 30, it is equivalent to the squared standard deviation.

TABLE 8.—VARIANCE TABLE (MEAN FREQUENCY, 7.27)

Variation (1)	Sum of squares (2)	Degrees of freedom (3)	Variance (4)
Between stations	254	20	12.7
Between years	2,334	31	75.2
Residual	4,029	620	6.50
Total	6,617	671	9.85

Table 8, Col. 2, gives the sum of squares of the differences of the frequencies from the appropriate mean frequency, stations, or years. Col. 3 is simply a number by which the "sum of squares" is divided in order to obtain the expected value of the variance. In this table "degrees of freedom" (Col. 3) is one less than the number of observations in the columns or rows for stations and years, one less than the total number of blocks for the total, and the remainder for the residual. Since the residual variance 6.50 represents the random variation in the table, it would be expected that, if samples were independent, the residual would be equal to, or greater than, the Poisson sampling variance, which is equal to the mean and less than the Bernoullian variance. The latter represents independent sampling conditions. Inasmuch as the residual is 10% less than the mean, it may be concluded that there is dependence within the table. It can be readily seen that this is true in Table 1.

This dependence upsets the application of the analysis of variance because the essence of this analysis is to compare the residual, to the explained or year and station, variances; but as the residual variance is subnormal and the between-year variance is therefore supernormal, no comparison can be made. A further criticism of the application of the analysis of variance is that the distribution within the table is not normal and a transformation would have to be made to make it normal. However, by comparison with an analysis of a similar table,[41] it may be concluded, from comparing the station variance to the residual by means of the z-distribution, that there is a significant variation from station to station and that, therefore, the stations with greater frequency have been similar in the different years, at least indicating that the station classification is important. As to the highly supernormal variation between years, nothing can be said. It will be noted that the author's σ_1^2 is the total variance of Table 8, whereas σ_{21}^2 is approximately the variance between years divided by 21. If the "sum of squares" between years had been divided by 32 instead of by 31 it would have been exactly equal to it. A better estimate of the variance is obtained, however, by dividing by the "degrees of freedom" rather than by the number of observations.

---

[40] "Statistical Methods for Research Workers," by R. A. Fisher, 4th Ed., 1932, p. 235 *et seq.*

It is seen further from Table 8 that the author's value of N_d is simply the between-years "sum of squares" divided by the total and multiplied by 21, or 0.353 times the number of stations. In fact, the author could have obtained N_d more easily in this way. However, the interesting fact is that 0.353, the explained "sum of squares" divided by the total, is like a squared correlation ratio of years on stations. The importance of this fact is that N_d is as inefficient as η^2 and further, having been estimated from a supernormal between-years "sum of squares" and a subnormal total "sum of squares," it is considerably too small. The squared correlation ratio can be interpreted only as the percentage of the total variation introduced by the year classification. It cannot even be interpreted as the percentage of common causes unless the causes are linearly related and *a fortiori*, not as the number of independent events. Since the distribution of η would be still skewed for thirty-two classifications,[40] its standard error has little meaning.

A word of caution might be inserted here about the standard error. The statistic "standard error" has sometimes been interpreted to be some standard or even mystical measure of error like the old probable error that has practically gone out of use. Neither the standard error nor the probable error, unfortunately, has any such connotations. The standard error is simply the standard deviation of a statistic, and the probable error is 0.6745 times the standard deviation. The standard deviation is a measure of the dispersion of the measures about their mean and only in the case of a normal distribution does it have any significance as a measure of error. Thus $a \pm \sigma$ means that the chances are about two to one that a measure or statistic will lie between $a - \sigma$ and $a + \sigma$, and $a \pm 2\,\sigma$ means that the chances are nineteen to one that it will lie between $a - 2\,\sigma$ and $a + 2\,\sigma$. Likewise, the probable error r is interpreted as even chances that a measure of the statistic will lie between $a + r$ and $a - r$ and nine to two that the measure lies in $a \pm 2\,r$. In modern statistical analysis the odds are usually taken as nineteen to one (that is, $a \pm 2\,\sigma$); thus only one observation in twenty will fall outside of $a \pm 2\,\sigma$ due to random causes. Even if the various standard errors that the author has computed had significance, they would still only give odds of two to one against observations exceeding them, or one out of three observations would lie outside the limits set by the author.

---

[41] "Statistical Methods for Research Workers," by R. A. Fisher, 4th Ed., 1932, p. 214 *et seq.*

In computing the standard deviation of the frequencies, the author has followed the questionable reasoning of Professor Grant[12] in assuming without *a priori* justification that the station frequencies follow a Poisson (exponential) distribution. The fact that large rainfalls are rare is not *a priori* justification for assuming that these events are distributed in a Poisson (exponential) distribution or the so-called "Law of Small Numbers." It can be shown[42] readily that if $p\ (= 1 - q)$ is the probability of a storm equaling or exceeding y then the frequency N_p will be distributed in a binomial distribution $(p + q)^n$, in which n is the total number of occurrences.

By Eq. 5, $p = \frac{N_p}{R\,\bar{N}}$; and

$$q = 1 - p = 1 - \frac{N_p}{R\,\bar{N}} \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Since it is well known that for the binomial distribution $\sigma^2 = n\,p\,q$, and by definition $n = R\,\bar{N}$, substitution gives:

$$\sigma^2 = R\,\bar{N}\,\frac{N_p}{R\,\bar{N}}\left(1 - \frac{N_p}{R\,\bar{N}}\right) = N_p\left(1 - \frac{N_p}{R\,\bar{N}}\right) \ldots\ldots\ldots (7)$$

Substituting:

$$\frac{1}{T} = \frac{N_p}{R} \quad \text{and} \quad N_p = \frac{R}{T}$$

$$\sigma^2 = \frac{R}{T}\left(1 - \frac{1}{T\,\bar{N}}\right) \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

If $\bar{N} > 50$ and $T > 1$, then $\sigma^2 \cong \frac{R}{T}$. Thus, in Table 3, $T < 1.00$, and $\bar{N}$, the (average annual) number of mutually exclusive and independent events, is not much more than 50, so that the standard errors for the two upper rows are not correct. The standard errors given in Fig. 2, however, are correct.

It is well known that the skewness of the binomial distribution[43] does not tend to zero as n increases if $p = 0\left(\frac{1}{n}\right)$, or if p is the order of magnitude of $\frac{1}{R\,N}$ or less. Under these conditions standard deviations cannot be interpreted as errors, as they can be with the normal distribution. Since $p = \frac{N_p}{R\,\bar{N}}$ (Eq. 5), this happens only when $N_p \leqq 1$, or when the frequency is defined by one storm.

Had the author computed the standard errors by the foregoing procedure there would have been less difficulty in interpreting the standard error for

---

[42] "Frequency Curves and Correlation," by W. P. Elderton, 3d Ed., 1938, p. 185.

[43] "Statistical Mathematics," by A. C. Aitken, Edinburgh, Oliver and Boyd, 1939, p. 58.

$N_p = 1$. Since this involves a binomial distribution with $p = \frac{1}{R\bar{N}}$, the standard error simply is the dispersion about the expected value of N_p, or $n\,p$.

KATHARINE CLARKE-HAFSTAD[44] (by letter).—The discussions have demonstrated a recognition on the part of engineers and hydrologists of a need for more reliable estimates of the intensities and frequencies of rainstorms through adequate analyses of existing rainfall data. Although this closing discussion must deal chiefly with points in the paper on which the writer and the discussers disagree, the writer wishes to express here her appreciation of the interest in the paper and of the constructive comments that will lead to a better understanding of the station-year method.

Because of the nature of the publication and the interests of the readers, it was felt that the mathematics and statistics should be simplified and confined to a minimum. As Mr. Smith states, "* * * the paper has its background in the mathematics of statistics, the major part of which the author has intentionally omitted * * *." Therefore, the statistical part of the paper is unsatisfactory to the statisticians.

At the present stage of development of statistics there is no method for the rigorous determination of the amount of dependence in data that are non-random in both time and space, such as station-year data. Nevertheless, the widespread use of the station-year method by hydrologists necessitated some means of obtaining a measure of persistence in such data and consequently of the reliability of the frequencies determined by the method, and led to the adaptation of the technique described in this paper.

Some of the questions raised in the discussions, such as the one pertaining to the relation between "analysis of variance," discussed by Mr. Thom, and Bartels' method of measuring dependence, had been carefully studied by the writer but were considered inappropriate for discussion in such a paper. They are covered more specifically in a paper[20] by L. R. Hafstad.

The writer protests the statement by Mr. Thom that "Statistical analysis * * * must be applied only to such problems for which it can give solutions—problems involving random variables." Although the philosophies and methods of modern statistics were developed on the premise that only random variables are involved, completely random or independent data are seldom found in natural phenomena. The outlook for progress in climatic and hydrologic research by the use of statistical analysis would be dark indeed if this tool could not be used on observations possessing persistence. It seems to the writer that it is imperative, first, to determine by statistical methods whether or not the data are non-random in character, and then either to eliminate any persistence before using the statistics applicable only to random data, or to devise new techniques for dealing with non-random observations.

Evidently Mr. Thom misunderstood the manner in which the data in Table 1 were derived. Every occurrence of 1 in. or more of rainfall in a day at every station, regardless of the amounts the other stations recorded, was tabulated. If these data were plotted on a correlation table such as Fig. 9, not all the points would fall in square *A*. Thus the data which the writer used are not comparable to those of Mr. Thom and the comparison he made of the square correlation ratio and Bartels' statistic is irrelevant.

---

[44] Asst. Climatologist, Section of Climatic and Physiographic Research, Div. of Research, Section Climatic Service, Washington, D. C.

Mr. Thom's criticism, that much of the dependence is ignored in taking only daily amounts of 1 in. or more, is not clear, since the purpose was to determine the amount of persistence only for those storm days on which 1 in. or more fell at one or more stations. If a lower limit, say 0.80 in., had been selected, one would, of course, expect to find more persistence in the data than in the case of the 1-in. amounts.

Throughout the paper the writer was careful not to use the word "storm" with reference to the daily occurrences of rain, because storm data are not available; and if they were, the storms would be of various lengths and statistical analysis very much complicated by this fact. Mr. Thom states "that only a single rainfall value at a particular station should be taken from each storm." Probably Mr. Thom means that only one daily amount should be used from each storm. The assumption has been made in the paper that the daily interval constitutes the single event, and it is known that these events are not mutually exclusive, or independent. The result of this temporal dependence is to make the data, such as those in Table 1, less random than if there were areal persistence only. Although the effects of these two types of persistence cannot be separated by the method proposed, at least the final measure of dependence, N_d, upon which the reliability of the frequency depends, does include all the persistence in both time and space which tends to decrease the reliability of the frequency.

The writer stated (see heading: "Factors Affecting the Accuracy of Frequency Determinations: Number and Distribution of Stations") that two general patterns of rainfall distribution result from two general types of physical processes taking place in the atmosphere—convection and frontal activity. Mr. Thom assumes that frontal activity consists only in the "simple process of lifting up a frontal surface," and on the basis of this assumption criticizes the writer for stating that frontal action is one of the chief causes of intense precipitation. Mr. Thom would attribute most high intensity rainfall to horizontal convergence.

The writer disagrees with Mr. Thom's concept of "frontal activity." Frontal action should include all processes that may take place in the atmosphere in and near frontal surfaces—vertical motion, convergence, and convection. This concept is supported by Sverre Petterssen, who states that:[48]

> "This kind of precipitation [intermittent or continuous from a continuous cloud cover of the alto-stratus or nimbo-stratus type] is caused by the slow upward movement of a large mass of air, due to convergence in the horizontal motion of the air. * * * this type of precipitation is called frontal precipitation."

---

[48] "Introduction to Meteorology," by Sverre Petterssen, McGraw-Hill Book Co., Inc., New York, N. Y., 1941, p. 38.

Messrs. Brunt and Douglas state,[39] "It is now widely recognized that continuous rain is usually associated with 'fronts,' or lines of separation of air masses of different temperature."

Convergence is a part of frontal activity. It is, also, an important factor in releasing and maintaining convection. The intensity of rain at frontal surfaces does not depend entirely on the amount of convergence and the upslope motion. "It depends also on the slope of the frontal surface, the moisture content, and the stability of the air."[46] Although high intensity rains have occasionally been observed to result from horizontal convergence alone with no clearly defined fronts in the vicinity, by far the greater number of occurrences of high intensity rains are associated with the passages of fronts or with convective activity.

In his discussion, Mr. Hodges has attempted to make a practical application of errors in pluvial indexes to the problem of flood forecasting. Unfortunately, the writer cannot agree to the transformation from error in frequency to error in pluvial index suggested by Mr. Hodges. The standard errors given in Fig. 2 are simply errors in the spacing in time of any given amount of rain, based on the assumption that the number of occurrences of that amount in the station-year record is known, and that the frequency distribution of these amounts follows the Poisson law. Since the analyst does not know the error in the number of occurrences of the given amount from which number the pluvial index is derived, nor the form of the distribution of rainfall amounts against number of occurrences, he is not justified in assuming that he knows anything about the error in the pluvial index.

The writer had never heard of the method for deriving rainfall frequencies from a station-year record mentioned by Mr. Jarvis—that of assuming that the second highest value in a station-year record has a frequency of once in one half the total years of record, the third highest a frequency of once in one fourth the total years, etc. Indeed, there is no logical reason for determining an average by such a method. If the procedure suggested by Mr. Jarvis were extended, the fifteenth highest value in a 500-station-year record would have an average frequency of once in 11 days. The usual method would give an average frequency of 33.3 years. The difference in these two values could scarcely be considered as the "range in uncertainty regarding the probable error."

Mr. Brod questions the application of station-year pluvial indexes to large drainage basins. As was stated in the paper (see heading "Factors Affecting the Accuracy of Frequency Determinations: Number and Distribution of Stations"): "no 2° quadrangle of the earth's surface will have uniform characteristics of rainfall"; and, as Mr. Bernard emphasizes, the station-year method should be applied only to a region having in all its parts the same rainfall regime. Although no detailed studies have been made to determine the size of such areas, it is certain from meteorological considerations that they are of extremely limited extent, certainly not as large as the area included within a 2° quadrangle of latitude and longitude. Professor Grant's study[12] concerned only the determination of areas homogeneous with respect to the frequency of very high rates of rainfall. The writer may perhaps be pardoned for emphasizing once more that areal dependence in the station-year data is just as important a factor detracting from the value of the method as is the dependence between successive years and successive storms and the dissimilarity of rainfall stations mentioned by Mr. Brod.

---

[46] "Weather Analysis and Forecasting," by Sverre Petterssen, McGraw-Hill Book Co., Inc., New York, N. Y., 1940, p. 425.

It may be of interest to engineers to know that the Climatic and Physiographic Division of the Soil Conservation Service is conducting an investigation of rainfall probabilities. At present (1942) the project is confined to the development of an improved statistical technique for determining the probabilities of various rainfall intensities for selected stations in the United States. The data being used are the actual maximum amounts for selected time intervals, read from the triple-register sheets of the recording rain gages.

Mr. Bernard has contributed a very clear explanation of the manner in which a station-year record is synthesized. One reading it cannot fail to understand why and how there is introduced into the composite record a certain amount of "dependence" between the station records. From Mr. Bernard's theoretical considerations of the morphology of rainstorms it is evident that the hydrologist needs to know much more about the size of areas receiving various depths of precipitation in rainstorms, and about the relations between the intensities and total amounts that actually occur in the storms and those that are recorded by various spacings of rain gages. Until some studies of these features are made one cannot hope to obtain reliable values of average frequencies of various amounts of rain, or of total actual precipitation falling on drainage basins.

Mr. Ruff's question as to whether, from a measure of the dependence between stations, one could estimate the frequency and amount of rain at surrounding stations when a given station has its 50-yr rainfall, must be answered in the negative. If the form of the mean depth-area distribution curve for rainstorms were known, one could calculate the probability that an area of a certain size received the 50-yr amount when it was observed at a single station; but as Mr. Bernard points out in his conclusion, the position of the station receiving the 50-yr amount with respect to the pattern of the rainfall for this single storm will not be known from the observations at this one station, and therefore its observed depth will give no clue to the depth or frequency of the rain occurring at surrounding stations.

Mr. Smith has compared the standard errors for the mean areal extent of rainstorms in South Carolina and Iowa (see Fig. 6 and supporting text) and concludes "that the standard error as found for 4 in. for South Carolina is definitely out of line with the others * * *." One is not justified, however, in comparing in this manner the standard errors in average extent of rainstorms for the two areas, since the length of record and the spacing of stations is not the same for the Iowa quadrangle and for the Carolina quadrangle. The Iowa rainfall data are for twenty-one stations for 32 years, or 672 station years, whereas the Carolina data are for fifteen stations for 20 years, or 300 station years. Since the size of the standard error of the mean number of stations receiving a given amount of rain in a day is a function solely of the number of observations of that amount in the total record, it is not unreasonable to find that the error for the 4-in. amounts in the Carolina quadrangle is larger than for the Iowa quadrangle which has the longer record.

Mr. Smith has indicated, also, that there is some difficulty in distinguishing between the definitions for N_a and N_d used in the paper. Symbol N_a is the notation for the average number of stations receiving a given amount of precipitation in a calendar day, and N_d is an index of the number of statistically dependent ordinates. In the theoretical case described under the heading "Determination of Dependence Between Stations," the writer set up an artificial situation with a known amount of dependence between stations by assuming that a certain amount of rain always fell at exactly the same number of stations (5) on each day of rain, and that the days on which this amount occurred were distributed at random among the years of record. Some misunderstanding of the definitions may have resulted because in this theoretical case $N_a = N_d$. In the application of the test for dependence to actual rainfall data, such as Table 1, there will be dependence both between years and between stations and $N_a \neq N_d$, as was stated under the heading "Determination of Dependence Between Stations."

Mr. Smith is correct in stating that several rain gages measured the rainfall associated with the flood on the Republican River in May, 1935. However, it is doubtful whether this flood would have been expected from the measurements of these gages alone. Although unofficial measurements in stock tanks, cans, etc., in the area of highest intensity reached 13 in. (one even 24 in.), the highest amount recorded by a Weather Bureau gage was 5.05 in.

It is unfortunate that the writer defined the pluvial index (see "Introduction") as "the maximum rainfall to be expected with a certain frequency." As Mr. Lowry states, the correct definition as used in the Miami study is "that amount which may be expected to occur or to be exceeded * * * on an average of once in the frequency cited." In the case cited by Mr. Lowry for Quadrangle I-14 of the Miami Charts, 12.6 in. is the pluvial index corresponding to an average frequency of 100 years. However, the "most probable value" of a distribution is usually defined as the mode, and if this definition is used it is not certain that the most probable maximum value to be expected in a time interval of 100 years will be higher than the pluvial index of 12.6 in. Mr. Lowry probably referred to the mean maximum value, which will be somewhat larger.

Although very little is known concerning the distribution of rainfall amounts, there is evidence to support the assumption that they form some type of exponential distribution. In the following example (contributed by George Blumenstock, Jr., of the Climatic and Physiographic Division of the Soil Conservation Service), a simple exponential distribution

$$f(x) = e^{-x} \qquad (9)$$

is used to clarify the distinction between the value of the variable x (the pluvial index) corresponding to a mean recurrence interval, T, and the most probable maximum and mean maximum values of x in an equivalent interval.

First, determine the value, K, of the variable, x, for which the mean recurrence interval is T (that is, the value of x which may be expected to be equaled or exceeded on the average once in every T trials). This value, K, is defined by the relationship:

$$\int_0^\infty e^{-x}\,dx = T\int_K^\infty e^{-x}\,dx \ldots\ldots\ldots\ldots\ldots\ldots(10)$$

from which:

$$K = \log_e T \ldots\ldots\ldots\ldots\ldots\ldots(11)$$

In a random sample of T events drawn from the population $f(x)$, the probability distribution of the largest value will be given by the relationship:

$$\phi(x) = T\,F^{T-1}(x)\,f(x) \ldots\ldots\ldots\ldots\ldots\ldots(12)$$

The mode, u, of this distribution is the most probable maximum value, and will be given by the solution of the equation:

$$\frac{T-1}{F(x)}f(x) + \frac{f'(x)}{f(x)} = 0 \ldots\ldots\ldots\ldots\ldots\ldots(13)$$

This leads to the result:

$$u = \log_e T \ldots\ldots\ldots\ldots\ldots\ldots(14)$$

It is to be seen, then, that at least for the type distribution $f(x) = e^{-x}$ for any given recurrence interval, T, the corresponding value, K, is exactly equal to the mode, or most probable value, of the probability distribution of the largest value of x for an equivalent time interval.

In the case of rainfall data, however, the mean of distribution (Eq. 12) will often be a more significant measure of the maximum value of x to be expected in T trials. R. A. Fisher and L. H. C. Tippett[47] have shown that for an exponential distribution similar to Eq. 9, the mean, $\bar{u}$, of Eq. 12 for large values of T is given by:

$$\bar{u} = u + \frac{c}{\alpha} \ldots\ldots\ldots\ldots\ldots\ldots(15)$$

in which u is the mode; c is Euler's constant, 0.57721+; and α is defined by:

$$\alpha = \frac{f(u)}{1 - F(u)} \ldots\ldots\ldots\ldots\ldots\ldots(16)$$

For the distribution defined by Eq. 9, it follows from Eq. 16 that α is equal to 1, and, since $K = u$:

$$\bar{u} = K + c \ldots\ldots\ldots\ldots\ldots\ldots(17)$$

The distinction between the value K corresponding to a mean recurrence interval, the most probable maximum u, and the mean maximum $\bar{u}$ is now clear. For the original distribution $f(x) = e^{-x}$ one may now say:

(1) The value K corresponding to a mean recurrence interval, T, is (Eq. 11): $K = \log_e T$. This is also the most probable maximum value, u.

---

[47] "Limiting Forms of the Frequency Distribution of the Smallest and the Largest Member of a Sample," by R. A. Fisher and L. H. C. Tippett, *Proceedings*, Cambridge Philosophical Soc., Vol. 24 (1928), pp. 180–190.

(2) The mean maximum value $\bar{u}$ in T trials is

$$\bar{u} = \log_e T + c \qquad (18)$$

For example, where T is assumed equal to 100 (a mean frequency of 1 in 100) the value of K and u is $\log_e 100$, or 4.605, but the mean maximum, $\bar{u}$, in 100 trials is 5.182.

It should be emphasized that these relationships have been selected only to show that a distinction between the three values does exist. In the case of rainfall data the exact character and extent of the distinction depend upon the distribution $f(x)$ which may be selected as representative of the total population of rainfall amounts from which the sample is drawn.

TUNNEL CONSTRUCTION, SIXTH AVENUE SUBWAY, NEW YORK, N. Y.

By Jacob Feld,[1] M. Am. Soc. C. E.

With Discussion by Messrs. John H. Myers, and Jacob Feld.

Synopsis

As part of the contract to construct Section 10 of the Sixth Avenue Subway, between 40th and 47th streets, in New York City, one double-track, and two single-track, tunnels were driven for three blocks under a busy city street, under the foundations of an operating elevated railroad, very close to buildings varying from two to sixteen stories in height, through a variety of rock formations, and with scant cover. This paper describes how the work was planned and organized to provide efficient and continuous progress, how it was executed, and at what cost; and it describes the type and adaptability of the equipment used. The major factor in the execution of this work was the necessity for safety.

General Description of the Contract

The contract included the construction of a four-track subway for a distance of 1,800 ft in Sixth Avenue, which is 100 ft wide, and crossed seven intersecting streets. The southerly part of the work, including a station, was built in open cut. The northerly end of the contract, about 260 ft long, was also built in open cut. Between these two areas the four tracks were built in tunnel without disturbing the street surface. The work was done under a unit price contract, the tunnel work being included in the total contract items. As far as plant and equipment were concerned, the construction of the tunnels was merely part of the total contract, except as certain special equipment was found necessary for the tunnel operation (see Fig. 1). The contract plans and specifications were prepared by the Board of Transportation of the City of New York. The contract was awarded on February 6, 1936, and the tunnel work described herein was executed from June, 1937, to April, 1938.

General Plan and Specifications

The plan of the east half consisted of a double-track tunnel running in a straight line under the easterly half of Sixth Avenue, from a point 50 ft south

---

Note.—Published in April, 1941, *Proceedings*.

[1] Cons. Engr., New York, N. Y.

of 46th Street for a distance of 720 ft. At approximately the middle of this length there is a ventilating and emergency exit shaft serving both of these tracks and running to the street surface. At two other points, in 44th Street and in 45th Street, the easterly tunnel is widened out to provide space for a cable-duct manhole connected to the street surface with a cable-pull pipe 10 in. in diameter. Starting at the 46th Street end, the third track from the east is in a single-track tunnel that dips sharply downward to the west emergency exit shaft (see Fig. 1) and a sump to which the drainage of all the tunnels is connected, and then is carried upward at the same grade, making a total distance of 814 ft, emerging into an open-cut area south of 43d Street at the west side of the street. This tunnel is built on a curve to change the track position from the third to the fourth lane. South of 45th Street, at about its lowest point, this tunnel connects to a ventilation and emergency exit shaft carried to the street surface. From the southerly face of this shaft the fourth tunnel starts near the west building line of Sixth Avenue directly over the third tunnel and crosses from the fourth to the third lane, entering the open-cut area at 43d Street. The double-track tunnel required an excavation approximately 18 ft high and 32 ft wide. Each of the single-track tunnels required an excavation approximately 18 ft high and 18 ft wide.

FIG. 1.—PLAN AND PROFILE OF TUNNELS

Specifications provided that the methods used for tunneling should be suitable to the local conditions, and must not cause any injury to the foundations, walls, or other parts of adjacent buildings, structures, or surfaces, such methods to be subject to the approval of the engineers before work was begun. Such methods were to be changed from time to time as local conditions required, but at no time was the approval of the engineers to relieve the contractor of his responsibility for the proper execution of the work. The contractor had the option to design and submit for approval any method of temporary timbering for the support of the rock before the concrete lining was placed. As local rock conditions made it advisable, the engineer had the right to order the tunnel lining placed before the excavation was completed.

FIG. 2.—TYPICAL TUNNEL SECTIONS

The single-track tunnels were to be lined with concrete as shown in Fig. 2, such lining to include no reinforcing or structural steel. The double-track tunnel was also lined. The two arches met in an umbrella section, in which a series of bents was concreted, consisting of double channels supported on two columns. The center wall between the two tunnels in which these bents are concreted has a series of cross-connecting openings spaced 15 ft apart. In each of the single-track tunnels there was a series of man safety niches in one side, spaced 15 ft apart. On one wall of the double-track tunnel, and on one wall of one single-track tunnel, a line of clay cable ducts was to be built, consisting of thirty individual 3.5-in. ducts connecting the manholes. On the other wall of the double tunnel, and in the other single tunnel, a raised walkway was to be built at the level of the subway car platforms for emergency and patrol use. The invert of all tunnels is 12 in., with cast-iron drain pipes laid in certain locations, cross-connected between the two tunnels near the north end, all draining to the sump.

The contract provided that the surface of the concrete lining was to be smooth and of a type known as "finished surface." The contractor had the option to use steel forms so as to eliminate the need for rubbing the concrete. Grout holes were left in the concrete lining for filling any spaces left between the rock and the concrete. The installation of track, cables, and other operating equipment was not part of this contract.

BORINGS AND GEOLOGY OF SUBSURFACE

Prior to beginning the work, the city had several sets of borings made in the area under which the tunnel was to go, and reports of these were furnished to the contractors. Four of the borings were driven almost 200 ft below the street surface, chiefly to check what leakage could be expected from the Catskill Aqueduct approximately that distance below Sixth Avenue. These borings were one in each block (260 ft apart) and showed a great variety of rock recoveries, the samples removed ranging from 1% to a maximum of 93% of the boring depth. In addition, there were seven other borings taken to rock surface with a 10-ft core into the rock, and the recoveries varied from 1.4 to 7.7 ft of that distance.

In addition to the borings several maps were also available showing the accumulation of previous information, none of which, however, indicated the complexity of rock formations actually encountered. For instance, a field report of June, 1937, described

> "* * * rock in both tunnels of great variety, from soft, disintegrated schist to an extremely hard igneous syenite with seams of feldspar, which in some cases is so disintegrated that it can be taken out by hand. Seams are generally almost vertical, slight tip to the West and running almost to South slightly to East."

In general, the basic rock was schist, but in the volume occupied by the tunnels there were a great number of intrusions in the form of bands running southward about 20° to the east and almost vertical, sometimes tipped 5° to 20° to the west. At the north end of the tunnels a band of very hard syenite with quartzite intrusions was found crossing the double tunnel. In the vicinity of 45th Street a very hard and fine-grained syenite crossed all four tunnels. To the south of this band was a layer of disintegrated syenite which was so soft that it could be broken easily by hand, and, in the terms of the blasters, was "dead." South of this point there was more mica schist, which again changed to disintegrated syenite a few feet in thickness, in contact with several layers of chlorite and serpentine, interspaced with disintegrated syenite. These latter layers were encountered at the extreme south end of the double tunnel, affecting the westerly part only, and crossed the south end of the Washington Heights southbound single tunnel near its southerly end, and also crossed the Queens southbound tunnel about 300 ft from its southerly end. Keeping in mind that these layers were encountered practically on edge and running diagonally across the face of the headings, the complexity of the drilling and blasting operations can be pictured easily. Practically no water was encountered at any point.

Surface and Subsurface Conditions

The street width is 100 ft, and buildings occupy every available piece of ground the full length of the tunnels. These buildings vary from altered four-storied brownstone residences with stores on the ground floor, built about 1880, to modern, fireproof, seventeen-story office buildings. In the middle of the street there was a two-track elevated railway, supported on wrought-iron columns spaced on 43-ft centers longitudinally, with two columns 23 ft apart in each bent. Train operation of this railway was continuous, with the average headway about 5 min each way. The columns rested on brick piers, some of which were carried to rock, and others were in the nature of spread footings several feet above rock elevation.

Prior to the beginning of any construction, a careful examination was made of each building on Sixth Avenue, and also the buildings within a distance of 100 ft east and west of Sixth Avenue. These examinations were made by representatives of the Board of Transportation and the contractor, and usually the owner of each building. Stenographic notes were taken during the examination, and the report was signed by all those present. Where unusual conditions were found, the contractor also took photographs for his records. At the completion of the work these buildings were again examined to determine whether any changes had occurred.

To avert breakage of windows as far as possible, a wire cable and timber trussing were placed over each window with either dimension greater than 6 ft. This included all of the show windows. These "spiders" were kept in repair during the entire operation, and not one of the show windows along the line of the tunnel was broken.

In the avenue itself, below the surface, there was an old brick sewer in the center about 14 ft down, built in 1890, or before, in a rock trench. At higher levels there were two cast-iron water mains, one 20 in. and one 12 in., with 12-in. lines crossing the avenue at each street. Two steel gas mains were constructed in the avenue under the subway contract, prior to any tunnel work, to replace a great variety of old cast-iron gas mains that were found. In some points as many as twelve old gas mains were thus replaced. In the easterly part of the roadway there was a large bank of telephone cables laid in clay ducts, containing approximately 25,000 telephone circuits. There were also two banks of clay ducts containing low-tension and high-tension power cables, one at each curb, with sub-branches and service lines. Similar subsurface equipment also existed in each of the cross streets.

Approximately 200 ft below the street surface there is a concrete-lined aqueduct tunnel of 15 ft inside diameter, bringing water under pressure into the city. The fear that subway construction would affect this tunnel delayed the construction of the Sixth Avenue Subway link until such time as the second aqueduct tunnel was completed in 1934. Such fear was unfounded, as proved by the record that no serious leakage was encountered at any point along the Sixth Avenue Subway construction.

Relation of Tunnels to Remainder of Contract

The open-cut work was the most important part of the contract, and the location of shafts for tunnel work was controlled by points fixed in the contract. Therefore, the plant layout in the tunnels, with the exception of special equipment used in the tunnel work, was included in the layout for the entire contract (see Fig. 3). As far as the tunnel excavation was concerned, all material was removed in cars on industrial track to a shaft at the southwest corner of 46th Street, which was located at the west building line about 60 ft north of the portals of three of the tunnels and about 200 ft north of the fourth portal. The subgrade elevation of the track adjacent to the shaft was 10 ft higher than the elevation of the subgrade of the tunnel portals. The disposal shaft was carried approximately 20 ft below the subgrade of the adjacent track, and a crosscut at the elevation of the lower tunnels was excavated to permit bringing cars to the shaft at tunnel grade. In the shaft a steel tower was constructed to accommodate a 6-cu-yd steel skip. By bridging the crosscut, cars could be dumped into the skip at two different levels 10 ft apart, the lower level taking care of the three tunnels, and the upper level taking care of most of the open-cut and the fourth tunnel. The skip was operated by a hoist located above 46th Street on a steel and timber framework, the drum thereby being spaced 50 ft from the guide sheave so as to permit a reasonable fleet angle of the hoist cable as it ran on the drum. The guide sheave was pinned for rotation about the vertical axis.

Adjacent to the shaft, there was a compressor house and transformer vault, from which compressed air and electricity were supplied for the entire contract. Equipment for the compressor house consisted of three, two-stage electrically driven air compressors, each with a rated capacity of 1,320 cu ft at 120-lb pressure. In the transformer room there were three sets of 100-kva units, providing current at 208 volts. The air receivers and coolers were directly below the compressor room, which was at truck elevation above street surface.

All water for cooling was taken from city mains and was metered. During tunnel operation, and also including supply for the open-cut work, power consumption per month ran from 130,000 to 190,000 kw-hr. Water consumption for compressors, for wet drilling, and for all other uses, averaged about 400,000 cu ft per month.

The cost of air production at the compressor plant, as determined during the last six months of 1937 (during which time the plant was operated on

FIG. 3. CONTRACT PLAN AND STATIONS

three shifts with an average production of 1,800 cu ft per min), was $0.0865 per 1,000 cu ft. This cost includes the following, per shift: labor, $13.30; insurance, $2.66; power, $52.00; water, $8.50; and miscellaneous, $1.42—a total (without plant construction or equipment costs) of $77.88.

Dynamite for the entire contract was stored in two separate magazines, one at 41st Street and the other near the compressor plant. The 41st Street magazine had a maximum capacity of 100 lb and the 46th Street magazine of 250 lb. Practically all of the dynamite for the tunnels came from the 46th Street magazine, with the exception that some of the night shifts would draw on the other magazine for completing a round. Delivery of dynamite could be made only during daylight hours, and to some extent the blasting was controlled by the quantity that could be stored at the end of each day (approximately 4:30 p.m. during the winter months) for use until 8:00 a.m. the next day. At each magazine, a dynamite watchman was assigned on each shift, and his duties were to mark each stick of dynamite with the license number of the magazine, keep a record of the withdrawals requested by each blaster, and prepare the information required by the Fire Department of the City of New York for the daily check on the use and purchase of dynamite. In the tunnel work, all dynamite was 40% gelatin. Most of the blasting in the tunnels was by delayed-action blasting caps.

The blacksmith shop for the tunnel operation was in the open-cut already excavated to subgrade beneath the street decking, a short distance north of the tunnel portals. The blacksmith shop was connected to all of the tunnels by industrial track.

All drill steel for the tunnels was 1¼-in. hollow steel, purchased directly from the mill in full random lengths. Typical gage diameters for the bits (standard four edge) were 1⅞ in. for drill steel 12 ft long, increasing ⅛ in. for each 2-ft reduction in steel length. All steel was sharpened, shaped, and shanked at the blacksmith shop, using two complete sharpening units with oil-fired furnaces. Two of these units were operated on one shift, with only one unit on each of the other two shifts. This continuous use required relining of the furnaces twice during the entire contract. This excellent service was due mostly to the use of a special firebrick and latite mortar. During the last six months of 1937 the drill-sharpening cost per cubic yard of rock was as follows: labor, $0.313; insurance, $0.04; fuel, etc., $0.038; and water, $0.006—a total cost per cubic yard of $0.40 (plus equipment costs). The average steel required from the blacksmith was 3.64 pieces per cubic yard of rock, making an average total cost of 11 cents per drill sharpened. A blacksmith unit, consisting of three men, produced 350 pieces of drill steel, sharpened, per shift. The extra gang of men on one shift took care of preparing new steel and reshanking old steel as required.

LABOR REQUIREMENTS, RATES, AND ORGANIZATION IN THE FIELD

Under the terms of the contract, labor requirements, work assignment, and the minimum rates were fixed by the State Labor Law. Under such rules, with the exception of the foremen, no man could work more than five days in one week nor more than eight hours in one day, except in cases of emergency.

In addition, except in cases of emergency, no Sunday work was permitted by city ordinances.

The job was organized on a three-shift basis, with eight hours in each shift, including one-half hour for lunch, payment being made on a straight basis for eight hours each shift. The foremen, including the blasters, worked six shifts a week, and the other men were rotated so that no man worked more than five days in one week. The exception to this rule was the "graveyard" shift, which omitted the shift starting midnight Sunday and only worked five days a week. Tunneling operation was continuous, therefore, from 8:00 a.m. Monday morning until midnight Saturday. However, concrete was poured only during the day shift, except that a part of the day shift was called at 6:00 a.m. to prepare the forms, and in cases of necessity the 4:00-o'clock shift would complete the concreting at the expense of their regular work.

The tunnel operation was considered a part of the entire contract, and under the supervision of the superintendent and master mechanic. However, three junior civil engineers were assigned to tunnel work only, one for each shift, in addition to the office work and planning, which were done by the engineering staff for the entire contract.

Labor rates were fixed in the contract, and they held for the duration of the work under an agreement with the union organizations. Practically no labor difficulty was encountered during the entire tunnel operation. The labor rates were as follows:

Item No.	Classification	Rate
1	Miners, drillers, and underpinners	$1.25
2	Helpers for item 1	1.00
3	Laborers	0.80
4	Blacksmiths	1.40
5	Blacksmith's helpers	1.00
6	Carpenters	1.40
7	Electricians (raised to $1.70 by agreement)	1.40
8	Operating enginemen	$1.65
9	Conway operators (by agreement)	1.25
10	Dinkey runners and maintenance enginemen	1.125
11	Blasters	1.65

Actually, distinct, separate trades were used as drillers and drill helpers, timbermen who did the underpinning and shoring, and timbermen helpers. By special arrangement, mucking operators were paid $1.25, the operating engineman classification only applying to men on the hoists and on a large concrete pump. The operator of the small concrete pump was an apprentice engineman, as were also burners, welders, pipemen, and other mechanics, all at the rate of $1.125.

Each group of drillers and helpers was under the direct supervision of the blaster; the timbermen and helpers were under their own foremen. The foremen were responsible to two shift bosses, each covering twelve hours, who in turn were directly under the superintendent. All the mechanical men were under the master mechanic, who assigned the work and was responsible for the performance of the equipment as well as the operators.

Fig. 4.—Excavation Progress

SEQUENCE OF OPERATIONS

The general sequence of operations, as planned and as actually performed, was to start excavation of the Queens southbound single tunnel and the center cut of the double tunnel at the same time at the north end, and proceed south. The rock was shored simultaneously with the excavation during the drilling periods, except that, where bad rock was encountered, drilling was postponed until the rock was shored to the face. For the single tunnel, the concrete operation was first to pour the two benches and follow with the complete arch, using the benches to support the form. Concreting the invert was postponed until the remainder of the tunnel was completed.

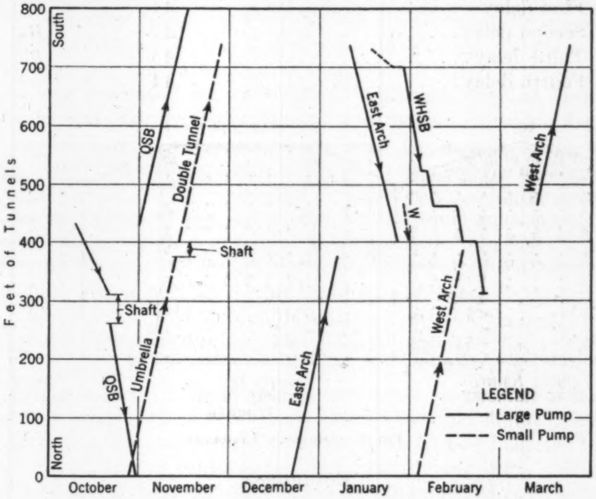

FIG. 5.—PROGRESS, POURING OF ARCH CONCRETE

In the center cut of the double tunnel after completion of excavation, the next step was ring drilling for the widening on each side of the center cut; then followed the concreting of the center bench of the "umbrella," erecting the structural steel columns, and concreting the umbrella section to the roof so that the side supports of the roof bracing could be eliminated. The posts of the roof bracing were then used to line the two faces of the umbrella concrete while the ring-drilled rock on each side was shot out and removed. This operation, in turn, was followed by concreting each of the benches, completing the arch, grouting, and concreting the invert. The excavation progress and timing are illustrated in Fig. 4. The corresponding concrete progress is shown in Fig. 5.

Although the original plan was to place the cut shot at the bottom of each heading, it was found too difficult in the field to drill diagonal holes nearer subgrade than about 15 in. The cut holes were raised about 18 in. above subgrade (see rounds C, Fig. 6). The typical hole locations were varied daily to suit rock and seam conditions in the heading, the normal loading schedule (Fig. 6) being as follows:

Equipment

To a large extent equipment purchased for the entire contract was used in the tunnels, except that the muckers were purchased chiefly for tunnel operation but were used partly in open-cut work. The drill jumbo and steel-erection jumbo were made especially for the tunnels; the concrete pumps were used chiefly in the tunnels; and the smaller unit was used in some open-cut work. The cars, track, dinkeys, pumps, and other small equipment were adapted for use both in the tunnels and in the open cut.

The drilling jumbo was fabricated at the site from drawings made to fit conditions of the job. The first design called for mounting six drills, and this was later changed for eight drills, seven of which were used at all times and one for a standby. In general, the idea was to have drills at three levels, dividing the 18 ft of total height into approximately three equal sections. Hinged side platforms at the intermediate and top levels permitted the use of the jumbo in the 18-ft single-track tunnel as well as in the 14-ft center cut of the double tunnels. To compensate for the lack of dead weight, the structure being made as light as possible for easy shifting, screw jacks were placed at the top and bottom of the vertical columns for wedging against the roof and the floor of the excavated tunnel. The mounting was on trucks from small muck cars used on a previous contract.

Tunnel drilling operation was started with drills with 3-in. pistons. As soon as it was found that drilling time was slowing up the expected schedule of a round per shift, these drills (which had been used on a previous contract) were replaced by drills with 3½-in. pistons. With these larger drills a round was drilled out in three hours. When the drill jumbo was changed from six to eight drills, the two additional drills installed were equipped with 4-in. pistons.

During the tunnel construction it was found necessary, due to changes in the New York City Industrial Code, to change all the drills for better dust and fogging control. This was done by installing round pistons to eliminate the air leakage into the water tube, to change the location of the exhaust port, and to increase the size of the water tube. With these changes, fogging of the smaller drills was entirely eliminated and greatly reduced in the larger drills.

All the mucking in the tunnels was with electrically driven machines. These machines were equipped with 50-hp, 208-volt motors; they were designed for an 18-ft cleanup width, and were equipped with a hinged boom and a chain-operated bucket at the end of the boom, with hard steel teeth and a rock-breaker knob. Four muckers of this type were purchased and used to some extent in the open-cut excavation before tunnel work was started. They were equipped with a 20-in. belt running in a 24-in. beam on the flat. In the first days of operation it was found that the flanges of the beam prevented proper contact between the mucked material and the belts. The upper flanges of the beam were cut away and rewelded to the web of the beam to form a sloping trough. This correction was made on the first two machines in the field and on the other two, which had not yet been shipped, in the shop. It was also noticed that considerable of the slip could be eliminated by a small stream of water running continuously down the sloping belt. Such slip was caused chiefly by the large quantity of mica in the mucked rock.

At no time were four of the mucker units actually in the tunnel, the fourth unit being kept as a reservoir for spare parts. In addition, quite a large stock of parts was kept in the storeroom. The use of the rock-breaker knob on the under side of the bucket was discontinued after a short trial because it was found much easier and more economical to drill and shoot a large boulder between mucking periods than to spend the time required in the mucking cycle to break up the few large pieces of rock that were too large for the mucker to handle through its throat.

Considerable study was given to the belts used in the mucking machines, not only because of the high cost of such belts, but also because of the time wasted when a belt broke and required replacement. The belts originally supplied by the manufacturer had been developed as the result of considerable research in the California tunnels. However, the rock conditions encountered on this contract were much more severe, especially because of the sharp edges and large quantity of mica. The average life of a belt was about 2,500 cu yd of rock removed.

All track was of standard 36-in. gage, composed of 40-lb industrial rail, with standard switch points and frogs. Dump cars were 5-cu-yd, water-level, steel body, side dump, with side top hinged. They were dumped into the skip

at the 46th Street shaft by the use of a pneumatic cylinder 12 in. in diameter with sufficient stroke to unload the car surely by gravity. Two dump levels were provided directly over each other, and by operating the dumping with only one cylinder, to which the car at either level could be attached, the danger of some one attempting to dump two cars at one time was eliminated (see Fig. 7).

The dinkeys for pulling the cars, the muckers being self-propelling, were electric-battery locomotives of 6-ton rated capacity, equipped with 42-plate batteries of the high cap type. Each dinkey had two sets of batteries, and four dinkeys in all were available for the tunnel work. The batteries were charged with a 30-kw, 108-volt, 1,750-rpm, 278-ampere generator direct-connected to a 50-hp, three-phase, 60-cycle, 220-volt motor. The batteries were charged at the upper level beneath the decking near the 46th Street shaft. By means of an overhead trolley hoist and beam track, batteries were raised from the dinkeys and placed into charging position quite efficiently.

Due especially to the long wheelbase of the muckers, it was found necessary to use a minimum radius of 40 ft on the track and to maintain the gage of the track with standard railroad track-gage rods made over to the 36-in. gage. Wood ties were used, spaced about 30 in. on centers; usually 6-in. by 12-in. timbers were available from decking lumber, or 6-in. by 8-in. timbers were purchased specially.

Practically all the concrete was placed by two concrete pumps. A small, gasoline-driven unit, with a 6-in. pipe, and with a conical hopper and integral agitator, was used in pouring benches. This smaller pump was also used on the umbrella and a part of the arch of the double tunnel, when the larger pump was being used elsewhere. The larger pump was the same make as the smaller, with a 7-in. pipe. It was propelled by a gasoline motor but of a model antedating the time when integral agitators were installed. The smaller pump gave an actual production of from 20 to 25 cu yd per hr, compared with 30 to 35 cu yd per hr for the larger pump.

Some of the smaller items in the tunnel, such as catwalk and duct-protection incasement, were poured manually from a special car with a high box body and side chute. However, about 98% of the concrete volumes, including the inverts, were placed with the pumps.

Miscellaneous equipment also used included two blowers, each of 2,000-cu-ft-per-min capacity, interconnected with each other and with the ventilator pipe in each tunnel, so that a maximum capacity of 4,000 cu ft for either blowing or sucking could be provided in either tunnel. The vent pipe was composed of 8-in. thin-shell steel pipe with dresser couplings. Two short lengths of flexible tubing were provided, but after a trial it was found just as easy to remove one or two sections of the steel pipe from the heading as to use the flexible pipe.

For trimming the roof, a stoper drill, with automatic feed, for 1-in. hexagonal shankless steel, was used. All other drill steel was 1¼-in. round.

The drill-sharpening plant (which was situated just north of the tunnels beneath the decking and connected by rail with all the tracks in the tunnels) consisted of two complete units for making up and sharpening drilling steel, as well as a small blacksmith shop. Each drill-sharpening unit consisted of a drill sharpener, with clamping dies for both 1¼-in. round steel and 1-in. hexagonal steel. The equipment for each set comprised: A collaring device for the hexagonal steel and lug shanking device for the round steel, gaging dies, fuller dies, dollies for sizes from 1⅝ in. to 3 in. inclusive, a shank and bit punch, an oil forge, and fuel-oil tank. No trouble was encountered with the operation of the blacksmith and drill-sharpening plants beneath the decking; the natural draft as a result of the difference in temperature between the street and the confined volume beneath the decking were found sufficient to take care of ventilation.

EXCAVATION OF SINGLE-TRACK TUNNELS

The nature of the rock exposed in the open-cut work made it necessary to begin tunnel excavation 10 ft north of the theoretical tunnel portal and only after a concrete beam protection had been placed above the tunnel portal (see Fig. 8). The purpose of the beam was to retain any loosened rock and thereby prevent damage not only to the street surface but to the subsurface structures, as well as the foundations beneath the elevated columns a short distance to the south of the tunnel portal. In the preliminary excavation, it was found that, because of the seamy nature of the rock, carrying the drilling holes 6 in. outside of the net lines on all sides, including the bottom, was necessary in

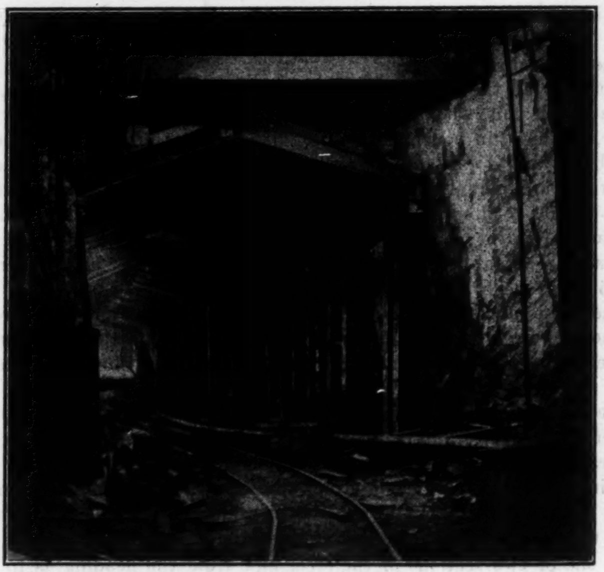

FIG. 8.—ENTRANCE AT NORTH PORTAL OF QUEENS SOUTHBOUND TUNNEL

FIG. 9.—EFFECT OF WILD CUT SHOT ON BRACING

order to reduce the amount of trimming. The cut shot normally did not follow the cut holes but broke away along the nearest seam (see Fig. 9).

The general plan of operation was to drill one round sufficiently to give an advance of 6 ft and then blast and muck all in one shift. The typical cycle of operations in both the single and double tunnels is shown in Fig. 4. It must be kept in mind that the blasting operation was governed by contract requirements that not more than 100 lb of dynamite could be used in any one round fired. As a result, it was necessary to load and shoot three times in each cycle of operations. The normal procedure was to shoot the cut by itself, using one delay in some instances; the second firing took care of the relievers and some of the trimmed holes with five delays; and the final round cleaned the entire section, using from three to five delays (see Fig. 6).

The Queens southbound single tunnel was the first of the single tunnels excavated. The record for August, 1937, the first full month of tunnel operation, shows 34 rounds averaging 7.62 ft. It was found that, with seven drills operating and with a cross section giving 12 cu yd per ft of advance, an 8-ft advance completely filled the entire shift of seven and one-half working hours. If a greater advance was drilled and shot, the entire cycle of operation was interfered with. On August 4 and August 26 seams of rock were encountered in this tunnel that were so badly shattered as to require steel bracing directly to the face before drilling could continue. This was necessary as a safety precaution not only for the men in the tunnel but to avoid failure of street surface and elevated columns above the tunnel.

During the entire month of September, 1937, this tunnel was in soft and seamy rock, the seams containing a slippery chlorite. Even with steel frames placed 3 ft on center, the pressure of the rock deformed the steel bracing.

In a number of areas the heading was progressed only after steel outriggers had been extended to the face at the roof and full timber lining was placed on both the roof and the sides. During the month the total progress was 170 ft, with the rounds averaging from 4 to 8 ft, some of them being greater than the actual depth of holes drilled. This tunnel was holed through on October 1, 5 ft south of the theoretical portal and in rock so soft that the normal quantity of dynamite was cut to less than one half because a large area outside of the cut would move and fall when the cut was shot. When shot, this material fell vertically, with practically no displacement beyond the limits of the drill-hole length.

The Queens southbound tunnel ran parallel to a part of the west track previously completed in the open cut in seamy rock. During the open-cut work the seamy rock was doweled by drilling across the seams and by grouting in 1-in. square rods approximately 4 ft long. Some of these rods were encountered in the tunnel excavation where breakage exceeded the drilled area by more than 1 ft. However, no damage was noticed at any time in the completed open-cut structure.

At the south end, the seams in the rock were so soft, and in a number of instances actually open voids, that shooting was reduced to a few holes at a time to reduce the wild breakage. In this area six 6-in. H-beams were carried as cantilever lagging ("crown bars") above the steel ribs up to the face, and after the top holes were shot the lagging was pulled ahead and blocked before the excavation was continued. During this work the advance in the single-track tunnel was given precedence over advance in the center cut of the double tunnel, and no attempt at any definite cycle was considered.

In the other single tunnel (Washington Heights southbound track), although much higher with less cover than the Queens southbound tunnel, rock conditions at the beginning were much better and holes were collared 3 in. outside of the net lines. However, after advancing about 100 ft, the rock turned to a fine-grained syenite with soft mud seams and chlorite jointing. Large quantities of this material would fall from the roof during blasting, and the bracing steel showed definite signs of rock pressure (see Fig. 10). Where this tunnel came beneath an "el" column footing, steel bracing bents were placed on 5-ft centers for a distance of 25 ft in the schist rock. In the seamy rock, steel bents were placed 5 ft on centers continuously. Where the rock breakage was irregular, steel framing was altered to fit the actual breakage, especially on the side adjacent to the double-track tunnel which was already completed and which was only 2 ft or 3 ft away from the actual breakage. Near the end of this tunnel the rock was so poor that no attempt was made to make more than one round in twenty-four hours, especially since additional steel framing was found necessary as intermediate bents when the original framing started to show a sag. Soft ground methods could not be used for tunneling because the individual syenite rocks between the joints were hard and irregular. In January, 1938, the last 50 ft of progress was made in one week, and the remainder of the month was used in rebracing to clear the concrete lines and to place concrete in back of the side-wall sheeting to prevent movement of the rock.

The proximity of adjacent tunnels was shown clearly when a duct manhole was excavated in the side of the Washington Heights southbound tunnel where a theoretical clear distance between the tunnels was 5 ft. Because of the over-breakage of the two adjacent tunnels, and the fact that concrete very often ran through the seams, the concrete of the Washington Heights southbound tunnel manhole was encountered in three places in the double tunnel excavation.

FIG. 10.—ROCK BREAKAGE AT SOUTH END OF TUNNELS AT CHLORITE SEAMS

The Washington Heights southbound single tunnel was started on November 8, 1937, with special shift periods. It was the only tunnel being excavated and was planned for 2 rounds in twenty-four hours, the drilling and blasting crews coming to the job at 8:00 a.m. and 8:00 p.m. and the mucking crews at 2:00 p.m. and 2:00 a.m. At first it was found difficult to push the drillers so that blasting was completed before the mucking crew came to the job. However, when the drilling crew was given an assignment to drill for a 6-ft round and the entire crew with the exception of one scaler was permitted to go home after the entire round had been shot out, the required progress was obtained easily. As a matter of fact, it was determined by the blaster that the one scaler who remained for the full shift was the driller who finished last. When this rule was instituted, the remainder of the crew usually went home in six to six and a half hours. Generally, between 100 and 110 holes were drilled, each 6.5 ft long, except the ten cut holes which were between 7 and 7½ ft long. Seven drills were operated on the jumbo, using the 4-in. drills for the cut holes and the 3.5-in. drills for the remainder. The average production per twelve hours was 5.42 ft up to December 20 when the seamy and blocky rock was encountered.

EXCAVATION OF THE DOUBLE TUNNEL

The general procedure in the double tunnels was to excavate the center drift for the full height, and about 14 ft wide, as a separate tunnel operation. Bracing was designed for future extension to incorporate the bracing of the enlargements on each side. After the center tunnel excavation had been completed, the two sides were ring drilled, and this was followed with concreting of the center wall footing. The structural steel of the center wall was then placed, and the umbrella, consisting of the center wall and parts of the two roof arches, was poured as a unit, incasing the steel beams of the temporary roof support. The side enlargements were then made by shooting the ring holes previously drilled, taking each side as a separate operation.

The center cuts of the double tunnel and the Queens southbound tunnel were started simultaneously from the same face in the open-cut excavation. During August, 1937, 36 rounds were taken with an average progress of 7.34 ft in fairly hard mica schist with some quartz intrusions. Near the south end of the tunnel the rock became quite seamy, and tunneling was stopped 40 ft south of the theoretical tunnel portal, although it had been planned to carry this tunnel 80 ft into the open-cut area not yet started south of 43d Street. Ring drilling was begun immediately thereafter, using the drillers who were working in the Queens southbound tunnel at such times as the latter operation permitted. Ring drilling was completed on October 16 and was followed by steel erection and concrete center bench construction, working from 46th Street southward.

FIG. 11.—EXCAVATION OF THE WIDENING IN THE DOUBLE TUNNELS

FIG. 12.—WEST WIDENING IN DOUBLE TUNNEL

Blasting for the east enlargement for the center tunnel was started at the north end on November 1, with a small crew, including two drillers for trimming in addition to the normal mucking crew (see Fig. 11). This work was done on a two-shift basis until the progress reached a point at which it was too close to the already excavated Washington Heights southbound tunnel, at which time the east widening was continued on a one-shift basis and the west widening was stopped until the adjacent tunnel was concreted and grouted.

Progress in the east widening during the first month was 288 ft on a two-shift basis. During the same month, beginning November 15, the west widening was extended 210 ft on a two-shift basis with separate and distinct crews and equipment. The intent was to keep the two widenings moving simultaneously but at least 75 ft apart north and south so that the blasting of one would not interfere with work on the other. Because of the dip of the rock seams, the east widening required much more additional longitudinal drilling than the west widening.

As each widening progressed, the timber supports placed in the center cut were removed and used as a protection for the concrete umbrella (see Fig. 12). It also was found that an excellent protection for the upper edge of the concrete umbrella from flying rock was the cushioning effect of discarded rubber belts hung from the temporary roof steel and almost in contact with the concrete.

The east widening of the double tunnel was completed on December 28, progress in December being 316 ft. Until December 22 work was done on three shifts, and after that one shift, per day, making an average progress per eight hours of 4.71 ft. The west widening of the double tunnel was closed

FIG. 13.—INCIDENTAL SEAM BRACING IN THE DOUBLE TUNNEL; WALL BENCH CONCRETED

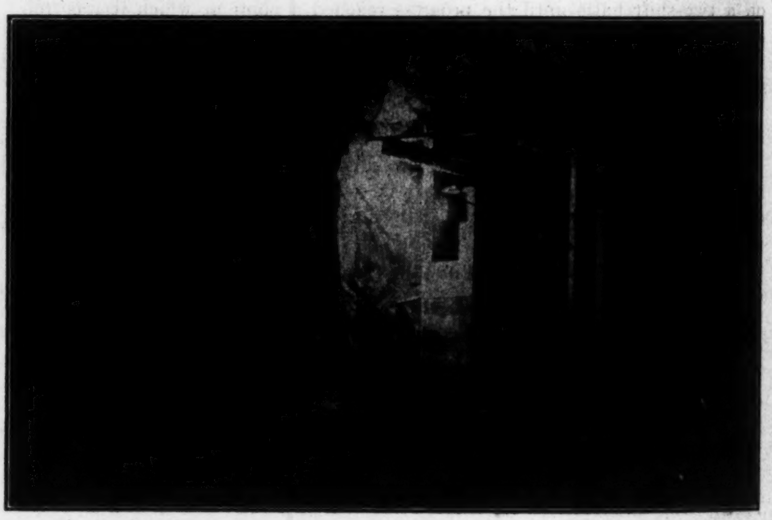

FIG. 14.—STEEL AND WALL FORMS AT DUCT MANHOLE IN TUNNEL

on December 17 with 193 ft still to go because of the proximity of the adjacent tunnel. In this tunnel progress of 334 ft in December showed an average of 7.79 ft per shift. The much better progress on the east side shows the favorable direction of the rock seams.

In both of the widening operations some steel bracing was found necessary because of the open seams, and such bracing was tied in to the roof steel previously concreted into the umbrella. The temporary steel bracing placed in the tunnels varied considerably, depending upon the rock conditions encountered. In some areas no steel was placed, and in others steel frames were placed about 2 ft apart (see Figs. 13 and 14). Such variation corresponded to the variation in the rock, which was from an extremely hard igneous syenite with seams of feldspar and quartz to soft disintegrated schist and chlorite which in some cases was so soft that the material could be dug out by hand. Seams in the rock were generally almost vertical, with a slight dip from 5° to 15° to the west, and the run of the seams was almost to south, or directly in line with tunnel progress. Worse rock conditions under the small cover and closeness of tunnels scarcely can be imagined.

In the single tunnels steel bracing frames consisted of four pieces of H-beams, which were usually 12-in. column sections cut to approximate shape and length with clip angles attached to each end of each piece. Connections were made by bolting the legs of the angles in contact and wedging with steel wedges as found necessary to take up the shape of the excavated tunnel. Typical sections of the type of bracing used, and details, are shown in Fig. 15. The steel bracing as well as temporary posts and lagging was placed by timbermen crews brought into the tunnel as found necessary (see Fig. 15). During July, 1937, working seventy-four shifts, 70 bents were placed in the single tunnel and 71 bents in the double tunnel. These bents were placed in the total tunnel length of 479 ft.

In February, 1938, after the single tunnels were concreted, the west widening of the double tunnel was completed in seventeen days on a one-shift basis with an average progress of 7.77 ft per day. The rock was soft mica schist with open seams, and steel bracing was placed every 5 ft. The average production for widening of the double tunnel for both sides was 6.50 ft per shift, which includes progress in 90 ft of bad rock at the south end of the west widening, where twenty-seven shifts averaged 3.36 ft.

At approximately the middle of the double tunnel where the vent shaft and emergency exit were to be built, 30 ft of the center umbrella arch was omitted and a crossover track was installed to connect the operations in the east and west widenings. This crossover expedited the mucking problem when both of the widening operations were south of this future shaft. To eliminate any possible damage to buildings in the vicinity of the shaft, the plan was not to break through to the street surface until all tunnel operations were completed.

In the three manholes excavated by widening the tunnels, 10-in. steel pipe connections were provided with the street surface to act as cable feed pipes for signal and other cables to be pulled in the ducts placed along the east sides of the Washington Heights southbound tunnel and of the double-track tunnel (see Fig. 14). These pipes were inserted in 12-in. cored borings taken from the street surface into the excavated tunnels. Two of these holes measured from rock elevation about 6 ft below street surface, and were each 22½ ft long; the third hole was 13½ ft long. A shot drill operated by a gasoline engine was started on December 14 at the first hole and all work was completed by January 10 for all three holes. Considerable difficulty was encountered because of the large amount of the shot that was lost in the seams of the rock.

However, the operation was quite successful, and the total cost of all labor, materials, and equipment was $11 per foot of core removed. There was no difficulty in placing a 10-in. (inside diameter) galvanized steel pipe in the cored holes. These pipes were grouted in and capped at the street surface.

LABOR SCHEDULES, PROGRESS, AND COSTS

The typical labor setup for tunnel excavation is shown in Table 1. The weekly summary and averages of tunnel progress, consisting of the completion of the Queens southbound and the completed center cut for the double-track tunnel, are shown in Table 2 (see Fig. 4(*a*)).

[a] Five days. [b] Completed. [c] From June 1. [d] Beginning September 7, 1937, all three shifts, ring drilling in two tunnels during spare time averaged 1.08 shifts per round.

Costs.—The average labor cost of all the tunnel rock removed in 1937 was $5.75 per cu yd. During August, with two tunnels being excavated, the total labor cost was $5.11, distributed as follows:

Operation	Dollars per cu yd
Blasting and mucking	4.23
Compressor plant operation	0.12
Blacksmith shop operation	0.35
Equipment repair	0.25
Cleaning up	0.16

The labor cost of ring drilling the double tunnel widenings was $26.20 per lin ft of tunnel, ring drilled on two sides.

A study was made of the comparative costs of tunnel excavation for the full face running two tunnels at one time, as occurred when the Queens southbound and the center cut of the double tunnel were worked, and the cost of excavating the widening tunnels of the double tunnel in the manner in which it was done with ring drilling, or as separate tunnels with longitudinal drilling. In general, the labor cost of driving two tunnels together is practically the same as the labor cost of the drilling and mucking in widening the double tunnel (see Table 3). However, considerable time was saved by the ring-drilling process. There is an indirect saving (which is difficult to estimate) in the continuous use of drillers while the Queens southbound tunnel was being finished, and there is a saving of 50% in the dynamite cost in the excavation of the widening cuts over that used in the other tunnels.

TABLE 3.—LABOR COSTS OF RING DRILLING VERSUS DRIFTING, IN DOLLARS PER CU YD

Operation	ACTUAL[a]		ALTERNATE[d]		
	Rock excavation[b]	Ring drilling[c]	1.5 shots per shift	1 shot per shift	Two, 6-ft shots per shift

Sharpening steel	0.35	0.35	0.35	0.35	0.35
Repairs to equipment	0.25	0.25	0.25	0.25	0.25
Total	4.95	5.00	5.80	6.58	4.54

[a] Cost of two tunnels as driven. [b] Comparative labor cost of rock excavation. [c] Ring drilling and widening as of December 13, 1937. [d] Probable costs of driving two drifts instead of using the ring-drilling method. [e] Very unlikely condition.

For the entire tunneling operation, the total labor costs were as follows: Charged to excavation of 30,000 cu yd, $190,000; charged to timber, placing 155 million fbm, $16,224; charged to steel, placing 578 tons, $23,306; and charged to grouting 2,300 bbl of cement, $3,235. To the foregoing should be added labor costs in the blacksmith shop; equipment repair outside of drills;

compressor-plant operation; the proportion of the cost for setting up the compressor plant and the mucking shaft; and the pay roll of the master mechanic, superintendent, timekeepers, storeroom keeper, and engineering overhead.

DUST CONTROL

After excavation was begun, instructions were received to comply with the then latest regulation of the New York State Industrial Code concerning dust control in rock excavation work. Such a code did not exist at the time the contract was awarded, and, with the exception of normal ventilation and wet drills, no special provisions had been made for such compliance. On June 16, 1937, the New York State Industrial Commission sent representatives, together with observers from the New York Labor Department and the U. S. Bureau of Mines, to take dust count samples during the drilling operation. Although no definite results were reported to the contractor, it was made known indirectly that compliance with the Code would be required and that some method must be submitted for approval unless the strict requirement of the Code (which at that time permitted only dust collectors) was provided.

Immediately thereafter, tests were run in the excavation with wet drills of various types (ventilation being both by blowing and by sucking within the maximum capacity of 4,000 cu ft per min available). Tests were also made to determine the effect of several types of wetting agents mixed in the drill water. Private dust counts were made under each of several combinations of the foregoing possible remedies.

As a result of all of this research, a method or formula for dust control was submitted to the New York State Industrial Commission and after approval was incorporated in the Code. The rules set up for compliance with the amended regulation included the following seven items:

(1) Wet drifters shall be fitted for 1½ to 2 gal per min of water applied to the drill steel;
(2) The exhaust port of the drifter shall be directed away from the face;
(3) A minimum amount of air shall pass through the hole in the drilling steel;
(4) No holes shall be directed upward except a minimum at the top of the tunnel;
(5) Air shall be exhausted at the rate of 1,200 cu ft per min per each drifter —maximum size, 4 in.;
(6) The half-throttle, air-bleeder port shall be plugged;
(7) All holes must be collared wet.

The quantity of water that flowed through the drill needles was tested under various pressures, both for the $\frac{1}{16}$-in. standard needle and for the ⅛-in. special needle. It was found that the rate of flow varied between 1 and 2 gal per min between the pressures of 20 and 70 lb per sq in. for the ⅛-in. needle, which was adopted for all drills.

Before any special control methods were used, dust counts were made of the air in the tunnel without drilling and also on the street surface. It was not unusual to find a dust count more than twice as high in the air at the street surface as in the tunnel without drilling.

A complete report of all these tests has been published by F. B. Flinn and P. S. Miller,[2] Assoc. M. Am. Soc. C. E.

In connection with compliance with the Code (which provides one permissible dust concentration for rock containing less than 10% free silica and a different permissible concentration for rock containing more than 10% free silica), a study was made to determine whether the average rock encountered came in the classification of more than, or less than, 10% free silica. Except for the approximate petrographic methods, the only reliable chemical method for this determination, found after a thorough detailed study by the experimental laboratories of the DuPont Company, was that described by A. Shaw[3] in 1934. This method is so detailed that only the best equipped laboratories could perform the test and then only after about a week of work. Another method reported by Sartorius and Jotten[4] is a combination of chemical separation and centrifuging the free silica from the solution. Neither of these methods was considered practicable enough for attempting a determination of the true amount of free silica in the rocks encountered. When the question was presented to the New York State Industrial Commission, and samples of rock were sent for inspection, it was reported that the rocks contained more than 10% free silica without giving the exact percentage or advising what method had been used.

THE EFFECT ON THE "EL" STRUCTURE

During tunnel operations, daily readings were taken on level points fixed on all elevated columns above the excavated parts of the tunnels and for some distance beyond the headings. Practically no deviation in elevations was found in any of the columns except the one column directly above the Washington Heights southbound single-track tunnel, near the south end. During excavation a slight settlement was noticed in this column. Since the excavation was through soft material that broke very poorly, steel bents were placed to support the roof. After the tunnel was completed, some of this steel bracing required readjustment to clear the concrete lines, and during this operation a considerable mass of loose material that had been resting on the roof steel fell down. This happened directly below the elevated column footing, which, however, was not a dangerous condition because the elevated column load had been jacked up on two temporary steel beams above the street surface as soon as the settlement in the column had reached 1 in. After all the loose material had been allowed to fall, exploratory drill holes were started from the street surface, and it was found that this footing was resting on a layer of rock about 5 ft in thickness with soft material below it. This rock was consolidated by grouting from the street surface, as well as through the concrete after it was poured. The column itself was loosened from its footing and jacked up to proper elevation, and the intervening gap was filled with a dry-packed grout.

DYNAMITE

Contract specifications limited the use of dynamite to not more than 100 lb of 60% gelatin strength in any one blast, including delayed explosions. As stated previously, the rock was of such nature that 40% gelatin dynamite was found more suitable.

The total quantity of dynamite used for excavating these tunnels was 2.98 lb per cu yd, net measurement, of 40% gelatin strength. Based on actual excavation, due to over-breakage, the total was actually about 2¾ lb per cu yd. On the average one cap was used for each six sticks of dynamite, or 3 lb.

The weight of dynamite per cubic yard moved varied from month to month, depending upon the type of rock encountered. The maximum was in June, 1937 (3.12 lb); the minimum was in January, 1938 (1.04 lb). The average dynamite consumption for straight tunnel excavation was approximately 3.10 lb per cu yd, and the average for shooting ring holes was 1.65 lb per cu yd.

All detonation was electrical, a separate blasting line being carried into each heading from a switch located at the portal.

CONCRETING

Concrete in all arches, including the umbrella portion in the double tunnel, was placed by concrete pumps, using steel forms. Total forms purchased for the job included a 30-ft section of umbrella form, a 30-ft section of side arch that was usable in either of the enlargements for the double tunnel, and a 30-ft section of single complete arch tunnel. The umbrella form consisted of two side panels and part of the arch with a trussed framework that supported the wheels. The form collapsed by sliding it on the wheel shaft. This was done by turning the shaft with a ratchet handle, thereby pulling the form away from the concrete. By means of screw jacks built into the wales, the form was collapsed vertically. In this manner the form tended to lean toward the concrete, and rollers were provided to run on the concrete while the form ahead was moved. Bulkheads at each stage were built up with wood. For the remainder of the double tunnel a usual type of traveling form was used, with jacks at the bottom, and it covered approximately three quarters of the arch. In detail it was very similar to the complete tunnel form.

The complete form for the single-track tunnel was 30 ft long built up in multiples of 6 ft. Two openings in the side-wall were spaced 15 ft apart for niches. The trussing and framework for the form, including the traveler, were so arranged that a muck car could be run through the form, and in a number of locations such a procedure was necessary. Usually, timber braces were placed across the legs of the traveler to increase the stiffness of the form. Because of the fact that the tunnel is wider on curves, a slip lap joint was provided for the top plate which, in the wider part, resulted in a flat spot at the top of the arch. This panel was really the key plate, placed last as the concrete came up to each section. The form was held in place by means of screw anchors embedded at accurate spots in a short height of the wall built with the benches. The same rail was used as for mucking, additional rail lengths being moved ahead to accommodate the wide gage of the traveler. Collapsing of the form was by lowering the screw jacks on to the axles. The concrete record and progress are shown in Fig. 5 and the location of equipment in Fig. 16.

Fig. 16.—Concreting Setups

In the single-track tunnel, concrete arches were poured at the rate of 30 ft each day, using the larger pump. In the double tunnel, the umbrella section was poured at the rate of 30 ft a day with the smaller pump, such a pour being between 40 and 45 cu yd. The complete arch pour was about 135 cu yd.

No difficulty was experienced in pouring once every day. The early morning shift collapsed the form and moved it ahead, and carpenters starting about 6:00 a.m. would build the bulkhead and prepare for the next pour to start at 10:00 a.m. After the first few days of operation, and after all the idiosyncrasies of the concrete pump apparatus were fairly well understood, the 135 cu yd of pour would be finished by 4:30 p.m. The concrete pumps were placed at approximately subgrade level, and the concrete was chuted down from mixing trucks at the street surface through circular 8-in. elephant trunk chutes. The rate of delivery was controlled by bell signals between the pump operator and the street surface. Pump operation was controlled by the engineers stationed at the pump in accordance with electric bell signals from the foreman at the form. Very little difficulty was encountered because of the rule that all signals, when received, must be repeated by the receiver, and the little additional expense of providing return signals from each line was found much worth while.

In some instances in the double tunnel it was found possible to place the pump in the shaft area at approximately the middle of the length of the tunnel and at the street surface, using a down-feed pipe to the tunnel level. With fairly uniform delivery of concrete, and starting each day's pour with approximately 3 cu yd of cement grout to lubricate the pipe, no difficulty was found in pumping concrete approximately 500 ft horizontally and 20 ft vertically.

At a point about 30 ft from the form an air-connection tee was added to the concrete pipe to be used as a booster for filling up the form. When the concrete had filled up the entire form and the end bulkhead had been completed, the short pipe sections inside the form were removed as the concrete filled up the volume. Air at 100-lb pressure was admitted into the concrete pipe, and the fluid concrete ahead of the air inlet, about 30 ft in length, was shot into the concrete mass inside the form. This operation, it was found, could not be repeated safely until the normal pumping had again filled up the entire pipe length; otherwise the back pressure clogged the pipe between air connection and pump.

With this procedure the concrete could be pushed up 6 ft above the outlet pipe inside the form where rock crevices were that high; and, as far as visual inspection was concerned, the concrete seemed to be tight against the rock. During pumping operations, it was found practically safe (although not unduly comfortable because of the high humidity and temperatures) for men to work inside the form when placing and tying grout pipes, spading concrete, and operating vibrators.

The typical labor setup for concreting, including stripping and shifting steel form, building bulkheads, setting and brazing copper water stops, setting up concrete pipe, setting and making up grout pipes, revising steel bracing, concreting, and cleaning up pipe and concrete pump, was as given in Table 4.

TABLE 4.—LABOR SCHEDULE FOR CONCRETE WORK

Description	Timbermen	Timbermen helpers	Laborers	Carpenters	Concrete foremen	Concrete laborers	Maintenance enginemen
Single Tunnel Form:							
Queens southbound tunnel	4	4	5	10	1	14	3
Washington Heights southbound tunnel	5	6	....	14	1	11	3
Double tunnel, west arch	6	7	2	16	1	11	5

The labor cost for stripping, moving, and resetting forms and building bulkheads was $0.23 per sq ft contact area of tunnel surface (not including areas of bulkheads).

The total labor cost of tunnel concrete in 1937 was $3.80 per cu yd, to which must be added the cost of the forms, insurances, overhead, and concrete, including the value of the excess concrete outside of pay lines. This labor cost includes all of the men involved in preparing, setting, and removing the forms, and the placing of the concrete inside the form, placing the grout pipes

FIG. 17.—SOUTH END OF DOUBLE TUNNEL

FIG. 18.—DOUBLE TUNNEL COMPLETED EXCEPT FOR CATWALK

and water stops, and any incidental work in connection with the concrete both for the arches and the benches.

STEEL ERECTION

In the double tunnel, structural steel columns and base and top grillages were erected in the center wall. Top grillages were continuous over two columns in the form of bents independent of each other. The structural steel was brought into the tunnel on the mucking tracks and set at the side of the tunnel until all the steel had been delivered. Erection was by hand, using the roof bracing for attaching block and falls. As the structural steel was set in place, the track had to be removed. A total of 102 tons of steel was brought in with a total labor cost of $22.37 per ton, including supervision, erection, labor, riveting, and trucking from lighters about 2 miles away.

COMPLETION OF TUNNELS

After the main arches were poured, in which grout pipes had been installed, the track remaining in place, a grouting gang was sent through to grout all the holes that would take it, at 50-lb to 60-lb pressures. This was followed by a second run at 60-lb pressure (and in some cases more), after which the grout holes were filled. At the same time, any finishing that needed to be done on the concrete, such as removal of fins, was completed (see Figs. 17 and 18). Grout pipes were 2 in., with a coupling set flush on the form. Grout cocks were connected by nipples, which were removed after the completion of grouting.

The grout used was approximately of 1 : 1 mix. The grouting machine ran on the track, and the sand and cement were brought up in bags on flat cars. The Queens southbound single tunnel, 700 ft long, required 1,210 bbl of cement, or approximately 1¾ bbl of cement per linear foot of tunnel. The total cost of this grouting was as follows: Labor, $1.24; insurance, $0.24; cement, $2.10; ⅛ cu yd of sand, $0.25; sales tax, $0.05; and air and equipment, $0.12—a total of $4 per bbl of cement. In the other tunnels the labor cost ran quite uniformly the same, at $1.25 per bbl of cement. The average day's production was 250 bags of cement, and the maximum day's production was 356 bags.

At convenient times the inverts were graded by hand, removing the track after grading was completed. The invert concrete slab was 12 in. thick, and in some locations covered cast-iron drain pipe was set slightly below the invert. This concrete was placed by pump, keeping the pipe on the side bench. One shift could easily do 250 ft of invert, or 125 cu yd, using the small pump.

In two of the tunnels a catwalk, or emergency walkway, was built in sections of about 30 ft, re-using a set of forms for the entire length of two tunnels. In the other two tunnels a bank of 30 clay ducts was laid against the wall and concreted in, the top becoming the catwalk.

SHAFTS

After the tunnels were concreted completely, two shafts were excavated down from the top. The west shaft required removal of only the thickness of rock between the two tunnels which crossed each other at that point—approximately 5 ft. Mucking was by crane and buckets from the street surface.

In the east shaft, where the cover was about 20 ft above the tunnels, earth and some of the rock were removed from the street surface to expose and protect the water main and utility ducts, and also to deck the opening in the street surface; then by means of long drilling, holes were driven through to the tunnel. The rock was then blasted into the tunnel by loading the bottom of the holes. Mucking, again, was by crane and buckets from the street surface.

In the east shaft niches were cut to provide for the exit stairways connecting the catwalk with the street surface, in this way avoiding open excavation immediately adjacent to the building. In spite of the seamy rock in the east shaft, steel bracing in the tunnel and in the shaft prevented any movement of the rock, and the operation was completed without hazard to the pedestrian traffic as well as the buildings immediately adjacent to the shaft.

ACCIDENTS

In general, the tunnel operation was remarkably free of accidents, although there was one fatal case. As far as equipment was concerned, at one time a mucking machine tipped over in the tunnel causing a loss of three hours in schedule but no injuries. At another time a piece of roof fell out on the boom of the mucking machine and broke the beam connection, without any personal injuries. The fatal accident occurred on the last night of tunneling when a small piece of rock fell from the roof and injured the mucking machine operator, who at the time was watching the track gang install the last piece of track for the final cleanup; the man died some days later.

To reduce accidents, every man in the tunnels was required to wear a safety hat and safety boots that were provided with nonskid bottoms and aluminum tips. The foremen were held personally responsible for accidents to the men in their crews. No separate record was kept of accidents in the tunnels as against those on the remainder of the contract. The total record of lost-time accidents from July, 1937, to April 1, 1938 (during which period most of the tunnel work was done), shows a total of thirty-seven accidents for the nine months, of which thirty-two were lost-time accidents. The number of men engaged in that period averaged between 400 and 500 per day. In this period of nine months the maximum number of lost-time accidents per month was eight in the month of July and the minimum was one in the month of February. There was no accident involving any one outside of regular employees. Alleged damage to neighboring property along the line of the tunnels was practically nil.

PERSONNEL

Contract for the construction of Section 10 of the Sixth Avenue Subway, which included these tunnels, was awarded to the Rosoff-Brader Construction Corporation, which, in August of 1938, became the Brader Construction Corporation. The chief engineer of the Rosoff-Brader Construction Corporation was Fred W. Stiefel, Assoc. M. Am. Soc. C. E.

The work was done under the supervision, and in accordance with the design, of the Board of Transportation of the City of New York, of which Jesse B. Snow, M. Am. Soc. C. E., is chief engineer. During the tunnel-construction period, the late Byron Houghtaling, M. Am. Soc. C. E., was first division engineer, with Charles M. Madden, M. Am. Soc. C. E., as section engineer at first. Later, Mr. Madden replaced the late A. M. Mayell as subdivision engineer. This work was completed under Francis V. Hayes, Assoc. M. Am. Soc. C. E., as section engineer. The design was prepared by Albert Goertz as design engineer for this section.

In the contractor's organization, all of the construction procedure and operations were under the control of the writer, who was in charge of the construction. The engineering staff not only designed the methods of procedure but ordered the materials, laid out the work for the various shifts, and in general scheduled the operation of construction. In the field one engineer was assigned to each shift in the tunnels, the three shifts being covered by S. M. Marks and Sidney Philip, Juniors, Am. Soc. C. E., and James Lyttle. The dust-control work, as well as some of the office work in connection with the planning of the drilling, equipment, etc., was done by Philip S. Miller, Assoc. M. Am. Soc. C. E., aided by Sol Rusitzky and W. Mortensen in the office work.

The superintendent was Jacob Siebert, to whom too much credit cannot be given for the success of the operation. Joseph Tinley was master mechanic and Walter Reed was master electrician. Shift bosses were Harvey Urey and Due Carroll. Credit must be given not only to these men but to all the loyal mechanics and laborers in their respective gangs.

DISCUSSION

JOHN H. MYERS,[5] M. AM. SOC. C. E.—There was a time when "rock men" had in mind only progress. Inasmuch as their work was done largely in the wilderness, it was not necessary to give much attention to safety. The rock men of that day were adepts in blowing down mountains and incidentally scattering spalls all over the landscape, or in making, with the machinery then available, what was considered remarkable progress in tunnel excavation. However, when engineers began to build large structures within existing cities, progress, tempered with the necessary precautions for the safety of life and of existing structures, was inevitable and as a result a new breed of rock men has been developed. Mr. Feld gives much evidence of this fact and he has done something very worth while in recording the methods used in the construction of the Sixth Avenue Subway.

The so-called "umbrella section" of double-track tunnel, described by Mr. Feld, has been used for many years in the tunnel work of the New York Rapid Transit Railroads. To the writer's knowledge, it was used in many places on the New York City subway work, among them being the connection between the Lexington Avenue Subway and the existing tunnels under Park Avenue; and also at many locations along Lexington Avenue north of the point where the subway emerges from under the Commodore Hotel. In fact, some of the tunnels under Lexington Avenue are two tracks high. The upper half of the tunnel is of the "umbrella section" and rests on a steel floor which is at the same time the roof of the lower half.[6] The fact that the "umbrella section" is still being used gives proof that although, when completed, it furnishes an adequate encasing structure for the Rapid Transit Railroad tracks, it is, at the same time, a practical structure to build under many difficult conditions. In the writer's experience with it, the difficult conditions were brought about by the rock encountered, and he has known the "umbrella section" to be constructed by many different methods. At times it was built by excavating a central drift, placing the concrete center bench on the floor of this drift, erecting the permanent steel work, bracing the rock roof from this steel work and then concreting the "umbrella." Following this step, the tunnel for one track was excavated without further timbering, the arch over the track was concreted, and temporary bracing was placed against the unexcavated rock on the other side of the center line to take up the unbalanced thrust of the completed half tunnel. The remaining half was then excavated and the concrete poured. In Mr. Feld's experience, however, he had to cope not only with bad rock conditions but, in addition, with buildings alongside the tunnel work and subsurface structures, and an elevated railroad above it. All in all, it serves to demonstrate that the "umbrella" form of tunnel is a flexible design and that it is possible to erect it under many and various difficult conditions. The designers of the subway construction have no reason to be ashamed of it.

[6] "Construction Problems of the Manhattan-Bronx, and Lexington Avenue Subway Junction and Queensborough Tunnel Connections," by George Perrine, *Transactions*, Am. Soc. C. E., Vol. LXXXII, December, 1918, p. 278; see also "Tunnel Work on Sections 8, 9, 10, and 11, Broadway-Lexington Avenue Subway, New York City," by Israel V. Werbin, *ibid.*, Vol. LXXXI, December, 1917, p. 341.

Jacob Feld,[7] **M. Am. Soc. C. E.**—At the time of organizing the construction procedure and methods for the tunnel sections of the contract for the construction of Section 10 of the Sixth Avenue Subway, a number of questions arose as to the most advisable procedure and methods, expected progress, as well as expected costs of each proposed method. Because of insufficient literature on the subject in attempting to determine what had been done under similar circumstances and what had resulted from the methods used, the writer decided that after this construction job was finished he would publish a paper, and list his own experience and the answers to the questions that arose. This paper is the result of that decision.

It might be worth while to enumerate some of the problems that arose, and their solutions:

1. Proper protection of soft and seamy rock at the tunnel portals, keeping in mind the close proximity of elevated column footings, street sewers, and utility lines, was provided by the construction of a reinforced concrete combination retaining wall and girder spanning across the tunnels. This method was very satisfactory and eliminated the expected trouble from the raveling of the rock at the portals.

2. The great variety of rocks encountered required a flexible drilling diagram, as well as flexible bracing methods. Especially helpful was the detail decided upon for connecting the individual units of the bracing frames.

3. The use of a full face drilling and shooting procedure—an unusual method in constructing tunnels within city limits—was found to be advisable and economical, and in no way increased the hazards of the work.

4. A flexible shooting cycle was necessary to coordinate the amounts of dynamite necessary at each face with the restrictions placed upon blasting within the city limits.

5. The method of mucking required a study of different strengths of dynamite for the type of rock encountered, to avoid the necessity for breaking up rock too large for the mucking machine.

6. The lack of large areas, or easy access to the tunnel work, required an unusual disposal method; and the double-deck dumping board was found satisfactory and safe if only one dumping mechanism was provided.

7. The elimination of hauling the drill steel from the shaft for sharpening purposes was definite when traffic conditions on the street were considered and the decision to place the drill-sharpening plant beneath the decking at subgrade level proved not only economical but also safe. The predicted complaints from neighboring properties because of this operation did not materialize.

8. The special control of air and dust, resulting from the drilling operation, required considerable emergency research to avoid delay in the construction schedule. The method used has become standard and was accepted by the New York State Industrial Commissioner as an alternate to the only approved method at the time the rules were issued. Incidentally, the rules were issued after this contract was started.

---

[7] Cons. Engr., New York, N. Y.

9. The provision of small diameter shafts for inserting cable feed pipes to connect the street surface with the manholes adjacent to the tunnels by core drilling from the street surface was a substantial economy over the normal shaft-sinking method previously used.

10. The use of a concrete pump for placing all of the concrete within the tunnels, with the addition of an air booster to fill the irregular rock roof completely, was considered a novelty and was instituted in spite of the objections of the field organization. However, this method proved satisfactory and resulted in the use of the same equipment in many later jobs.

Many of these methods are new if compared with the reports of the rock-tunnel operations in the subway sections referred to by Mr. Myers in his discussion, even though the design of the subway tunnels has not changed.

This report proves that, contrary to usual feeling in the construction industry, satisfactory and uniform progress can be obtained in a short job by proper planning and, at the same time, can result in a low accident record. The accident frequency of one lost time accident per 25,000 man-hr is far below any record on similar work in previous years.

It is hoped that the data in this paper will be useful to engineers finding themselves in a similar position of planning and coordinating tunnel work within congested areas.

FORT PECK SLIDE

By T. A. Middlebrooks,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Jacob Feld, Joel D. Justin, William Gerig, Alfred J. Ryan, Glennon Gilboy, Frank E. Fahlquist, Irving B. Crosby, and T. A. Middlebrooks.

Synopsis

Tests and analyses conducted on the soils and rocks encountered at the Fort Peck Dam (in northeastern Montana, on the Missouri River) which have a bearing on the slide that occurred on September 22, 1938, are the basis of this paper. Since very little information has been published on the investigations conducted prior to the slide, the first part of the paper has been devoted to that subject. The major part is devoted specifically to the studies conducted after the slide, to determine its cause and to outline a method of repair.

Introduction

After preliminary investigations were completed, it was realized that, in addition to the difficulties normally expected from the construction of a full hydraulic fill dam of this magnitude, the foundation conditions were complicated (see Fig. 1). A thick plastic clay stratum approximately 60 ft below the natural ground surface extended over the center two thirds of the valley and well outside the upstream and downstream toes of the dam. Overlying, underneath, and outside the limits of the clay stratum, there were stratified pervious materials varying from fine sand to gravel. At each abutment the shale was either exposed or lay under a relatively shallow overburden. An extensive program of foundation exploration and laboratory investigations was planned to obtain the necessary information for design purposes. A soil testing laboratory was established and equipped to perform all types of soil tests, including the determination of photoelastic stress distribution. In addition to the regular shear, consolidation, and permeability tests, numerous special tests and experiments were performed, such as: (1) Expansion tests on shales and tills; (2) large-scale shear and consolidation tests; (3) clay model tests to observe action during plastic deformation; (4) photoelastic tests on gelatin models to develop a rational means of computing the stress distribution in the embankment and

foundation; (5) earth-dam models of the main dam on approximate scales of 1 to 50 and 1 to 200 and earth models of dike sections on a scale of 1 to 2; and (6) sand models to obtain information on the effect of consolidation of the core of the shells.

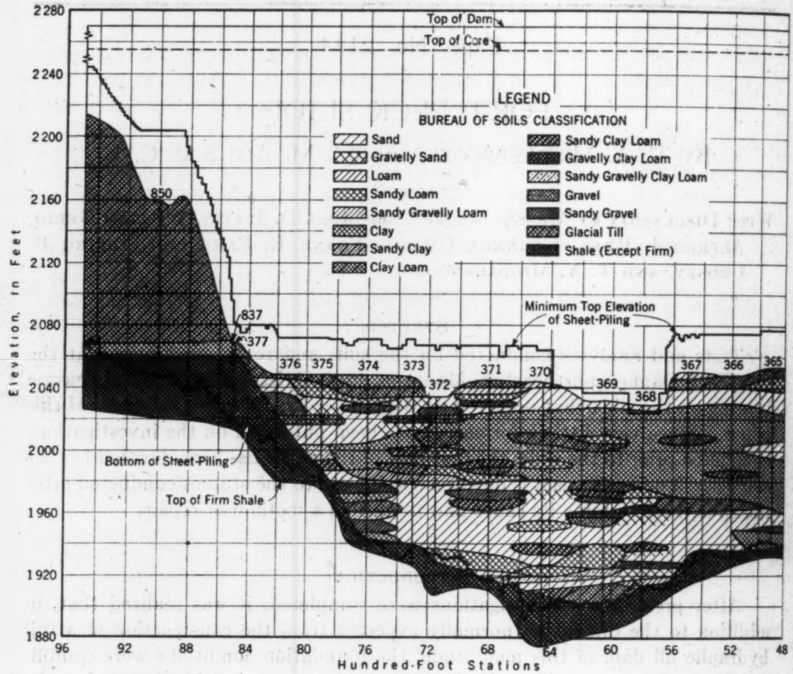

FIG. 1.—SOIL PROFILE ALONG

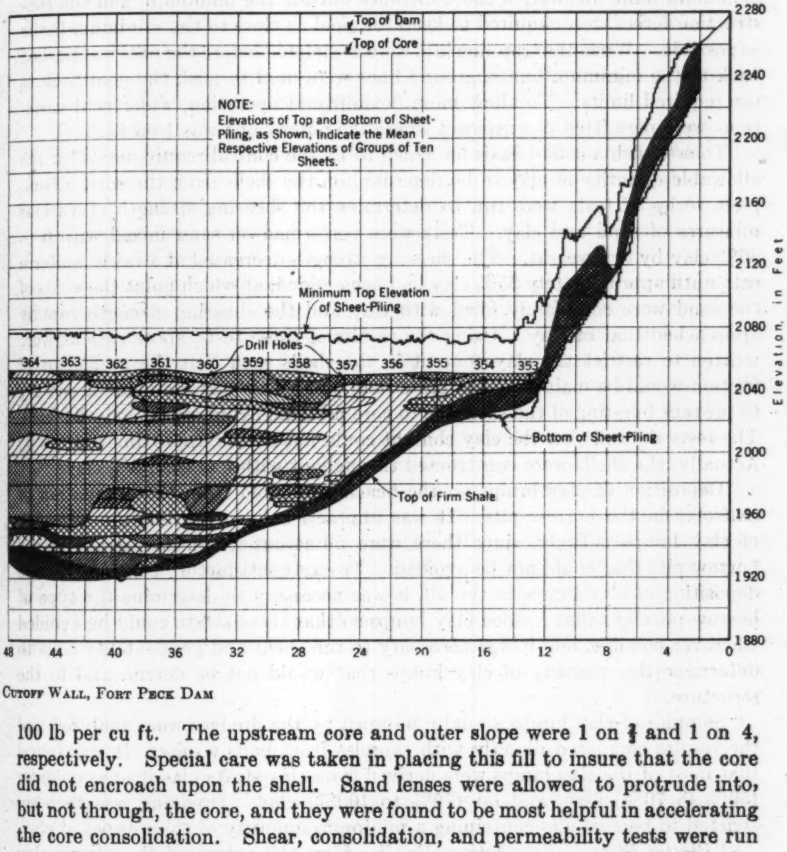
In order to keep a close check on the settlement and seepage during and after construction, settlement plates and perforated pipes were installed in the fill on several cross sections of both the dam and dike sections. In addition, hub stakes were set outside both toes of the dam and on the surface of the completed part of the slopes. The elevation and location of these hub stakes and plates were determined periodically. They were usually read monthly, but in some cases critical locations were observed daily.

TEST AND ANALYSIS PRIOR TO SLIDE

Investigations were conducted prior to and during construction to insure a safe structure with reference to the following possible sources of trouble: (*a*) Bursting of the shell due to excessive core pressure; (*b*) slides in the shells due to excessive deposition of core material and clay balls; (*c*) plastic flow of the foundation clay; (*d*) slides in the foundation sands or silts; and (*e*) slides on the shale surface.

"Bursting of Shell."—The possibility of the core bursting the upstream shell was investigated prior to and checked during construction, using the method proposed by Glennon Gilboy,[3] Assoc. M. Am. Soc. C. E., in 1934. It was found that the dam was safe even when the core was assumed to be a liquid, weighing 100 lb per cu ft. The upstream core and outer slope were 1 on $\frac{2}{3}$ and 1 on 4, respectively. Special care was taken in placing this fill to insure that the core did not encroach upon the shell. Sand lenses were allowed to protrude into, but not through, the core, and they were found to be most helpful in accelerating the core consolidation. Shear, consolidation, and permeability tests were run on undisturbed samples taken from the core during construction. Density samples were taken every 5 ft in elevation through the core on each 500-ft station at the center line every three months in orden to check closely the amount and rate of consolidation. These tests indicated that the core material consolidated at an exceedingly rapid rate.



Cutoff Wall, Fort Peck Dam

"Slides in Shell."—Consideration was given to the fact that slides in the shells might occur from two conditions: (1) Deposition of core material on the beaches due to wide pools; and (2) deposition of large pockets of clay lumps from the pocket discharge lines. Daily control samples, as well as permanent

---

[3] "Mechanics of Hydraulic-Fill Dams," by Glennon Gilboy, *Journal*, Boston Soc. of Civ. Engrs.. July, 1934, p. 185.

record samples, at fixed intervals were taken to check on the core limits and the type of material being placed in both the core and the shells. It was found necessary to establish maximum and minimum core limits, since it was obvious that a fixed limit was not practical in construction. Upstream, the allowable maximum limit was only a short distance outside the minimum, and the construction forces were required to keep the pool as close to the minimum limits as possible. When the trap-line lifts were completed before the pool was pushed back to the minimum limits, ground lines were used to push the pool back to the required limits. To allow more flexibility of operation, wider pool variations were permitted downstream where the outer slope was 1 on 8½.

To establish a sound basis on which to fix the control requirements for the allowable quantity of clay to be deposited on the shells from the core, a complete series of tests were run to determine the shearing strength of various mixtures of sand and clay. Tests were performed on sand mixed with 0 to 30% clay by dry weight. The shearing strength decreased at a fairly uniform rate until approximately 25% clay had been added, at which point the voids of the sand were completely filled with clay and the shearing strength rapidly approached that of clay. Using the results of these tests, specifications were written to restrict the clay content in the shells such that the coefficient of friction would be maintained at more than 0.6. This was the value necessary to prevent bursting of the shell due to core pressure assuming no consolidation. The tests showed that the clay content could not exceed approximately 8.0%. Actually, the shells were constructed throughout with less than 3% clay.

Deposition of clay lumps on the beaches resulted from the excavation of stiff clay in the borrow pits. It was impracticable to prevent the pumping of clay lumps entirely, since there were numerous small clay strata in the borrow pits that could not be avoided. To exert satisfactory control over the deposition of clay lumps in the fill, it was necessary to determine the type of borrow-pit clays that formed clay lumps so that these strata could be avoided wherever possible, and it was necessary to run shear and permeability tests to determine the quantity of clay lumps that would not be detrimental to the structure.

Samples of clay lumps actually pumped by the dredges were analyzed and the results compared directly with samples from borrow pits. It was found that most of the clay lumps were derived from clay strata classified as medium (50% to 70%) clay, and fat (70% to 100%) clay. Dredging was then restricted to borrow pits containing a minimum quantity of these types of clay.

"*Plastic Flow of Foundation Clay.*"—After the extent of the plastic clay in the foundation had been outlined by the preliminary explorations, an extensive investigation was made to check the stability of the proposed sections both for the completed dam and for the 1-on-3 construction slopes in the closure section.[3] The special foundation exploration consisted of ten 6-in. borings through the clay strata. Continuous undisturbed samples were taken for the full thickness of the clay strata, and shear and consolidation tests were run on representative samples from each hole. Since considerable deformation occurs in a clay prior to ultimate failure in shear, it was feared that sufficient deformation might occur in the thick plastic clay stratum (60 ft maximum thickness) to cause failure in the dam before the full strength of the clay could be mobilized. After a careful study of this condition in clay models constructed in the laboratory, it was decided the shearing strength should be taken at the "yield point" instead of the point of "ultimate failure." The result was a decrease in the deformation of approximately 75% from the ultimate without decreasing the strength more than approximately 25%. Strength of the clay was determined from consolidated and unconsolidated shear tests by taking into consideration the percentage of consolidation during construction.

---

[3] "Foundation Investigation of Fort Peck Dam Closure Section," by T. A. Middlebrooks, *Paper G-3*, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Cambridge, Mass., 1936.

Since failure of clay would occur due to plastic flow, the Swedish slide method[4] for determining the stability was not considered applicable. The elastic-theory method was used for determining the stress distribution in the clay strata. The works of J. Boussinesq,[5] S. D. Carothers,[6] Leo Jürgenson,[7] and others were utilized to develop a rational method for determining these stresses. Photoelastic experiments on a gelatin model were performed to check the mathematical application of the elastic theory to this type of structure. As a result of this investigation,[8] the construction slopes in the closure section were flattened from 1 on 3 to 1 on 5, and a berm was added upstream for the full length of the clay stratum, Station 30+00 to Station 70+00, Fig. 1.

"Slides in Foundation Sands and Silts."—During the investigation of the clay stratum sufficient undisturbed samples of the foundation sands and silts were obtained to determine their strength. It was found that there was ample factor of safety against failure of these materials.

"Slides on Shale."—Explorations in the right abutment disclosed that beneath several feet of exposed disintegrated shale, there was a zone of blocky weathered shale approximately 30 ft thick. There was a gradual transition from the blocky weathered shale into subfirm and firm shale. In the valley adjacent to the abutment a pervious overburden averaging 30 ft in thickness overlays a thin stratum of clay 1.5 ft thick. This clay rested directly on subfirm shale.

The possibility of failure in the shale in this vicinity was considered as highly improbable, since subfirm shale of similar classification excavated in other locations on the project had shown that the subfirm shale and the bentonite seams contained therein possessed ample strength to prevent failure. Detail investigation of this zone after the slide showed that the upper part of stratum classified as subfirm shale was actually weathered shale. It was also found that the clay stratum adjacent to the abutment would consolidate 100% during construction. For this reason, all shear tests on the clay were performed on consolidated samples. Stability analyses made on the basis of the results obtained from the tests indicated that the dam was safe against failure from this source.

TEST AND ANALYSIS AFTER SLIDE

Directly after the slide occurred near the right abutment on September 22, 1938 (see Fig. 2), all previous test data and analyses were reviewed to assist in arriving at the most logical probable causes of the slide. Preliminary investigations indicated that the slide may have been caused by one or a combination of the following conditions: (1) Movement along some weak zone in the shale; (2) movement along the shale surface; (3) bursting of the shell due to excessive core pressure; or (4) temporary liquefaction of the shell or foundation sand, or both.

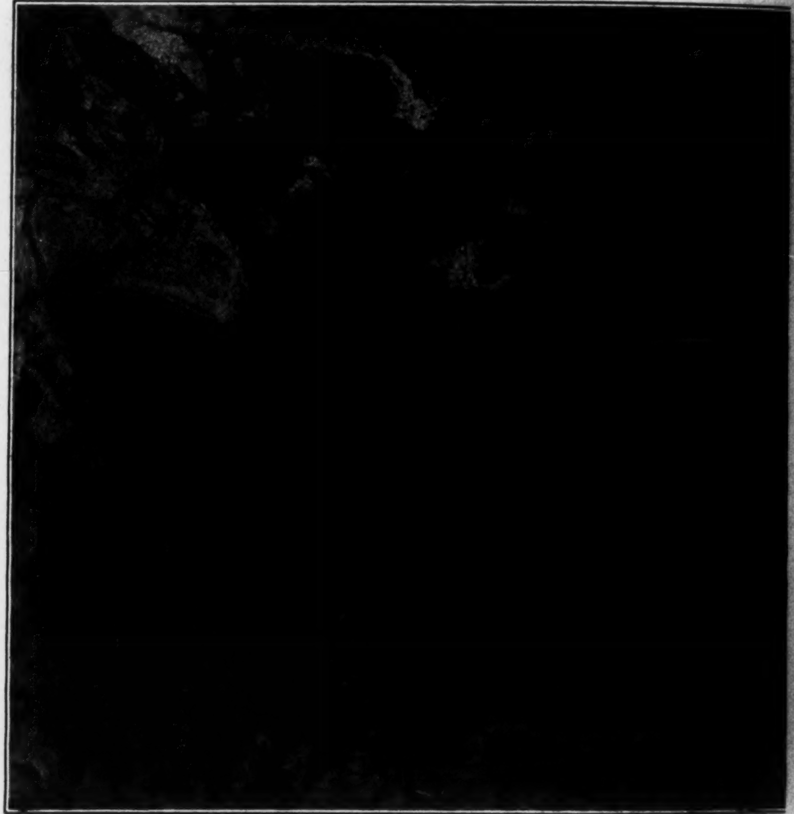

FIG. 2.—AERIAL PHOTOGRAPH OF

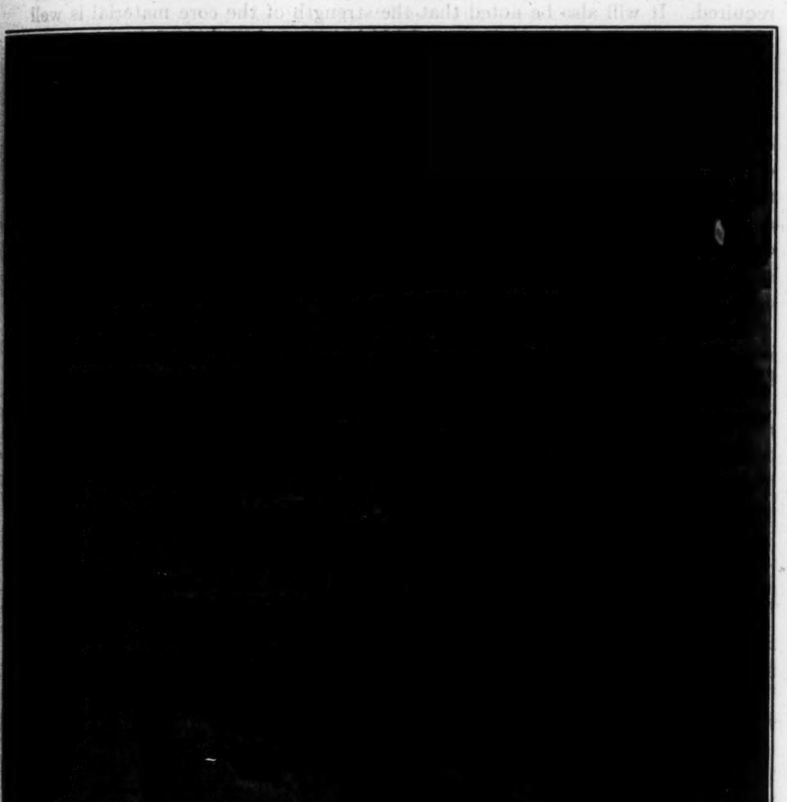
To determine the extent of additional laboratory work necessary for a complete investigation, tests were run by the latest approved methods to check previous testing, so that there would be no unnecessary duplication. The standard direct shear apparatus was used for most of the testing, but the shearing strength of the core and the critical density of the shell material were determined by the latest developed triaxial shear machine.

Movement in Shale.—In order to investigate possible movement along some weak zone in the shale, undisturbed samples were taken from test pits, drift, and large-diameter (12-in. to 36-in.) core borings. A considerable number of small (3-in. to 6-in.) borings were made through the slide material and overburden and 40 ft into the shale to outline the distribution of the various materials. Continuous drive samples were taken of the slide material and overburden and cored samples from the shale. Undisturbed samples of clay, weathered shale, and bentonite from the test pits, drifts, and large-diameter borings were tested for shear and consolidation characteristics in the laboratory.



DAM IMMEDIATELY AFTER SLIDE

In addition, large-scale field tests were run on undisturbed weathered bentonite in the drifts driven into the weathered shale. Representative results of these tests are shown in Fig. 3 which also shows the required strength to give a safety factor of 1.0 for the section prior to failure. It will be noted that most of the tests on bentonite show a strength below the required strength line, whereas most of the tests on clays and weathered shale show a strength above that required. It will also be noted that the strength of the core material is well above that required, the coefficient of friction averaging about 0.6.

Results of these tests indicate clearly that the bentonite and weathered shale were the weakest materials in the foundation, and that undoubtedly the weathered bentonite was by far the weakest material encountered. This conclusion is substantiated by all the explorations. Numerous movement zones or slide planes were found in the weathered shale by the drive samples taken from the small borings. In practically all cases bentonite was mixed with gouge material in these zones of movement. In some cases, the large-diameter cores showed that bentonite seams had been completely removed by the slide; some were thoroughly mixed with shale along a gouge zone, others remained as definite seams but were drawn out showing considerable movement.

Observations made on holes drilled into the shale revealed another very important factor that was difficult to take into consideration in the analyses but which, it is reasonable to assume, had a major effect on stability. Holes drilled into the shale downstream of the slide and on the west abutment showed that there was a high hydrostatic pressure in the shale, which was considerably in excess of the maximum lake level or the saturation line in the dam. In Table 1, which shows the water levels obtained in the various drill holes, it will be seen that one hole developed a pressure head equal to that of a water column extending to El. 2,310, approximately 60 ft above the maximum height of the fill and 90 ft above the saturation line. Other holes developed pressures of more than 100 ft above the lake level or the saturation line in the dam. Borings prior to the construction of the dam showed no artesian water in the

[b] Elevation of a column equal to hydrostatic pressure.

shale. All artesian wells in this vicinity are drilled through the Bearpaw shale to a depth of from 600 to 1,000 ft, and none of these wells developed a pressure even closely approximating those obtained from these later holes drilled through the dam.

The most logical reason for the existence of such a high hydrostatic pressure in the shale is that trapped water was squeezed out of the shale, due to the superimposed load of the dam, most likely along weathered bentonite seams.

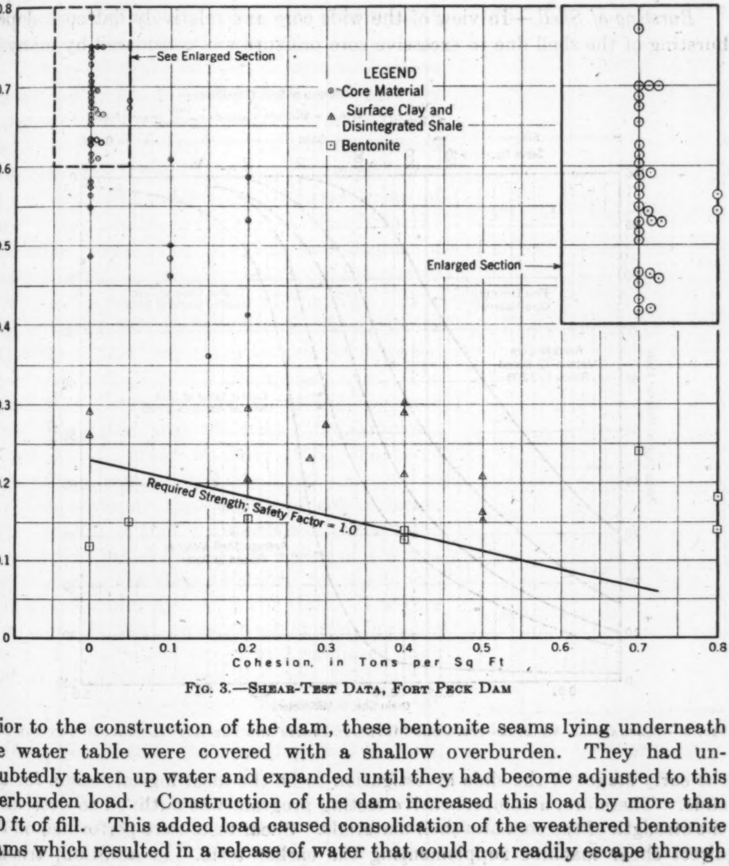

FIG. 3.—SHEAR-TEST DATA, FORT PECK DAM

Prior to the construction of the dam, these bentonite seams lying underneath the water table were covered with a shallow overburden. They had undoubtedly taken up water and expanded until they had become adjusted to this overburden load. Construction of the dam increased this load by more than 200 ft of fill. This added load caused consolidation of the weathered bentonite seams which resulted in a release of water that could not readily escape through the overlying impervious shale. It was trapped along the seams, developing the high hydrostatic pressures which were later observed. It is the firm conviction of the writer that this excess hydrostatic pressure which was found to exist in the shale was one of the major causes of the slide and accounts in large part for the speed at which, and the distance to which, it moved.

Movement on Shale.—In the slide area there was approximately 1.5 ft of clay and disintegrated shale overlaying the subfirm shale. This clay was in direct contact with a free draining foundation sand. Additional tests confirmed earlier investigations and showed that the thin clay strata would consolidate rapidly with the application of load. Consolidated shear tests were used for determining the shearing strength of this material. All of the strengths so determined were well above the required strength to give a factor of safety of 1.0.

Bursting of Shell.—In view of the wide core and relatively flat core slopes, bursting of the shell due to excessive core pressure was considered by many in the early stages of the slide investigation to be the most logical reason for the slide. Therefore, a comprehensive testing program was outlined to determine the strength of the core and shell materials. Shear tests were performed on the direct shear machine supplementing the earlier tests. In addition, triaxial tests were run at Harvard University, Cambridge, Mass., at the U. S. Waterways Experiment Station, Vicksburg, Miss., and in the laboratory of the Fort Peck District. Results of some of these tests on the core material are shown in Fig. 3. The coefficient of friction of the core material averaged approximately 0.6, with only a small degree of cohesion. The triaxial tests showed the

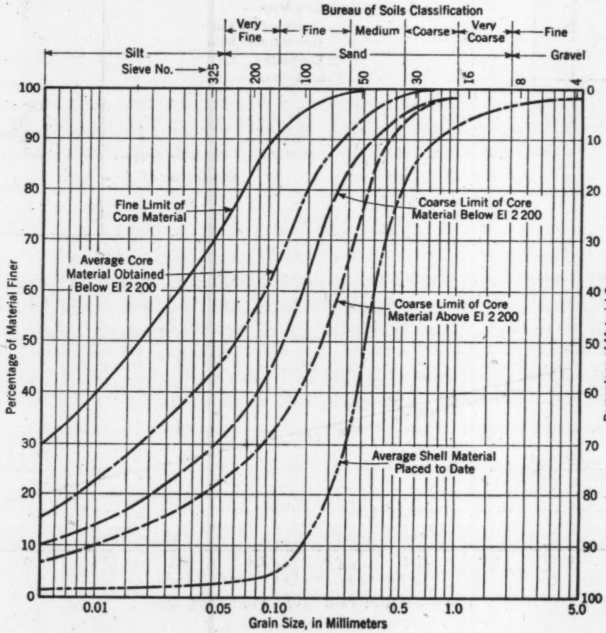

FIG. 4.—MECHANICAL ANALYSES FOR CORE-MATERIAL LIMITS AND THE ACTUAL MATERIAL IN THE FILL

core material to be even stronger than the direct shear tests indicated. After watching some triaxial tests run and studying the results, one engineer remarked that "the core material appeared to brace itself against failure." It was concluded from all the tests that the core material was practically as strong as the shell material.

An attempt was made to measure the horizontal pressure exerted by the core by the use of Goldbeck earth pressure cells attached to a long pile. The high degree of consolidation of the core material made it impossible to set the pile in the core without impairing the accuracy of the cells.

Composition of the average core material is shown in Fig. 4. Limits of the core as actually constructed did not vary greatly from the design limits, except for sand lenses which extended into, but not through, the core. Consolidation of the core was accelerated by these lenses of sand which protruded into the core from the transition zone. Fig. 5 shows the degree of consolidation for core material on the center line for different elevations of the fill. These data were obtained about two months prior to the slide. The tests comprise samples between Station 15+00 to 85+00, along the axis. The void ratios (averages plotted in Fig. 5) were determined volumetrically from drive samples 2 in. by 18 in., taken in July, 1938. The core pool varied from El. 2,213 to 2,200.

The relatively high degree of consolidation and strength of the core, as shown by the tests, was further borne out by the action of the material during the slide as shown by the topography and exploration after the slide. The core remaining in place on the west end of the slide stood on very steep slopes and exhibited high resistance to scour from the core pool water. Borings showed that the downstream part of the core did not move out with the slide, but remained intact while the overlying shell material moved upstream over it. Boring No. 4 at Station 14+75, approximately on the axis, showed that a large hole had developed during the slide down to natural surface. Core material did not squeeze into it as might have been expected, but it was filled with sand.

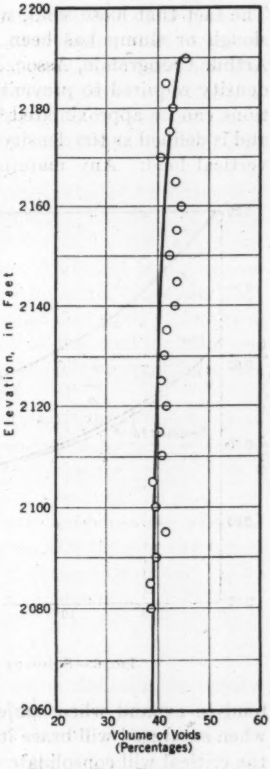

Fig. 5.—Core Consolidation

The upstream toe trestle was pushed out ahead of the slide. If the shells had burst due to core pressure, the most likely path of failure would have been over the trestle. Failure did not occur where the core was the least consolidated, which was the closure section. This part of the dam was raised approximately 150 ft in four months, whereas the dam at the east abutment was raised to this height over a period of twenty-eight months.

Therefore, it was concluded from the test data, explorations, and surface observations made directly after the slide that the core was decidedly stronger than anticipated in the original design and consequently possessed a good safety factor against bursting the shells.

Temporary Liquefaction of Sand.—"Liquefaction" of the sand shell or foundation sand (or both) was advanced as another possible cause of the slide. The fact that loose sand, when subjected to a shock or change in stress, will slough or slump has been recognized by engineers for ages past. In 1936 Arthur Casagrande, Assoc. M. Am. Soc. C. E., showed a method whereby the density required to prevent sloughing for different sands and different conditions can be approximated.[9] It has been designated as the "critical density" and is defined as the density at which no change in volume will occur at a given vertical load. Any material having a density greater than the critical will tend to expand when subjected to shearing stresses; therefore, this material when saturated will brace itself against failure; whereas, a material looser than the critical will consolidate when subjected to shearing stresses, thereby allowing the load of a saturated material to be partly carried by the water which reduces its shearing strength.

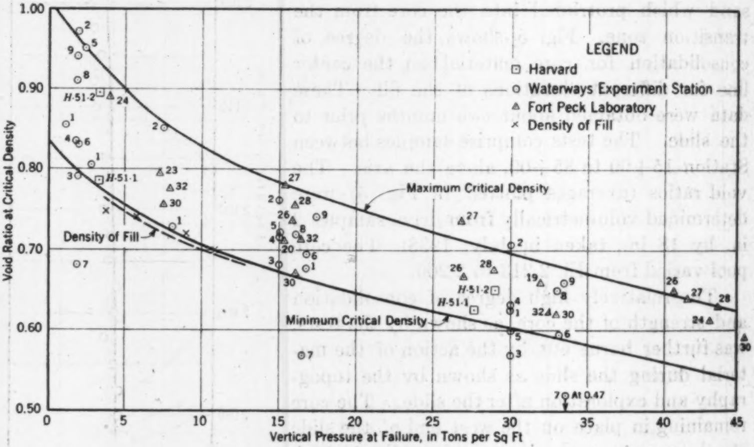

Fig. 6.—Summary of Critical Density Tests on Shell Material

It has been concluded that a material denser than the critical is definitely safe against flow. On the other hand, it does not follow that all materials looser than the critical density are unsafe. This looser material will definitely have some reserve strength, depending on its density. This problem did not enter into the slide investigation since it was found that density of the shell material was equal to, or greater than, the critical. It is a problem, however, that deserves careful consideration by investigators in the future.

[9] "Characteristics of Cohesionless Soils Affecting the Stability of Slopes and Earth Fills," by Arthur Casagrande, *Journal*, Boston Soc. of Civ. Engrs., January, 1936, p. 13.

In order to determine the actual density of the shell material and to obtain samples for tests, several test pits were excavated in the undisturbed upstream shell. Continuous 6-in. undisturbed samples were taken, and the density and mechanical composition determined. Critical density tests using the triaxial machine were run on representative samples at Harvard University, U. S. Waterways Experiment Station, and Fort Peck. Results of these tests are shown in Fig. 6. Density of the Fort Peck shell material is shown as a heavy broken line. These tests show that the hydraulic fill is denser than required. In addition to the critical density tests on disturbed shell materials shown in Fig. 5, tests on undisturbed samples to determine the effect of stratification were run in the Fort Peck Laboratory. These test results showed that there was an even greater margin of safety against flow of the shell material than was indicated by the other tests.

The conclusions drawn from the test data were substantiated by inspection of the undisturbed 36-in. cores. The inspection disclosed that definite stratification, as it existed in the hydraulic fill, was undisturbed by the movement except for numerous shear planes. This stratification might not be destroyed by streamlined flow of the shell material, but it can be stated definitely that there would be no shear planes in the sand if flow had occurred. Therefore, it can be concluded from the tests and explorations that the shell material was of sufficient density to prevent it from becoming liquefied even under the severe stress conditions that occurred during the slide.

The distance that the slide moved upstream may have been due to some liquefaction of the slide materials, as has been concluded by the Board of Consultants. It is the opinion of the writer that the evidence proves such a liquefaction must have occurred along the bentonite seams in the shale, especially after sufficient movement had occurred to mix the bentonite with the trapped water. The inlet channel, cut approximately 800 ft from the toe of the dam, also had a major influence on the distance that the slide moved. The cut is approximately 500 ft wide and 30 ft deep (bottom elevation, 2,030.0).

General Questions

Before proceeding to the stability analysis, it seems desirable to discuss briefly a number of questions raised during the investigation which, directly or indirectly, affect any stability analyses that might be made. The questions are listed below and discussed in subsequent paragraphs:

(1) What effect did filling and lowering of the reservoir have on the slide?

(2) Was the construction rate too rapid?

(3) Did excessive settlement occur in the slide area prior to the slide?

(4) Did seepage away from the abutment through the fill have any appreciable effect on the slide?

(5) Was the core at the east abutment finer or coarser than the remaining portion of the dam?

(6) What effect did the slide have on the adjacent abutment and dam?

Effect of Reservoir Water.—At the time of the slide the reservoir was at El. 2,117.5, having been drawn down from El. 2,137.0 in approximately 60 days. The shale and bentonite in which the slide occurred were below the natural water table and were therefore saturated before the dam was constructed. Since the load of the dam was much greater than the reservoir pressure, the water was actually being squeezed out of the foundation. The water in the reservoir, therefore, could not enter the shale and bentonite to weaken it. The reservoir water at El. 2,117.5 decreased the stresses in the foundation from what they would have been if it had been empty. This decrease in stress, however, was in part counterbalanced by the increase in stress due to the drawdown; but, on the whole, the water in the reservoir had very little effect on the stability of the structure. Although the effect was small, these conditions were given full consideration in the stability analyses.

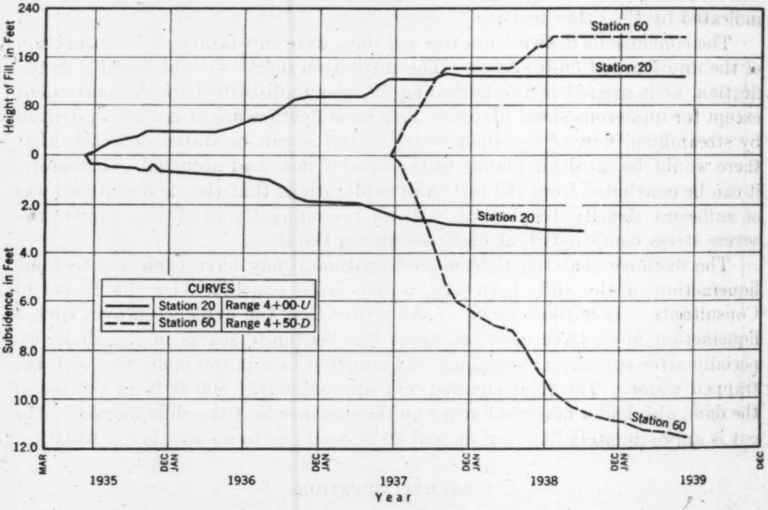

FIG. 7.—RECORD OF FOUNDATION SUBSIDENCE AND FILL HEIGHT, STATIONS 20+00 AND 60+00

Rate of Construction.—The rate of construction for the part of the dam in the slide was comparatively slow. The rate of construction is shown as a curve in Fig. 7 in connection with the subsidence. It will be noted that the fill was brought up in stages. The first five months of construction brought the fill up approximately 40 ft, followed by a winter rest period of five and one half months. Then in seven months the fill was raised approximately 55 ft, and another rest period of five months occurred. This was followed by about two months of operation, prior to closure, in which the fill was raised approximately 30 ft. Closure operations allowed this fill to rest another four months, after which approximately 15 ft of fill was placed in one month. Following a rest period of five months, the fill was then raised approximately

60 ft in the five months prior to the slide. Increase in the fill height averaged approximately 5 ft per month including the shutdown periods. The maximum rise per month in any one period was approximately 15 ft.

In the slide area the construction rate was extremely slow compared with the closure section. The fill in the closure section rose 160 ft in four months, rested five months, and then rose 60 ft more in five months. The average rise per month was nearly 15 ft and the maximum was 40 ft. Therefore, if trouble was to be experienced in the embankment due to rapid construction, surely it would have occurred in the closure section.

Any reasonable extension of the construction period could not have been expected to increase materially the strength of the weathered shale or bentonite or to release the pressure in the relatively impervious shale where the source of the trouble existed.

Settlement.—The question concerning excessive settlement can be easily answered by reference to Fig. 7. It will be noted that the settlement at a point about the middle of the upstream slope had practically stopped. The settlement in this area amounted to only about 2% of the fill height, whereas in the closure section where the plastic clay is approximately 60 ft thick, the settlement amounted to more than 10 ft, or more than 5% of the fill height. Settlement in the slide area occurred at a rate of less than 0.08 ft per month; but in the closure section this rate was approximately 0.6 ft per month. Obviously then, it is most unlikely that excessive settlement contributed to the failure.

Seepage.—Seepage moving outward from the abutment undoubtedly raised the saturation line in the dam slightly, but the additional stress added to the foundation was negligible when compared with the total stress set up by the embankment.

Texture of Core Material.—During the preliminary stages of the investigation some engineers thought that the core was composed of finer material at the abutment and that greater core pressure was exerted there. Actually the major portion of the core was coarser at the abutments, a condition which it was impractical to prevent.

Effect of Slide on Adjacent Abutment and Dam.—The slide had no material effect on either the abutment or the dam outside the slide area. A small surface slough occurred in the abutment due to the toe support being removed quickly. However, it was of no importance.

STABILITY ANALYSES

Stability analyses were made, using the Fort Peck elastic theory method[3] and the static slide method.[4]

Section Prior to Slide.—Several cross sections were analyzed in the slide area. Station 15+00 has been selected because it is a representative cross section and because the slide started at approximately this location. Figs. 8 to 10 show the stability analyses of the section by the elastic theory method, prior to failure. Distribution of shearing stresses along the rigid boundary was computed and plotted in Fig. 8. The effect of seepage forces, the difference in weight of shell and core material, and the elevation of the lake were taken into consideration in determining the stress distribution. All fill materials were assumed to be homogeneous and isotropic, and had the following weights:

Material	Weight (lb per cu ft)
Sand material above the saturation line	105
Sand material below the saturation line	60
Core material (buoyed)	65
Disturbed shale (buoyed)	78

Using values of tan $\phi = 0.185$ (ϕ = angle of internal friction) and cohesion $C = 0.2$ tons per sq ft, the shearing strength of the shale (broken line in Fig. 8) was plotted so that a direct comparison could be made with the shearing stress. It will be noted that there was an overstressed zone from range 4+00 to 6+25. Failure of the weathered shale and bentonite undoubtedly started in this overstressed zone and gradually increased until a sufficiently large area had been overstressed to produce failure of the entire structure. This is borne out by statements of the eye witnesses concerning the fact that the shell moved nearly straight out and the core pool and adjacent shells moved down as if dropping into a hole.

Attention is directed to the fact that in this analysis no consideration is given to the strength of the fill material. Where the weak material is in the foundation, failure starts in this material and progresses back into the embankment. It follows, therefore, that failure of the fill material in this case is incidental to the prior failure of the foundation material. This is one of the fundamental weaknesses of any static slide method, since progressive failure is not taken into consideration.

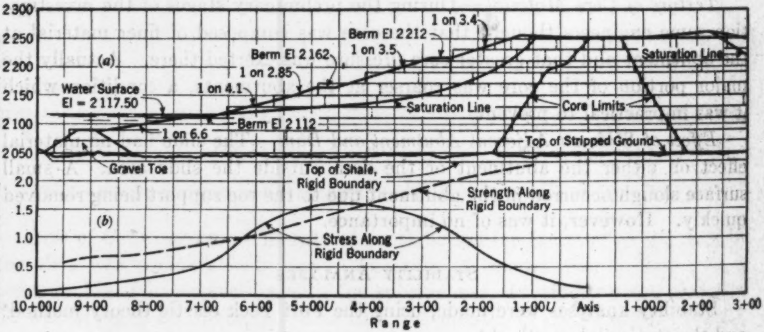

FIG. 8.—STRESS AND STRENGTH (TAN $\phi = 0.185$, $C = 0.2$ TON PER SQ FT) ALONG RIGID BOUNDARY

In this method of analysis the over-all safety factor (Fig. 9) is computed by taking the ratio of the accumulated shearing strength and stress by starting at the toe (Fig. 8) and progressing back to a point where it becomes a minimum. It will be noted in Fig. 10 that the safety factor drops below 1.0 at approximately range 4+00 and remains below to approximately range 2+00.

Attention is also directed to the fact that the test (Fig. 10) data, except for the weathered shale and bentonite, lie above the required strength line for a safety factor of 1.0.

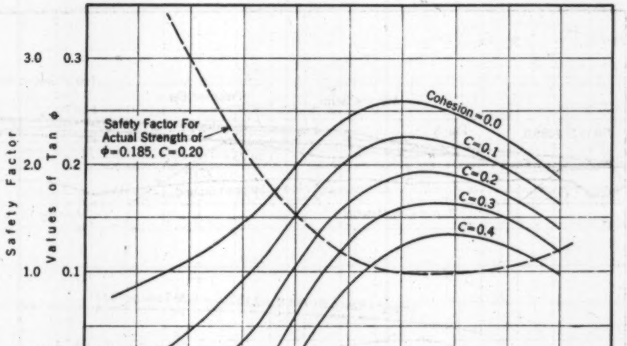

FIG. 9.—RELATION OF COHESION AND TAN φ ALONG THE RIGID BOUNDARY FOR A SAFETY FACTOR OF 1.0

FIG. 10.—VALUES OF COHESION AND FRICTION FOR SOIL ALONG RIGID BOUNDARY FOR A SAFETY FACTOR OF 1.0

A stability analysis was made on the same cross section using the static slide method. Since the weakest plane across the dam passes through very little shell material, the strength of the core is the governing factor. If a value of tan $\phi = 0.3$ is used for the core material, this method checks the elastic theory method. On the other hand, if a value of tan $\phi = 0.6$, which is more in line with the test data, is used, the section is shown to be stable by this method. The failure plane as shown in the shale for all stability analyses was determined from the foundation explorations after the slide.
